COMPLICATIONS FROM TRANSFUSION THERAPY

While this is not intended as an exhaustive discussion of the risks and complications associated with blood transfusion, clinicians should be aware of a number of complications, in particular the following.

Transfusion-Related Acute Lung Injury

The highest number of transfusion-related deaths are now, most likely, caused by TRALI, with an incidence of 1 death per 1700 to 5000 patients. Its onset is within 6 hours after the transfusion (Box 1). Clinical findings include tachypnea, dyspnea, tachycardia, hypotension, cyanosis, and fever. In intubated patients, froth may be noted in the endotracheal tube. The mechanism is thought to be human leukocyte antigen–specific or neutrophil-specific antibodies that exist in donors' plasma—antibodies that cause neutrophil aggregation and complement activation with subsequent endothelial damage, capillary leaks, and the release of inflammatory cytokines. Treatment includes oxygen supplementation and, if necessary, vasopressor support.

Of patients who develop TRALI, 80% will survive with normal lung function, and it does not affect the ability to receive blood transfusions in the future. The risk of TRALI is highest among recipients of FFP (Figure 5), particularly from multiparous women, but other blood products are also culpable. It is of utmost importance to inform the blood bank of any case of TRALI, so that both the donor and the recipient can be tested; if the donor has a significant number of antibodies, he or she can be deferred as a donor in the future. In the United Kingdom, blood bank authorities have moved to collect plasma only from males, and some U.S. blood banks are adopting a similar approach, particularly in light of data showing that such a policy can reduce the incidence of TRALI; however this is not universal, in part due to shortage in supply of AB or "universal" plasma.

Transfusion-Associated Circulatory Overload

A new name for a long-standing problem, transfusion-associated circulatory overload (TACO) is thought to be precipitated when a patient's circulatory system is overcome by either the volume or the speed of a transfusion of blood products. Clinically underrecognized, TACO has a reported incidence of only 1 out of 700 patients. But its true incidence may be as high as 8%, taking into account all blood products; in fact, it may be responsible for as many as 20% of all reported transfusion-related deaths. TACO is characterized by an acute onset of tachypnea, dyspnea, hypertension, and tachycardia. It is difficult to distinguish from TRALI. Usually, in TACO patients

BOX 1: Criteria for transfusion-related acute lung injury

- Acute onset: during, or within 6 hours of, transfusion
- Hypoxemia
 - O_2 saturation < 90% at room air
 - Ratio of PaO_2/FiO_2 < 300 mm Hg
- Bilateral infiltrates on chest x-ray
- No evidence of left atrial hypertension
- No preexisting acute lung injury prior to transfusion
- No temporal relationship to alternative risks for acute lung injury

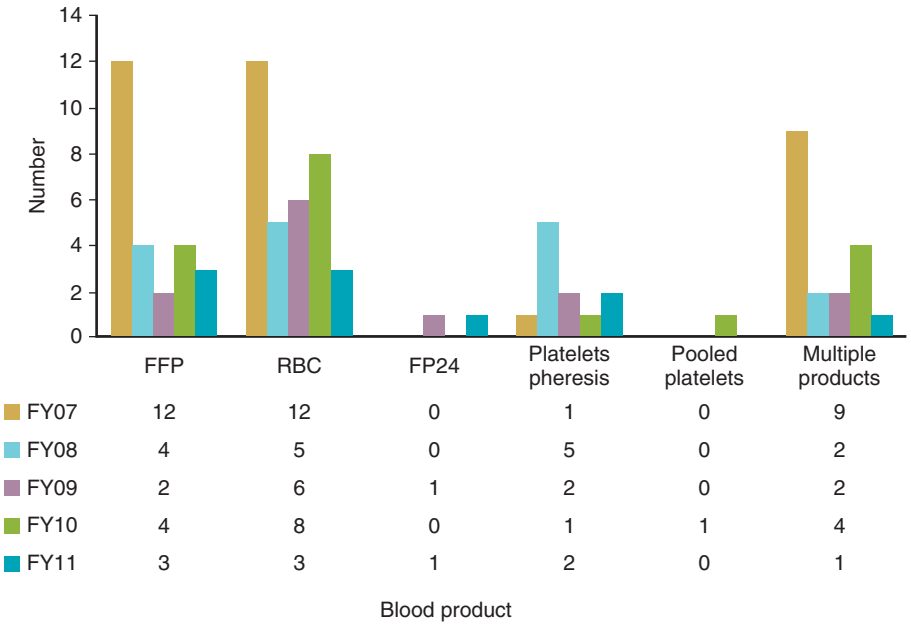

FIGURE 5 Risk of developing TRALI based on specific blood component transfusion. *FFP,* Fresh frozen plasma; *RBC,* red blood cell; *TRALI,* transfusion-related acute lung injury. *(From Food and Drug Administration Vaccines, Blood and Biologics website: http://www.fda.gov/BiologicsBloodVaccines/default.htm.)*

(unlike in TRALI patients), serum brain natriuretic peptide levels are significantly elevated above baseline.

It is not surprising that TACO is more common in older patients with poor cardiopulmonary reserve and/or those with renal insufficiency. TACO increases ICU and hospital length of stay as well as morbidity and mortality rates. Treatment is limited to supportive care (e.g., oxygen therapy, diuresis, mechanical ventilation if necessary). The best strategy is prevention by only the judicious administration of blood products.

Fever and Allergic Reactions

About 1 out of 100 to 200 patients will develop a fever or have an allergic reaction after a transfusion of a blood product. Nontoxic, circulating, immune complexes are thought to be responsible. Usually, fevers and allergic reactions can be safely treated with Tylenol and Benadryl. In addition, it is prudent to discontinue the transfusion and report the complication to the blood bank, in the event that it may be an early sign of a more serious hemolytic reaction.

Hemolytic Reactions

Hemolytic reactions can be either acute or delayed. Patients can develop different symptomatic patterns, depending on the timing of the presentation of the reaction. Acute hemolytic reactions typically occur within 24 hours after a transfusion with intravascular symptoms; delayed hemolytic reactions more commonly occur 1 to 10 days after a transfusion with extravascular manifestations (Table 3). The incidence is 1 out of 12,000 to 25,000 patients, but the mortality rate is as low as 1 out of 650,000 patients.

Reactions are caused by the immune-mediated lysis of RBCs. Acute hemolytic reactions are usually related to preformed antibodies. The transfusion should be immediately halted and the reaction reported to the blood bank. Treatment consists of supportive care and fluid resuscitation, with an emphasis on preventing acute kidney injury. To confirm the diagnosis, the patient's workup should include a direct Coombs test.

Electrolyte Disturbances

RBCs gradually leak potassium into the supernatant in which they are suspended, putting patients who receive multiple units of PRBCs at risk for hyperkalemia. In clinical practice, this is rarely an issue in patients with normal renal function. Even in patients who undergo massive transfusions, recent data have suggested that the potassium level rarely rises high enough to be a problem.

A more significant concern is the hypocalcemia associated with multiple transfusions: it can lead to cardiac depression because of the citrate contained in the buffer storage solutions, which chelates the Ca^{2}+ ions. Patients who undergo multiple transfusions should have their ionized calcium level checked regularly; if it is low, supplementation should be aggressive.

TABLE 3: Incidence of symptoms in hemolytic reactions

Symptom	Acute (intravascular)	Delayed (extravascular)
Fever, chills	80%	55%
Renal failure	35%	5%
Pain	15%	2.5%
Nausea, vomiting	10%	—
Hypotension, tachycardia	12%	—
Disseminated intravascular coagulation	10%	5%
Jaundice	—	10%

Infectious Risks

Since the mid-1990s, transfusion-related infectious risks have decreased dramatically and are now extremely rare. Estimates of the current incidence of various infections are shown in Table 4. These numbers represent the risk of exposure; actual seroconversion is also related to multiple host factors. Bacterial contamination is obviously much more common from transfusions of platelets, whose storage requirements are ideal for bacterial growth.

Hypothermia

Inattention to detail, especially in patients undergoing multiple transfusions, can lead to fairly profound hypothermia, with deleterious consequences for enzymatic functioning of the entire body. A number of commercially available warming devices (e.g., Level 1 and Hotline, Smiths Medical, Rockland, Mass; Belmont, Belmont Instrument, Billerica, Mass; enFlow, Vital Signs, Totowa, NJ) can be used to allow for the warming of fluids (usually to 40°C). Such devices should be used whenever more than 1 or 2 units of blood products are to be transfused.

NOVEL ANTICOAGULANTS

Increasing problems with novel anticoagulants have recently emerged in our older trauma population with numerous comorbidities. As clinicians, we are well aware of the problems associated with antiplatelet therapy or warfarin in trauma patients, but new medications

TABLE 4: Risk of exposure to an infectious agent per unit of blood component therapy

Infectious agent	Risk per unit
HIV	1:1,860,000
Hepatitis B	1:365,000
Hepatitis C	1:1,650,000
HTLV	1:3,390,000
Bacterial contamination	1:1000 to 1:100,000 for platelets 1:100,000 to 1:1,000,000 for red blood cells
NvCJD	Unknown, not yet described
Rabies	Unknown
Dengue, West Nile virus	Possible, risk unknown

HIV, Human immunodeficiency virus; *HTLV,* human T-cell lymphotrophic virus; *NvCJD,* new variant Creutzfeldt-Jakob disease.

such as the direct thrombin inhibitor argatroban pose fresh challenges. Licensed for use in patients with nonvalvular atrial fibrillation, argatroban currently has no specific "antidote" per se, although up to 72% of its activity can be removed via hemodialysis. In the case of massive hemorrhage, manufacturers of argatroban suggest the use of PRBCs, FFP, and even factor VIIa, but with minimal human data to support the recommendation.

The anticoagulant effects of a similar drug, rivaroxaban, were completely and immediately reversed by the administration of PCCs, according to a study of healthy human volunteers. PCCs were ineffective, however, in reversing the anticoagulant effect of yet another new drug, dabigatran. Other new anticoagulant drugs also exist that are not yet currently available in the United States, which may pose even more challenges.

NEW DIRECTIONS

The largest randomized clinical trial ever performed on blood management in trauma patients is currently enrolling patients. It was specifically designed to determine the most effective ratio of plasma to PRBCs in the civilian arena. Its two randomization strategies are a 1:1:1 ratio versus a 1:1:2 ratio of PRBCs to platelets to FFP. The trial will likely be completed in 2014. It is hoped that the trial will help answer, once and for all in civilian patients, whether the higher ratio leads to improved outcomes or to increased complications.

We are also rediscovering some of the lessons of the past, as recent work has highlighted a technique that the U.S. Navy incorporated into its practice many decades ago, namely, the use of cryopreserved deglycerolized blood. Initially described in 1950, this practice allows blood to be stored for up to 10 years when frozen at −80° C. Although this seems to be counterintuitive to the usual adage that older blood is worse for patients, a pilot study published in 2013 by Fabricant and colleagues suggests that results are at least equivalent to, and possibly better than, results obtained in trauma patients requiring transfusion. Further work needs to be done to confirm these preliminary findings.

Blood substitutes continue to be the holy grail of transfusion therapy in trauma patients. Theoretically, such substitutes would provide the benefits of transfusions with few, if any, of the infectious risks; would obviate the need for blood donation; and would, ideally, cost less. To date, however, none of these substitutes have made it out of clinical trials, and interest in them has waned, especially after the well-publicized and unfortunate negative results of the Hemoglobin-Based Oxygen Carrier (HBOC) trial.

In contrast, the use of lyophilized, freeze-dried plasma continues to garner significant interest, in both civilian and military arenas. At least one phase 1 human safety trial has been completed, and phase 2 human trials in trauma patients will begin soon. The U.S. Department of Defense has identified such work as a top research priority and has awarded millions of dollars to help develop this resurgent field.

Coagulation Issues and the Trauma Patient

Jeffry L. Kashuk, MD, FACS, and Reuven Rabinovici, MD, FACS

OVERVIEW

Postinjury coagulopathy accounts for more than half of trauma-related deaths globally. Despite improvements in surgical techniques and critical care, including advances in damage control surgery, the death rate associated with this condition has changed little over the past 25 years. Furthermore, the exact relationship between trauma-induced coagulopathy and death has not yet been established.

Previous studies have shown that in patients presenting with massive hemorrhage after injury, refractory coagulopathy ultimately leads to death even when surgical control of the wound has been accomplished, a phenomenon termed "the bloody vicious cycle." Furthermore, survivors of the hemorrhagic insult are at increased risk of late death associated with multiple organ failure.

Although the bloody vicious cycle has been recognized for more than 35 years, its pathogenesis is still obscure, and improved understanding of the coagulation issues associated with the trauma patient has evolved only recently. This understanding resulted primarily from knowledge gained in three principle areas: (1) evolution of the cell-based model of coagulation; (2) improved analyses via rapid, point-of-care determination of whole blood coagulation (thromboelastography [TEG] or thromboelastometry [ROTEM]); and (3) clinical experience gained in recent international military conflicts (hemostatic resuscitation).

ETIOLOGY AND NATURAL HISTORY

Traditionally, clotting factor depletion, dilution from crystalloid administration, hypothermia, acidosis, and hypocalcemia were considered the primary factors that fuel postinjury coagulopathy. Indeed, multiple protocols were developed to carefully address these issues during the resuscitation of the injured patient.

Clotting Factor Depletion and Dilution With Fluid Resuscitation

Recent evidence suggests that traditional Advanced Trauma Life Support (ATLS)–guided crystalloid resuscitation for the patient in shock may be detrimental. Frequently, excess fluid administration in patients with hypotensive conditions results in cyclical swings in blood pressure, which necessitate additional fluid administration. Consequently, intravascular volume is increased and clotting factors are diluted. This dilutional coagulopathy, combined with clotting factor depletion from blood loss, exacerbates the bleeding and shock state. In response to this deterioration, more fluids are administered, and this vicious cycle perpetuates. Recent reports suggest that the procoagulants fibrinogen, factor V, and factor VIII are particularly important and can be restored to adequate levels (>20%) to promote timely hemostasis in the injured patient. In addition, platelet counts have been shown to be slower to fall compared with red blood cell counts or coagulation factors, likely because approximately one third of the platelets are trapped in the spleen or attached to the vascular endothelium. Specifically, platelet counts of less than 50,000/mL are uncommon in patients who need less than 20 units of packed red blood cells (pRBC).

Hypothermia

Severely injured trauma patients are at substantial risk for hypothermia, which is a known independent risk factor for death in this group. Hypothermia has direct detrimental effects on the coagulation enzymatic cascade, including fibrinogen cross linking and platelet adhesion and function. Recent data suggest that although hypothermia compromises the activity of procoagulant plasma proteins, it exerts a more significant effect on platelet activation through traction on the glycoprotein Ib/IX/V complex by von Willebrand's factor. This important phase of platelet activation is completely inhibited in 50% of patients with hypothermia at 30°C. Accordingly, major efforts to control the environment of the injured patient should be accomplished as soon as the patient presents to the trauma center. These efforts should include the use of the Baer Hugger device (Arizant, Inc., Eden Prairie, Minn), warm resuscitation agents, and warm irrigating solutions during surgery.

Acidosis

Acidosis develops in injured patients with shock, hypoperfusion, and concomitant anaerobic metabolism. This condition has been shown to affect multiple aspects of coagulation. Recent reports have clearly established that acidosis is a highly reliable indicator of hypoperfusion and shock, is associated with an increased risk of death, and is best corrected with appropriate resuscitation with restoration of oxygen delivery to the tissues. Because the coagulation pathway is dependent on multiple enzymatic reactions eventuating in a stable clot, completion of these reactions is an essential aspect of hemostasis. Accordingly, acute alteration in pH impedes the process, mainly through compromising fibrinogen cross linking, platelet aggregation, and thrombin generation. In addition, acidosis has been shown to accelerate fibrinogen consumption with no effect on fibrinogen production, resulting in a deficit in fibrinogen availability. Lastly, acidosis prevents the congregation of procoagulant complexes in which calcium and negatively charged phospholipids interact. For example, a pH of 7.2 decreases the activity of the Xa/Va/prothrombinase complex by 50%, and a pH to 6.8 turns the complex off.

Hypocalcemia

Hypocalcemia frequently occurs in the patient who undergoes massive transfusion, conceivably through chelation by the citrate used to preserve banked blood (each unit of pRBC contains approximately 3 g of citrate). Because this electrolyte is a key cofactor to many procoagulation proteins, it likely plays an inhibitory role in the evolution of trauma-related coagulopathy. Indeed, some studies suggest that ionized calcium concentrations of less than 0.6 to 0.7 mmol/L could lead to coagulation defects and recommend maintaining a concentration of at least 0.9 mmol/L. In contrast, other reports suggested that hypocalcemia per se does not clinically affect coagulation but rather induces hypotension and tetany in the patient with massive transfusion.

Anticoagulants

Anticoagulants may contribute to the coagulopathic state and may complicate the management of trauma patients taking such medications. Thus, injured patients need a careful history to ascertain whether preexisting antiplatelet or anticoagulant agents have been administered. Current evidence suggests that empiric protocols for reversal of these agents reduce mortality and improve functional outcomes, particularly in elderly patients with intracranial hemorrhage. One study showed that the activation of a warfarin protocol consisting of fresh frozen plasma (FFP) improved functional survival in patients who sustained intracranial hemorrhage. Other reports support the use of factor VIIa to reverse coagulopathy in patients with an international normalized ratio (INR) of more than 1.4 and traumatic brain injury (Glasgow coma scale [GCS], <14). Because many of these patients are elderly with cardiac comorbidities, recombinant factor VIIa (rFVIIa) also prevents the fluid overload associated with large volumes of FFP, otherwise necessary to reverse coagulopathy.

More injured patients increasingly arrive in the trauma room taking a new variety of direct thrombin inhibitors, such as Pradaxa (dabigatran) (Boehringer Ingelheim Pharma GmbH & Co., Ingelheim, Germany). Because no established reversal agent exists for these novel anticoagulants, current protocols have suggested that activated charcoal or dialysis may be helpful to clear the drug from the body. Both techniques are of little use in the patient with acute bleeding, so direct thrombin inhibitors remain a challenge to the trauma surgeon. Accordingly, current protocols continue to emphasize all traditional methods of support, including FFP, blood, and specific factor replacements, although no current evidence supports such use.

CURRENT CONCEPTS OF COAGULATION

Several new concepts regarding trauma-related coagulopathy have evolved recently. The first suggests that coagulopathy occurs very early after trauma independently of clotting factor or platelet deficiency. Because this condition, termed "acute endogenous coagulopathy," occurs in the presence of normal concentrations of coagulation factors and platelets, it is unresponsive to factor replacement therapy. Experience from the U.S. military conflicts in Iraq and Afghanistan and civilian data suggest that nearly 30% of severely injured patients arriving at the hospital have coagulopathy (based on conventional coagulation testing) despite the absence or deficiency of clotting factors. In a recent trial of hemoglobin-based oxygen carriers, such early coagulopathy was noted in 29% of patients based on field blood obtained within 15 minutes of injury. Of note, this subset of patients was shown to have a substantially increased risk of multiple organ failure and death. Furthermore, a 2012 prospective study of 101 trauma patients showed clinically relevant platelet dysfunction measured with multiple electrode impedance aggregometry in the presence of normal platelet count. Although conventional coagulation tests are still most commonly used to evaluate for the presence of coagulopathy, a true definition of the entity is not clear because most reports use varied and arbitrary thresholds such as prothrombin time

(PT) more than 18 seconds, activated partial thromboplastin time (aPTT) more than 60 seconds, and INR more than 1.5. All of these commonly used assays have substantial limitations for evaluation of the patient with acute bleeding. They are static tests, have buffers added, and are plasma based, meaning that the contribution of the platelet and associated thrombin generation to clot strength cannot be appreciated. In addition, they are performed at normal pH and 37°C, which may not accurately reflect the in vivo status of coagulation in the bleeding trauma patient.

Another evolving concept in trauma-related coagulopathy is the introduction of a new cell-based model of coagulation. This concept, which challenges the traditional paradigm of intrinsic and extrinsic pathways, emanates from in vivo studies that highlight protein and other cellular components in the presence of an active vessel wall. According to this paradigm, tissue injury/ischemia, exposed tissue factor, inflammatory mechanisms, hypoperfusion, and hyperfibrinolysis combine to drive the initial process. Later, as factor and platelet deficiency from blood loss and dilution occurs, systemic coagulopathy evolves. The model defines initiation, amplification, and propagation as three distinct activation phases. The initiation of primary hemostasis, which includes clot formation through adherence of platelets to the injured endothelium, occurs via thrombin generation induced by interactions of tissue factor expression at the endothelial level under the influence of activated factors VII (VIIa), X, and Va. This process has been shown to involve significant "cross talk" with inflammatory mechanisms, and current research suggests that the complement system may represent a common pathway linking inflammation and coagulation. Secondary hemostasis is initiated by thrombin generation via the coagulation cascade, resulting in deposition and cross linking of fibrin. The net result of platelet aggregation, fibrin deposition, and fibrin cross linking should be a stable clot. On the basis of this new cell-based model, it is apparent that burst thrombin generation is a central event for hemostasis because it triggers platelet activation and subsequent cleavage of soluble fibrinogen into fibrin. Interestingly, experimental studies have shown that the inception of clot propagation occurs with only minute amounts of thrombin being present, accounting for less than 5% of the total amount generated. After clot initiation and achievement of maximum clot strength, the process of fibrinolysis is initiated. Thus, this lytic process allows for a global assessment of the duration and strength of the clotting factors. Current understanding of fibrinolysis suggests that the beta globulin plasminogen is converted to a physiologically activated form via tissue plasminogen activator (t-PA), although the process of fibrinolysis may be initiated via several mechanisms, including activation of streptokinase or kallikrein, which directly activates plasminogen. Of particular current interest, protein C is believed to stimulate release of t-PA from the endothelium after injury, resulting in plasminogen activation. These processes result in breakdown of fibrin and fibrinogen with generation of fibrin split products, which are often measured in the clinical scenario.

Unfortunately, most currently used tests to assess coagulopathy do not address the events identified by the cell-based model of coagulation. Furthermore, they are too nonspecific or time-consuming for use in the trauma setting. Accordingly, two new clinical approaches have evolved. First, growing evidence suggests the empiric use of antifibrinolytic therapy in patients at risk for postinjury coagulopathy. Second, viscoelastic tests, such as TEG or ROTEM, to identify the hyperfibrinolytic state were developed and implemented in clinical use (see subsequent).

TREATMENT OF THE BLEEDING TRAUMA PATIENT: OPTIMAL USE OF COMPONENT THERAPY

Warm whole blood appears to be the ideal resuscitation method for the patient with acute bleeding, but this product is rarely available in the civilian setting, except for the occasional use of autotransfused intracavitary blood (cell saver). This technique is not commonly used for several reasons. First, it can be applied only in the absence of contamination. Second, it requires citrate addition to prevent coagulation in the collection device. And third, its logistics often cannot be accommodated because of the emergent nature of the traumatic injury. Thus, the current techniques of component transfusion therapy remain the mainstay of treatment. Unfortunately, refrigeration and storage result in multiple changes in blood products, including decrease in factors V and VII concentration and rapid deterioration of red blood cell and platelet function. Interestingly, recent clinical evidence suggests that platelet dysfunction is the earliest defect that should be treated because endogenous bursts of circulating clotting factors during the hyperacute phase seem to maintain procoagulant effect.

Fresh Frozen Plasma

FFP remains the major source of clotting factors for component transfusion in the United States. FFP is prepared by isolating the plasma from the cellular components via centrifugation of whole blood within 6 to 8 hours of collection. With most systems, the hemostatic activity of the various coagulation factors can be maintained for long periods of time when frozen, although on thawing, the factor concentrations begin to rapidly decrease. Thawed FFP contains excellent concentrations of the various coagulation factors, including up to 400 mg of fibrinogen. Accordingly, FFP should be maintained until a rapid need is present, at which time thawing can be initiated via warming baths in the blood bank. Several busy trauma centers, where larger volumes of plasma are anticipated for use, have initiated the use of prethawed plasma, which is cycled for less than 24 hours to allow for optimal levels of coagulation factors. This plasma (primarily type O or A) may be readily available in the emergency room without the need for waiting the additional 15 to 20 minutes for the thawing process.

The exact dosing and timing of FFP administration is one of the most widely debated topics in trauma. Current evidence from both civilian and military data suggests that early preemptive administration of FFP combined with minimal crystalloids infusion and permissive hypotension improves survival and reduces risks for complications, such as multiple organ failure and abdominal compartment syndrome. Most up-to-date clinical practice suggests that an initial resuscitation transfusion ratio of FFP to red blood cell (RBC) in the range of 1:2 appears to result in optimal survival thresholds. The need for ongoing transfusions, however, may be best determined based on the clinical course of the patient, surgical hemorrhage control, the need for damage control procedures, and the clinical assessment of clot strength, which may be best ascertained via point of care viscoelastic testing.

Platelets

Platelet concentrates were traditionally prepared from pooled platelets obtained from centrifugation of individual units of whole blood. Nevertheless, apheresis or single donor collections, which result in fewer donor exposures for a given dose of platelets, are used in most centers. Transfusion of 1 unit of apheresis platelets, which contains approximately 3×10^{11} platelets in 200 to 250 mL of donor plasma, increases platelet count by 30 to 50 K/mm^3. Although the classic threshold for platelet transfusion has been 50 K/mm^3, a higher target level of 100 K/mm^3 has been suggested for those patients at risk for postinjury coagulopathy. Similar to plasma and packed red cell administration, platelet transfusion has been associated with immunologic complications, with a reported incidence rate of more than 200 per 100,000 transfused patients. Because the cell-based model of coagulation emphasizes the central role of the platelet towards thrombin generation, it is likely that platelet function rather than any absolute threshold of platelet count should be the focus of future

therapies. Lastly, current evidence supporting routine prophylactic platelet administration in the patient who has been injured and is at risk for coagulopathy seems less convincing than that for plasma, and the risks of transfusion-related complications may be significant.

Cryoprecipitate

Cryoprecipitate is the cold insoluble fraction formed when FFP is thawed at 4°C. "Cryo" is rich in factors VIII and XIII, von Willebrand's factor, and fibrinogen. Generally, fibrinogen levels greater than 50 mg/dL have been considered sufficient to support hemostasis. Although current evidence suggests that fibrinogen should be replaced early in trauma patients at risk for coagulopathy, this can usually be accomplished via administration of FFP. Further, many guidelines recommend a replacement threshold for plasma fibrinogen levels of less than 100 mg/dL (1 g/L), with either fibrinogen concentrate, which is used increasingly in Europe (3 to 4 g), or cryoprecipitate (50 mg/kg, or 15 to 20 units). It is often underappreciated, however, that FFP, pooled platelets, and even some pRBCs contain fibrinogen (Table 1). Current recommendations, therefore, call for evaluation of plasma fibrinogen levels after administration of component FFP or platelets during massive transfusion with supplementation of cryoprecipitate as necessary based on such testing. Currently, no clinical evidence supports routine preemptive administration of cryoprecipitate in patients at risk for coagulopathy.

Aminocaproic Acid, Aprotinin, and Tranexamic Acid

Although shock has long been recognized to induce fibrinolysis, the contribution of this process to reduced clot strength in the injured patient has been poorly understood and difficult to identify in the clinical setting. Growing clinical evidence, however, suggests that patients with significant trauma with associated blood loss and coagulopathy likely have hyperfibrinolysis develop as an integral aspect of their pathophysiology. Furthermore, patients with development of this state, as identified with viscoelastic testing, likely need antifibrinolytic therapy to reverse this process, which has been associated with the highest mortality in this cohort. Accordingly, the most common agent administered in the United States is epsilon aminocaproic acid (Amicar), a lysine analogue that binds reversibly to plasminogen, preventing its activation to plasmin. Other agents available include aprotinin and tranexamic acid, which is being extensively used in Europe. The authors' preliminary experiences suggest that in the face of suspected or proven hyperfibrinolysis, Amicar (5 to 10 g/20 mL) should be administered as necessary to reverse the lytic process and restore hemostasis.

TABLE 1: Composition of various component blood products

Component	Fibrinogen (mg)	Clotting factors
Fresh frozen plasma (4 units)	1600	1 mL contains 1 unit of each coagulation factor*
Cryoprecipitate (10 pack)	1200-1500	VIII/VWF: 800-1000 units
Apheresis platelets (6-10 pack)	300	>3 × 10 platelets/ apheresis unit 200-250 mL of plasma equivalent†
Packed red blood cells	50-300‡	None

*Thawed plasma (day 1-5) has a 230% decrease in factors V and VIII.
†As a result of room temperature platelet stroage, factors V and VIII are decreased in the plasma portion.
‡Most red blood cells preservations via Adsol (Fenwal, Inc., Lake Zurich, Ill) have low fibrinogen levels, whereas preservations with CPDA (citrate-phosphate-dextrose-adenine) have higher fibrinogen concentrations.
From Kashuk JL, Moore EE, Sawyer M: Postinjury coagulopathy management: goal directed resuscitation via POC thrombelastography, Ann Surg *251(4):604-614, 2010.*

Recombinant Factor VIIa

rFVIIa is approved by the U.S. Food and Drug Administration (FDA) for the treatment of hemophilia with inhibitory antibodies. However, because factor VII is thought to play a key role in local hemostasis at the site of injury, it was targeted as a potential therapeutic agent for the bleeding trauma patient. In spite of extensive efforts to show efficacy, including several randomized placebo-controlled double-blind clinical trials, no clear evidence shows that rFVIIa alone or as an adjunct to standard resuscitation improves mortality in exsanguinating trauma cases. Unfortunately, the last such study (the CONTROL study), which included 150 centers in 26 countries, was prematurely discontinued after enrolling 573 patients because of unexpected low mortality prompted by futility analysis and difficulties consenting and enrolling sicker patients. Nevertheless, several observations regarding the use of rFVIIa in trauma patients emerged based on the best available data. First, rFVIIa seems to be safe with no increased risk for thromboembolic complications compared with placebo. Second, the administration of rFVIIa, as a single therapeutic agent, is unlikely to be efficacious. Third, rFVIIa possibly decreases blood transfusion requirements in blunt, but not penetrating, trauma cases. Fourth, the administration of rFVIIa in patients with coagulopathic conditions with traumatic brain injury seems to be cost effective, reduces time to surgery, and is efficacious. Given the previous observations, many trauma centers use rFVIIa off label to control massive bleeding, although its efficacy as a general hemostatic drug has not been confirmed. This practice may lose popularity with the evolution of the new principles guiding damage control resuscitation.

Massive Transfusion Protocol

Current evidence suggests that an institutional massive transfusion protocol, which allows for preemptive administration of readily available blood products in a "push" rather than "pull" system, can improve management of postinjury coagulopathy and result in improved survival of the injured patient. Although only 3% to 5% of civilian patients who present to the trauma center need a massive transfusion, it is precisely this cohort that maximally consumes costly hospital resources. Of paramount importance, the protocol, which defines an initial automatic blood bank response to the exsanguinating patient, should be tailored to the individual hospital's local support system, with particular attention to establishing cooperation between the trauma department, anesthesiology department, and laboratory or blood bank. This facilitates a smoothly functioning mechanism that is reliably activated when required to instantly address the needs of the trauma patient with massive bleeding. Although no class 1 data prove that such protocols save lives, it is doubtful that such studies will ever be performed because of wide variability of transfusion and institutional protocols. Despite this, most protocols allow for early, preemptive administration of high-ratio FFP:RBC (approximately 1:2), with the addition of platelets and cryoprecipitate depending on ongoing blood losses. Many

trauma centers use a predetermined amount of blood products sent to the trauma room, operating room, or surgical intensive care unit immediately on activation. This usually consists of 2 to 3 trauma packs, each including 8 to 10 units of group O blood (either O-positive or O-negative, based on patient age and gender), 4 to 6 units of thawed type AB plasma, and 1 unit of single donor platelets. Additional support beyond these packs is discussed between the trauma attending and the blood bank. Other hospitals have developed protocols that rely on the frequent (every 30 minutes, if needed) assessment of laboratory coagulation function and point-of-care TEG. Conventional coagulation tests include PT, usually via the INR; aPTT; platelet count; and fibrinogen level. Clinical evidence suggests that ongoing coagulopathy occurs in the face of an INR more than 1.5, PTT more than 1.5 normal, platelet count less than 100 K, and fibrinogen less than 100 mg/dL. A growing number of trauma centers base their massive transfusion on TEG readings, as described subsequently.

Viscoelastic Testing

The viscoelastic test is the only currently available method with which thrombosis and lysis may be simultaneously evaluated in the injured patient. Although the PT is limited as a measure of only the extrinsic clotting system (factors VIIa, Xa, and IIa), and the PTT is limited by the reactions of the intrinsic system (factors XIIa, Xia, IXa, and IIa), TEG allows the evaluation of the whole system and of platelet function and thrombolysis in whole blood. Rapid TEG is a technique that involves addition of tissue factor to the whole blood specimen, resulting in an even more rapid reaction, particularly suited for the trauma patient. In brief, TEG is a graphic representation of the evolving blood clot (Figure 1) generated via a transducer, which senses the resistance to motion of a microprobe inserted into a small vial of whole blood that is under motion to generate the clot. The resulting tracing is then computer generated and reflects component deficits in the plasma, fibrinogen, platelets, or fibrinolysis. In addition, this methodology assesses clot initiation, maximal clot strength, and rates of subsequent lysis. These capabilities allow for component-specific treatment of traumatic coagulopathy, as described subsequently.

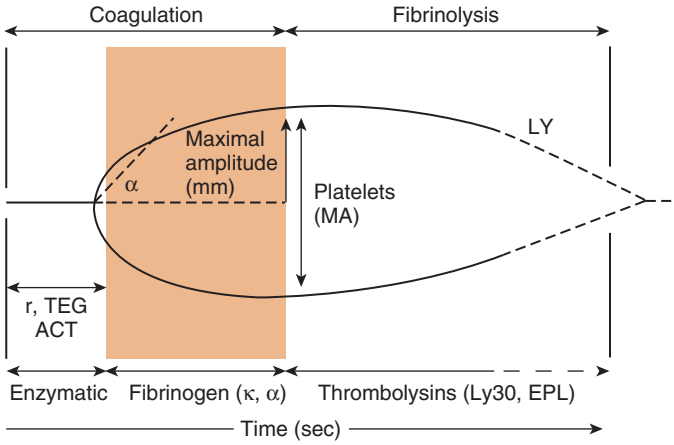

FIGURE 1 Graphic representation of clot formation in rapid thromboelastography *(r TEG)*. The *r* value (TEG-ACT [activated clotting time] in r TEG) represents initial thrombin generation and is a reflection of enzymatic clotting activation. κ value is the interval measured from the r (TEG-ACT in r TEG) to a fixed level of clot firmness or the point that the amplitude of the tracing reaches 20 mm; this reflects thrombin's ability to cleave soluble fibrinogen. The α angle is the angle between the tangent line drawn from the base horizontal line to the beginning of the cross-linking process, measured in degrees, and is affected primarily by the rate of thrombin generation. Thus, the α angle represents clot rapidity; a higher angle indicates an increased rate of clot formation. The maximal amplitude *(MA),* measures the end result of maximal platelet-fibrin interaction, reflecting the formation of the platelet plug and thus, the clot strength. The final reading of the tracing is the estimated percent lysis *(EPL),* also expressed as the *LY30,* or degree of lysis at 30 minutes of the tracing. An EPL of greater than 15% reflects significant hyperfibrinolysis. In addition, the TEG can measure the clot strength (G), which is a computer-derived value, suggested to be the best measure of clot strength because it reflects components of both the enzymatic and the platelet components of hemostasis.

Goal-Directed Therapy of Trauma-Induced Coagulopathy

Transfusion therapy guided by viscoelastic testing has become an integral part of resuscitation strategy in many institutions in the United States (TEG) and Europe (ROTEM). Because of the rapidity of results and point-of-care, this technology has allowed for evolution of goal-directed therapy of specific coagulation deficits identified during massive resuscitation. Such an approach has allowed for accurate, stepwise correction of coagulation dysfunction with comparative analysis of various tracings generated (Figure 2).

Institutional experience with these techniques is growing despite a significant learning curve for all providers, and TEG and ROTEM–guided therapy is gaining popularity. The potential benefits of such an approach could result in reduced transfusion requirements, earlier correction of coagulation deficits, and ultimately improved survival in this critically ill cohort.

MILITARY EXPERIENCE

The recent Iraq-Afghanistan conflicts have significantly advanced our knowledge and understanding of thrombosis and hemostasis in the injured patient. The most significant progress has been the recognition that decreased crystalloid administration combined with the principles of hemostatic/damage control resuscitation is beneficial. Although the military demonstrated impressive advantages to the use of warm whole blood for shock resuscitation, this product has not been available in the civilian sector for more than 30 years because of cost concerns and quality control issues related to the transmission of blood-borne pathogens. Accordingly, the military showed that resuscitation strategies that attempt to mimic whole blood with use of component therapy in ratios approaching 1:1 FFP: RBC resulted in significant, often dramatic improvements in survival of patients at risk for postinjury coagulopathy. Some studies also advocated equal use of preemptive platelets. These concepts have been embraced over the past 5 years by the civilian sector as well. Although there are still no level one evidence studies, current civilian experience learned from the military has established the importance of preemptive plasma to RBC in ratios of at least 1:2 as being effective while maintaining a reduced risk of transfusion-related lung injury, multiple organ failure, and abdominal compartment syndrome. Thus, these military-derived resuscitation paradigms have led to a major shift in our approach to the injured patient at risk for coagulopathy.

SUMMARY

Postinjury coagulopathy is a multifactorial syndrome that demands meticulous attention in the acutely bleeding patient. Current approaches include early recognition of the patient at risk, with

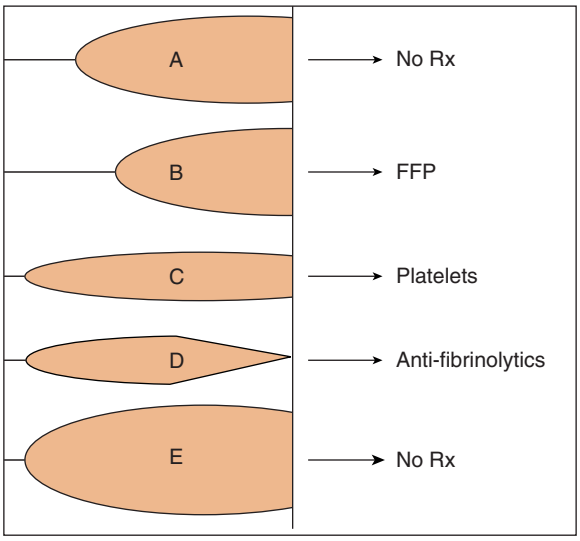

FIGURE 2 Thromboelastography (TEG) tracing patterns indicating specific coagulation deficits. *A,* Normal TEG graphic. *B,* Prolonged r value (TEG-ACT [activated clotting time] in rapid TEG), suggestive of the need for additional fresh frozen plasma *(FFP)* treatment. *C,* A narrowed maximal amplitude (MA), or decreased clot strength, is suggestive of the need for platelet therapy, and an increased MA and short r value may indicate a hypercoagulable state. *D,* Hyperfibrinolysis, which should prompt antifibrinolytic treatment. *E,* Decreased clotting and clotting formation time, elevated α-angle, and increased MA represent a hypercoagulable state. *(Reprinted with permission from Haemonetics Corp, Braintree, Mass.)*

prompt resuscitation techniques, which include early provision of blood component therapy, significantly reduced crystalloid administration, and particular attention to the effects of hypothermia, acidosis, and other associated factors. Because of the difficulty in estimating the massive transfusion needs of the injured patient, current evidence suggests that an established massive transfusion protocol with preemptive blood product availability significantly assists in the successful resuscitation of the injured patient. Finally, growing experience with viscoelastic testing suggests that this technology may offer great promise for the continuing management of these patients.

The Abdomen That Will Not Close

Jordan A. Weinberg, MD, and Timothy C. Fabian, MD

The appreciation of abdominal compartment syndrome (ACS) in the 1980s ultimately led to a fundamental change in the management of the laparotomy wound. The "open abdomen" has become the standard treatment both for the management of ACS, by decompressive laparotomy, and for the prevention of ACS, by leaving the abdomen open after operations in the setting of shock. Although the open abdomen has contributed to the salvage of patients who may otherwise have died, the surgeon is then faced with the subsequent management of this open wound, with its inherent acute and chronic challenges. The acute challenge involves prevention of potential collateral damage, including the disastrous complication of intestinal fistulae. The chronic challenge created by the successful avoidance or treatment of ACS is that of definitive reconstruction of the large abdominal wall defect in the patients who recover from the acute insult. At the authors' institution, a fairly standardized staged approach for managing the abdominal wound has developed. The three stages are (1) prosthetic insertion and attempt at delayed primary closure, (2) staged split-thickness skin grafting for planned ventral hernia, and (3) definitive reconstruction with a modification of the components separation technique (Figure 1).

STAGE 1: PROSTHETIC INSERTION AND ATTEMPT AT DELAYED PRIMARY CLOSURE

Ideally, temporary wound closure should allow for containment and protection of the bowel from mechanical injury, prevention of adherence of the viscera to the closure materials and the abdominal wall, minimization of fascial injury, protection against abdominal compartment syndrome, and minimization of the loss of abdominal domain. Multiple methods and techniques have been advocated, and all optimize some of the characteristics described at the expense of others. It is also important to consider the time course of the open abdomen because techniques that optimize protection against abdominal compartment syndrome should be employed immediately after initial laparotomy, whereas techniques that limit fascial retraction my be indicated once the risk for abdominal compartment syndrome has waned and the primary goal becomes abdominal closure.

The authors' institutional approach to stage 1 is as follows. After the initial laparotomy, the authors favor the vacuum pack technique as described by Brock and coworkers in 1995 (Figure 2). A plastic drape is inserted in the peritoneal cavity covering the viscera, and on top of this is placed a surgical towel along with two sump drains

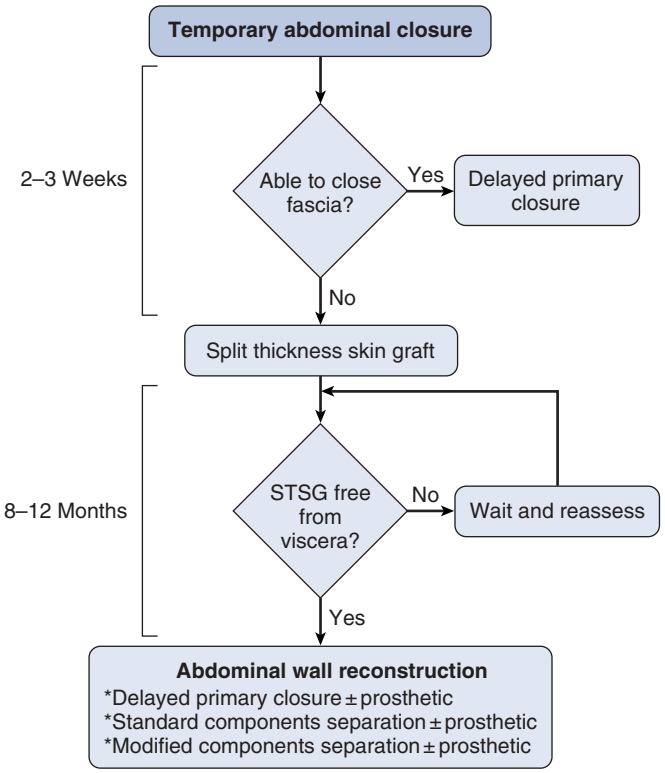

FIGURE 1 Flow diagram representing three-staged approach to management of the open abdomen. *STSG,* Split-thickness skin graft.

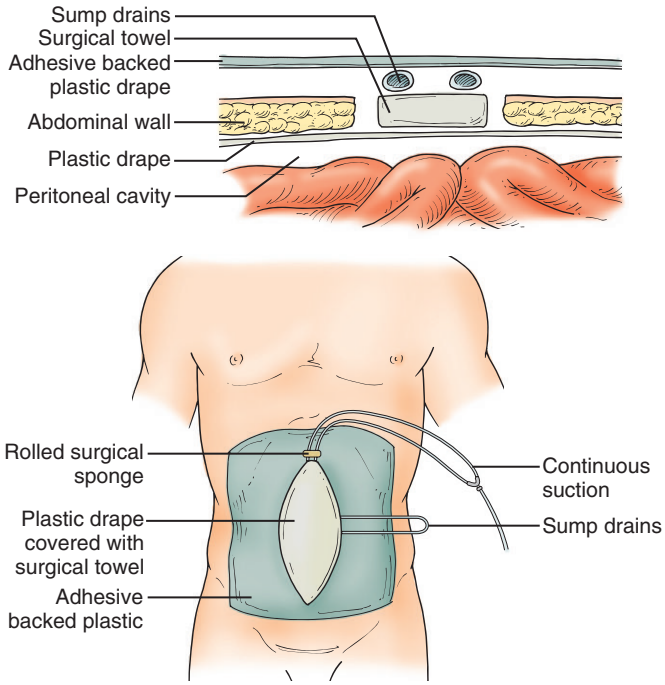

FIGURE 2 Vacuum pack technique for temporary abdominal closure.

covered with an adhesive-backed plastic drape attached to the patient's skin. The sump drains are placed on continuous suction. The advantages of using this technique after initial laparotomy are that it can be rapidly completed, it prevents abdominal compartment syndrome, and the material is easily removed at subsequent abdominal exploration for pack removal or bowel anastomosis. The authors have also found proprietary negative-pressure appliances designed for the open abdomen to be similarly efficacious. In cases of exceptional bowel and retroperitoneal edema in which the viscera protrude well above the level of the skin incision, the authors utilize a modification of the Bogota bag, whereby an x-ray cassette cover is fashioned as a silo and sewn to the skin with running heavy nylon suture.

The second phase of stage 1 is the attempt at delayed fascial closure. Once the resuscitative phase after initial laparotomy is completed and the patient has returned to the operating room for pack removal or definitive management of hollow viscus injuries, or both, delayed fascial closure may be possible, but often closure at this time would place too much tension on the fascia with risk for subsequent fascial necrosis and dehiscence. It is at this point that a technique that emphasizes minimization of fascial retraction should be employed. The preference at the authors' institution is to bridge the fascial wound gap with woven polyglactin 910 mesh, secured circumferentially to the fascia with running suture. Patients either recover and mobilize fluids over the next several days, which allows for gradual closure of the abdomen, or develop varying degrees of multiple organ dysfunction or sepsis. In the latter group, it is often not possible to close the fascia by progressive approximation. In that circumstance, the viscera granulate and adhere to the abdominal wall laterally and to the prosthesis, and the patient's wound is managed according to the principles of stage 2 (described next). If, however, the patient's hemodynamic status recovers and tissue edema begins to resolve, attempts are made at the bedside to pleat the mesh gradually with suture, with the goal of maintaining midline tension to attain a potential secondary fascial closure. If it becomes apparent that secondary fascial closure is feasible, as manifested by laxity in the mesh and physiologic improvement in the patient, the patient can be taken back to the operating room for mesh removal and fascial closure.

It has been the authors' experience, however, that the minority of open abdomens achieve delayed primary closure. In their reported experience from a randomized trial in which the authors compared polyglactin 910 mesh with vacuum-assisted closure utilized up to postoperative day 9, the authors found that closure rates were low, regardless of the technique employed (31% for vacuum-assisted closure, 26% for mesh). Other researchers, however, have reported much higher rates of fascial closure in single-institution case series, on the order of 70% to 100 % with the utilization of vacuum-assisted closure or other techniques that limit fascial retraction, such as the Velcro-like Wittmann patch. The challenge in accounting for these disparate results lies in the fact that the indications for utilizing the open abdomen are not uniform and in fact vary from center to center and from surgeon to surgeon. Institutions that err toward leaving abdomens open after laparotomy for trauma probably have a much higher rate of closure than do institutions that utilize the open abdomen less liberally, and in fact, there is growing concern that the open abdomen is being overutilized. In the authors' institutional experience, approximately 15% of trauma laparotomies are left open after initial operation.

STAGE 2: STAGED SPLIT-THICKNESS SKIN GRAFTING FOR PLANNED VENTRAL HERNIA

Should delayed fascial closure prove to be unattainable, a more permanent solution is required for the large ventral defect. The goal at this stage is to create a planned ventral hernia, whereby the absorbable mesh protecting the viscera is exchanged for split-thickness skin graft.

Although conventional wisdom suggests that absorbable mesh would be absorbed completely and not have to be removed, that has not been the authors' experience with the woven variety of polyglactin 910. Usually within 2 to 3 weeks, granulation occurs and a suppurative interface between mesh and viscera develops, which begins

to separate the two. At this point of healthy granulation, the viscera are stuck together and circumferentially to the abdominal wall, and patients are taken to the operating room. The mesh is removed easily because of the suppurative interface. After removal of the mesh, a pulsatile pressure irrigation system is used to reduce colonization of the granulation tissue, and a split-thickness skin graft is harvested and applied to the granulating viscera. The authors routinely mesh the graft 2:1 with a Brennan meshing device and secure the graft to the skin edges with staples or absorbable suture, depending on the surgeon's preference. For relatively large defects, multiple grafts may need to be secured together with absorbable suture in the manner of a quilt, and the authors have found it useful to additionally secure the graft with the application of aerosolized fibrin glue, which can also be applied to the donor site for hemostasis. A nonadherent dressing is then placed over the graft, and a Wound Vac sponge is placed on top, with negative pressure set at 75 mm Hg. On postoperative day 4, the Wound Vac sponge is removed, and the graft is covered with nonadherent dressings until healed. The final result is demonstrated in Figure 3.

Prevention and Management of Fistula

During the interval between mesh coverage and skin graft placement, development of fistulas is of concern. The authors analyzed their experience with fistulas in the open abdomen setting in 380 trauma patients managed over a 10-year period. The fistula rate in this group of patients was 8%, and the majority (65%) arose from the small bowel. Most fistulas formed during the interval of mesh coverage (nearly 70%), and patients in whom fistulas formed were more likely to have had mesh coverage for a significantly longer time than the patients who did not develop this complication (27 vs 18 days). It is therefore important to perform the skin graft relatively early rather than late because the longer the wound is left to granulate without coverage of the bowel, the more likely the bowel wall is to erode through the granulation tissue and instigate fistula formation. It appears as if a skin graft would not necessarily give much support to the wound and that this sort of coverage would not necessarily prevent a fistula. In the authors' experience, however, skin grafting does stabilize the wound significantly. Skin coverage of the open granulating wound also helps to decrease the proteinaceous losses through the wound, similar to the benefit of early grafting of large surface burns, as these large open wounds produce a tremendous ongoing catabolic drain.

If a fistula ultimately does occur, it may range in severity from a relatively minor nuisance to a life-threatening catastrophe. Should a low-output fistula develop on the lateral aspect of the wound, there is a reasonable chance for spontaneous closure as the wound granulates and contracts over the fistula. Small fistulas that do not close can be handled as semiformal ostomies with bags placed over them until definitive repair is performed.

Fistulas that occur away from the lateral wall, in the midportion of the wound, are problematic (and have been dubbed "enteroatmospheric"). For relatively low-output fistulas that occur in this area, the authors' approach is to apply a skin graft on the entire wound around the fistula. After the graft adheres and heals, a bag can usually be fixed to the abdominal wall, effectively converting the fistula to a controlled ostomy. Although not always successful, this approach works better than might be anticipated. In contrast, midwound proximal, high-output small bowel fistulas have significant rates of morbidity and mortality. The authors' usual approach is to operate early to prevent the complications secondary to metabolic derangements and nutritional depletion. Surgery consists of sharply incising the granulation tissue right at the ostium of the fistula. In general, a relatively normal serosa is identified. Once the serosa is identified, the bowel loop is isolated gradually and resected back to nonindurated, nonedematous tissue. A primary anastomosis generally is performed. After anastomosis, an attempt is made to bury the anastomosis as deeply as possible in the abdomen beneath other bowel loops to minimize the likelihood of fistula recurrence. Following this, the large open wound is managed with the replacement of absorbable mesh to maintain the viscera within the abdomen. If the viscera are relatively "stuck," the authors perform skin grafting at this time in lieu of replacing the absorbable mesh. Resection of these fistulas is an arduous task that takes many hours. We believe, however, that patients do better with this early approach rather than waiting several weeks to months and having their nutritional status and overall recovery continue to erode while they are receiving total parenteral nutrition.

STAGE 3: DEFINITIVE RECONSTRUCTION WITH A MODIFICATION OF THE COMPONENTS SEPARATION TECHNIQUE

The appropriate timing for abdominal wall reconstruction is of paramount importance. If performed too early, dense adhesions make split-thickness skin graft removal difficult, often leading to multiple enterotomies or significant bowel deserosalization. When reconstruction is delayed for an excessive amount of time, the musculature of the abdominal wall tends to contract with a progressive

FIGURE 3 Well-healed planned ventral hernia with split-thickness skin graft.

loss of domain, which makes reconstruction considerably more difficult. The authors generally proceed with the operation when the intra-abdominal adhesion process has matured to the point that flimsy adhesions develop between loops of bowel and skin graft. This can be ascertained simply by pinching the skin graft between the fingers, and, if the bowel falls away, it is time for reconstruction. If the loops of bowel seem to be densely adhered to the skin graft, reconstruction should be delayed. The authors' experience suggests that most patients develop these flimsy adhesions in the 6- to 12-month interval after hospital discharge. Beyond 12 months, it is unlikely for the graft to become any less adherent, and deferring reconstruction any longer increases the patient's risk for ongoing loss of domain.

The authors' own modification of the component separation technique described by Ramirez and colleagues is the preferred method of reconstruction in the majority of these cases. The original component separation technique consisted of local myocutaneous flap advancement after extensive relaxing incisions in the abdominal wall. It provides autologous continuity with dynamic support of the abdominal wall. The original technique provided for 3 to 5 cm of mobilization on each side. These large abdominal wall defects, however, usually cannot be repaired with this amount of mobilization. After recognizing this drawback of limited mobilization, the authors added a modification of Ramirez and colleagues' component separation technique, outlined as follows.

Modified Component Separation

Step 1: Removal of Skin Graft

The skin graft is grasped between the fingers or with tissue forceps and sharply incised in an area that is obviously free of underlying bowel. Once the incision is made, the skin graft is divided in its midportion from top to bottom. After this, adhesions of small bowel to the skin graft are mobilized bilaterally, and dissection extends a few centimeters beyond the lateral edge of the rectus abdominis muscles bilaterally.

Step 2: Raising of Full-Thickness Skin Flaps

Full-thickness skin and subcutaneous fat are mobilized on each side of the wound, just superficial to the fascia. Musculocutaneous perforator vessels will be encountered and should be preserved when possible. In general, each flap is raised laterally beyond the anterior axillary line, always several centimeters beyond the lateral border of the rectus sheath. The skin edges should now be free enough to be pulled together in the midline. If additional distance is required, further lateral mobilization of the flaps is performed.

Step 3: Release of External Oblique Component of Anterior Rectus Fascia

The rectus abdominis muscle is grasped in the palm of the hand with the thumb on top and the fingers inside the abdominal cavity. The external oblique fascia is divided approximately 1 cm lateral to the rectus abdominis muscle with use of a hemostat to dissect the external oblique freely from the internal oblique component. The external oblique fascia then is divided superiorly and inferiorly, over the lower costal region superiorly and down to the pubic symphysis inferiorly (Figure 4).

Step 4: Dissection of Posterior Rectus Sheath

The medial border of the rectus sheath is incised for the entire length of the muscle. This exposes the anterior and posterior fascia and rectus muscle as three distinct layers (Figure 5). The posterior sheath should then be freed from the rectus muscle, from the superior aspect of the wound to the level of the arcuate line (inferior to this level, the posterior component comprises only peritoneum).

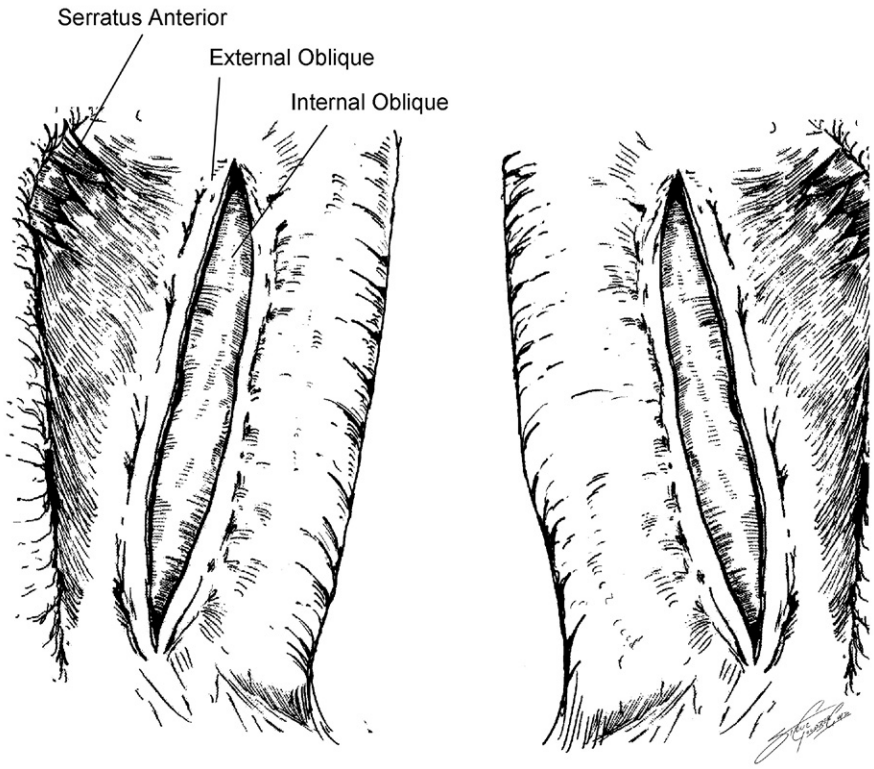

FIGURE 4 The external oblique release is extended cephalad over the costal margin and caudally to the pubic symphysis.

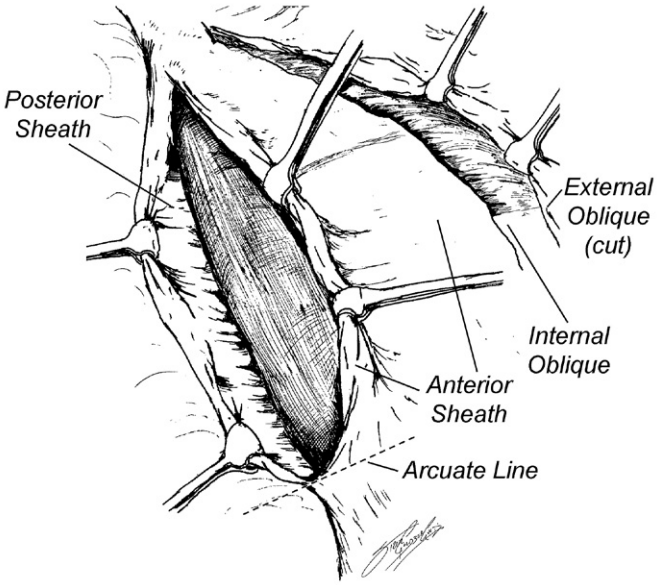

FIGURE 5 The medial edge of rectus sheath is divided, and the posterior sheath is freed from the overlying rectus muscle.

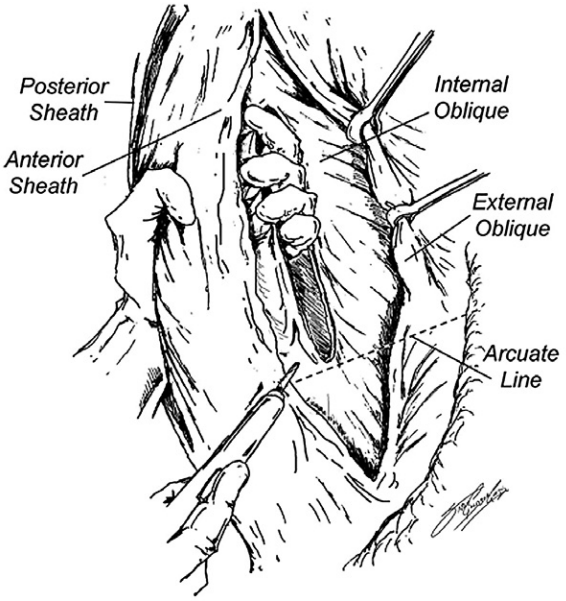

FIGURE 6 Release of internal oblique component. The dorsum of the surgeon's hand is lying on the posterior sheath as the palmar surface cups the rectus muscle. The incision is made over the surgeon's finger to ensure that only the anterior component is divided.

Step 5: Release of Internal Oblique Component of Anterior Rectus Fascia

This step constitutes the Memphis modification of Ramirez and colleagues' components separation. The internal oblique component of the anterior rectus sheath is divided. This is done by sharply incising the anterior fascia approximately 1 cm lateral to the rectus muscle (Figure 6). This opening is then extended for the length of the rectus muscle from the costal border, down to the level of the arcuate line. It is imperative that the incision be stopped at the arcuate line. If the internal oblique component of the anterior rectus sheath is divided below this point, a large hernia will develop because there is no posterior fascia below the arcuate line. At this point in the procedure, the anterior rectus sheaths (with adherent rectus muscle) have been freed medially and laterally.

Step 6: Translocation of Anterior Fascia and Midline Closure

The medial aspect of the posterior sheath is sutured to the lateral aspect of the anterior sheath, typically with running monofilament suture. The abdominal wall is then closed by suturing the medial components of the anterior rectus fascia. The appearance of the completed fascial reconstruction is depicted in Figure 7. Four flat closed suction drains then are inserted to drain the skin flaps, two superiorly and two inferiorly bilaterally. The skin then is approximated in the midline to complete the procedure.

The procedure as just described provides approximately 10 cm of medial advancement in the epigastrium, 20 cm in the midabdomen, and 8 cm in the lower abdomen. The authors have found that when this mobilization is sufficient for fascial closure, the incidence of hernia after reconstruction is low (5% over a 15-year experience). Some patients, however, have a remaining fascial gap despite performance of the reconstruction as described, which necessitates the use of a prosthetic to complete the procedure. It has become the authors' preference to use biologic prosthetics in this scenario because of the possibility of serosal tears (and in some cases, ostomy reversal may have been performed concomitantly). The preferred technique is an underlay with at least 2 cm of overlap with healthy fascia. The underlay technique is used selectively to buttress the repair when the quality of the fascia is questionable or appears attenuated, even when able to close the fascia without a prosthetic. Not surprisingly, patients who require adjunctive prosthetics are at greater risk for recurrence (20% in the authors' experience) but have improved outcomes in comparison with patients who undergo standard components separation (i.e., without the Memphis modification) with prosthetic (44% recurrence rate). Thus the additional releases required for the Memphis technique are preferable to using a larger prosthetic.

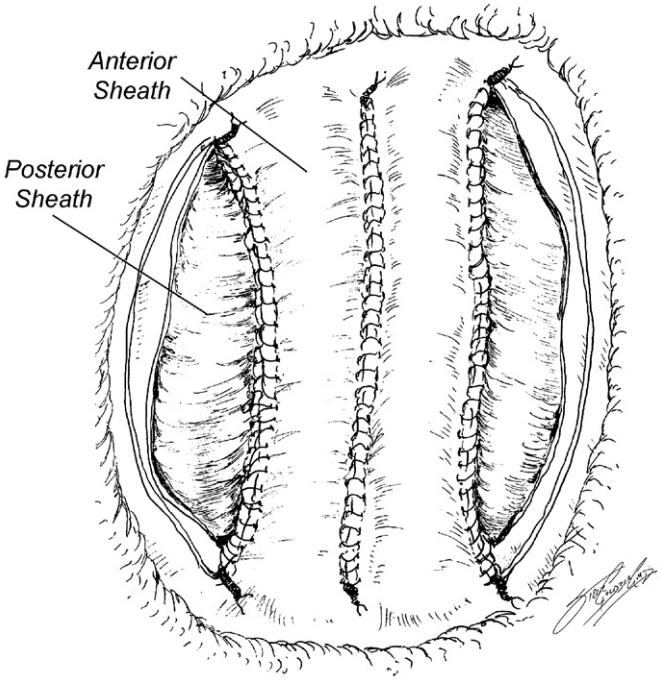

FIGURE 7 Final fascial closure with three suture lines.

The Management of Vascular Injuries

K. Shad Pharaon, MD, and Donald D. Trunkey, MD

OVERVIEW

Vascular injuries are associated with high morbidity and mortality. Management is transitioning from open surgery to endovascular repair for many of these injuries. Unstable patients still need to proceed to the operating room without delay, and the operation will be directed based on the clinical exam performed in the emergency department. If the patient is stable after the initial resuscitation, then assessment of vascular injury by computed tomographic angiography (CTA) should occur. In patients with contrast allergy, magnetic resonance angiography (MRA) is an option. The contrast media used for MRA is usually less toxic than those used for CTA and catheter-based angiography, with fewer people having any risk of allergy. MRA is typically more expensive, takes longer, and is unsafe in patients with metal such as a pacemaker. Duplex ultrasonography can be used to diagnose vascular trauma, but subcutaneous air, fragments, and hematomas make ultrasound less reliable.

After undergoing high-quality imaging, the patient is often taken to a hybrid operating room to undergo endovascular repair with the option of an open procedure. In recent years, endovascular repair of certain injuries has become the norm and often has better outcomes. Numerous small studies have documented the successful management of traumatic arterial injuries with endografts. This chapter will describe the treatment options of vascular injury to the neck, chest, abdomen, pelvis, and extremities.

INITIAL EVALUATION AND MANAGEMENT

Vascular injuries can be caused by blunt forces, deceleration forces, or penetrating injuries due to knives, gunshot wounds, or impalement. Thorough prehospital assessment of these patients—including measurement of vital signs and determination of the presence or absence of shock, as well as early resuscitation—is now standard practice. This prehospital resuscitation starts in the field, continues with transport, and carries through to the emergency department. The use of tourniquets for vascular injury to extremities has seen resurgence. Bleeding is the leading cause of potentially preventable death on the battlefield, and the availability of tourniquets has increased among military medics. This has carried over into the civilian population. Although tourniquets have been used for many years, their safety and efficacy have recently been looked at more closely, and their availability as a commercial device has increased. Debates will continue on the best tourniquet design, duration, and inflation pressure.

If the patient has a systolic blood pressure of 80 mm Hg, pushing fluids is not necessary to achieve a normal blood pressure. Fluid management should not contribute to the bleeding process. In hemorrhaging patients without traumatic brain injury, permissive hypotension is acceptable in the short term. A blood pressure of 80 mm Hg achieves cerebral perfusion and minimizes excessive hemorrhage. It must be emphasized that the grossly unstable patient with a systolic blood pressure less than 80 mm Hg should go immediately to the operating room and bypass the CT scanner. The body cavity that needs to be opened so that the source of bleeding can be found will be dependent on the surgeon's physical examination and assessment of entry and exit wounds. In unstable patients with blunt trauma, a chest x-ray and focused assessment with sonography for trauma (FAST) are the only imaging that is needed prior to the operating room. If the patient can be stabilized, a pan CT scan with CTA for suspected vascular injury can be invaluable for identifying the location of injury as well as planning the repair. Increasingly, Level 1 and some Level 2 trauma hospitals are developing endovascular hybrid operating rooms, allowing the surgeon to bring a trauma patient directly to the room and perform endovascular repair, endovascular adjunctive care, or an open operation. In those that are unstable who undergo an open operation, the objective is to obtain proximal and distal control of the bleeding vessel. The surgeon must quickly develop a strategy of repair, bypass, or ligation. For all patients, the proximal thighs should be prepared and included in the operative field for potential vein conduit. A longitudinal incision over the lateral portion of the sartorius muscle exposes the superficial femoral-popliteal vein (SFPV). The SFPV has been used in the reconstruction of the innominate artery, common carotid artery, inferior vena cava (IVC), and portal vein.

BODY REGIONS AND TYPICAL VASCULAR INJURIES

Neck

All neck injuries require a neck and chest x-ray to look for fractures, missiles, associated hemopneumothorax, widened mediastinum, and subcutaneous emphysema. Unstable patients with a penetrating neck injury are taken directly to the operating room. If the patient has stable vital signs, CTA of the neck and upper chest is the best initial screening tool for a penetrating neck injury. It gives a sense of the trajectory of the bullet, associated cervical spine fractures,

involvement of the spinal cord, fragments, and hematomas. If the CTA images have excessive scatter from metallic fragments or excessive air, conventional four-vessel angiography might be useful. If the patient has neurologic deficits, a brain CT scan without contrast is needed. CTA of the neck is also performed on patients with suspected blunt carotid injury. Although MRA is impractical in an unstable trauma patient with multiple injuries, it is an attractive noninvasive modality, particularly to assess the intracranial architecture for signs of stroke. The mainstay of treatment for blunt carotid injury is antithrombotic therapy.

The neck is divided into three zones. Zone 1 is the base of the neck below the cricoid cartilage. Zone 2 extends from the cricoid cartilage to the angle of the mandible. Zone 3 extends from the angle of the mandible to the base of the skull (Figure 1). Zone 1 and zone 3 injuries are more difficult to expose than zone 2 injuries. Zone 1 requires proximal intrathoracic control, often with a median sternotomy. Exposure of zone 3 is difficult because of the retromandibular position of the carotid artery. Exposure of this area may require manipulation of the mandible. Zone 2 injuries are readily accessible surgically.

The approach to zone 1 injuries is through an incision along the sternocleidomastoid muscle and occasionally extended inferiorly into a median sternotomy when more proximal control is needed. The innominate veins (brachiocephalic) can be seen deep to the thymus. Retraction or division of innominate veins will expose the aortic arch. Dissection along the arch will reveal the origin of the innominate, left common carotid artery, and perhaps a portion of the proximal left subclavian artery. Due to its posterior location, most of the left subclavian artery is difficult to isolate from this incision, and a high anterolateral thoracotomy may be needed. The origin of the common carotid is identified and encircled with vessel loops or a vascular clamp. Before clamping, identify the vagus nerve. The preferable approach to these injuries, if a simple laceration cannot be repaired, is resection and either primary anastomosis or replacement with an interposition graft, preferably of autogenous tissue.

Zone 2 exposure is best approached using an incision along the sternocleidomastoid muscle. When bilateral structures of the neck are potentially injured, a collar incision may be preferable. The facial vein is divided to obtain better exposure of the carotid artery bifurcation, which is located deep to the vein. On rare occasions, a clean laceration to the carotid may be amendable to simple lateral repair or end-to-end anastomosis. Shunts should be used in patients already at risk for cerebral hypoperfusion secondary to shock and to injuries of the internal carotid artery. Heparin should be given before clamps are placed on the vessel. Most external carotid injuries may be ligated without consequence. Ligation of the common or internal carotid artery should be avoided because it can result in devastating neurologic sequelae. The great saphenous vein is a good size match with the internal carotid artery and can be used as an interposition graft with excellent patency and limited risk of infection. Vein does take more time to harvest and prepare. The external carotid artery is an ideal conduit for interposition grafting in injuries to the internal carotid artery near the areas of the bifurcation. Transposition of the mobilized external carotid to connect it to the internal carotid artery is also an option. Polytetrafluoroethylene (PTFE) can also be used to reconstruct the common or internal carotid arteries, but in the setting of an esophageal injury, autogenous conduit should be used. The injured vessel is débrided and a 5-0 polypropylene suture is used for the anastomosis. Intraoperative duplex ultrasonography should be considered after the repair to confirm flow and to look for an intimal flap. Patients who undergo carotid artery repair are prescribed lifetime daily aspirin.

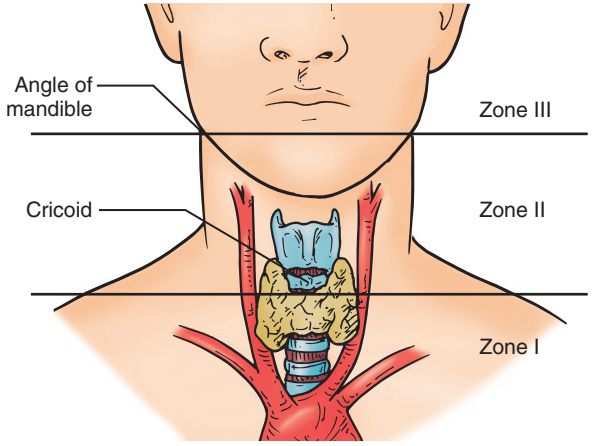

FIGURE 1 Definition of the three anatomic zones used in neck trauma. Zone I is base of neck to cricoid cartilage. Zone II is cricoid cartilage to angle of mandible. Zone III extends from angle of mandible to base of skull.

The retromandibular position of the distal carotid artery makes zone 3 a challenging operative exposure. Exposure often requires subluxation of the mandible or mandibular osteotomy. The latter adds risk to the marginal mandibular and inferior alveolar nerves. Anterior subluxation usually requires that the patient be nasotracheally intubated so that the mandible can be wired to the maxilla to hold exposure. The digastric muscle is divided, the styloid process may be excised, and injury to the glossopharyngeal, hypoglossal, and facial nerves is possible.

Operative exposure of the vertebral artery is problematic. The vertebral artery can be divided into four anatomic zones. The first portion of the vertebral artery (V-1) extends from the origin of the vertebral artery off the subclavian to the foramen of the transverse process of C6. The second portion (V-2) is the interosseous portion ascending from C6 to C2. The third portion (V-3) is that portion from C2 to the base of the skull. The fourth portion (V-4) extends from the base of the skull to the confluence of the right and left vertebral arteries, which forms the basilar artery. One option for rapid control of the proximal vertebral artery is to approach it where it comes off the subclavian artery. However, even after clamping, there may be continued backbleeding from the circle of Willis. Insertion of a Fogarty balloon catheter (Edwards Lifesciences, Irvine, Calif) may achieve temporary control of bleeding. As the vertebral artery ascends through the transverse foramina toward the base of the skull, access becomes very difficult. Bleeding from this area may be better served with packing of bone wax into the hole until an endovascular approach is possible. Embolization of the vertebral artery is preferred, and the collaterals are usually sufficient to avoid an ischemic stroke.

Chest

Most patients with blunt injury to the descending thoracic aorta die immediately at the scene from exsanguination. The injury to the descending thoracic aorta usually occurs at the isthmus, just distal to the left subclavian artery. The patients that do survive the initial aortic injury may have other injuries that are a more immediate threat to their lives. If the patient has a stable thoracic hematoma and concomitant abdominal injury, laparotomy should be the initial procedure. If the patient has a rapidly expanding hematoma around his or her aorta, the chest should be addressed expeditiously. The lesion that is most likely causing the exsanguination should be addressed first.

In rare cases, a patient with blunt aortic injury (BAI) makes it to the hospital in extremis. This patient should be resuscitated and should undergo an anterolateral thoracotomy through the fourth intercostal space on the side of injury. On the left, this provides rapid access to the pericardium, pulmonary hilum, and aorta. If further exposure is needed, a clamshell is performed by transecting the

sternum and extending the incision to include a right thoracotomy. Ligation of both sides of the internal mammary arteries should occur if a clamshell is performed; otherwise, delayed bleeding is likely to occur. The lung is mobilized by dividing the inferior pulmonary ligament. The pericardium is opened anterior to the phrenic nerve to rule out a tamponade. The descending thoracic aorta, particularly in the hypotensive patient, is flaccid and pulseless. The aorta can be manually compressed against the spine until an aortic clamp can be placed. A small window through the parietal pleura on either side of the aorta assists in getting a vascular clamp securely on the vessel. Clamping of the thoracic aorta is a double-edged sword. It may improve circulation to the brain and the heart, but if the patient becomes hypertensive, the left ventricle can become overdistended and result in demise of the patient. Previously, injury to the descending thoracic aorta was repaired with clamping and direct reconstruction. The most feared complication of this technique is paraplegia. Ischemic bowel and renal failure may also result from prolonged clamping. Lower mortality and almost nonexistent paraplegia now make the use of thoracic endovascular aortic repair (TEVAR) for BAI very compelling.

For the patients that survive BAI, the usual presentation is one with normal hemodynamics and with multiple other injuries. The tendency is to focus on the aorta and overlook the other injuries. Recent evidence suggests that some BAIs do not need repair at all. There is a new way of classifying BAIs based on the absence (intimal tears and large intimal flaps) or presence (pseudoaneurysms and ruptures) of external contour abnormalities of the aorta. Intimal tears can be managed nonoperatively. Patients with large intimal flaps do well, and most are treated with a stent graft. If a pseudoaneurysm is going to rupture, it does so early. Most pseudoaneurysms and ruptures are now treated with endovascular repair, within 1 week, if the patient has a reasonable likelihood of survival. Hypotensive patients with hematoma around their aorta may benefit from earlier repair. Patients who undergo endovascular repair should be monitored with CT imaging at 1 month, 6 months, 1 year, and every other year thereafter. For penetrating injury to the descending thoracic aorta, lateral suture repair is usually possible in those who survive because the trauma is limited frequently to lacerations. Of course, larger arterial wounds are not compatible with survival.

Median sternotomy provides access to the superior mediastinum. Dividing the left innominate vein improves exposure and gives the surgeon access to the aortic arch and its branches. Repair of the aortic arch often requires cardiopulmonary bypass. Occasionally, minor injuries to the innominate artery can be repaired primarily. More often, injuries to the innominate artery require repair via the bypass exclusion technique (Figure 2). A piece of synthetic interposition graft is sewn from the ascending aorta to the distal innominate artery. The proximal innominate artery is oversewn. With transection of the left common carotid artery, a bypass to the aorta using PTFE is preferred over end-to-end anastomosis. The SFPV has been used in the reconstruction of the innominate artery and common carotid artery.

The right and left subclavian arteries are exposed differently depending on the location of injury with respect to the vertebral artery. For right-sided injury distal to the vertebral, the preferred method is to start with a right supraclavicular incision. This incision starts at the sternoclavicular junction and extends over the length of the clavicle (Figure 3, *A*). Should additional exposure be needed, such as those with injury proximal to the vertebral, median sternotomy is performed (Figure 3, *B*).

The choice of surgical incision for left-sided injury is more difficult because of the orientation of the aorta and the very posterior origin of the left subclavian artery. There are three ways to expose the left subclavian artery—a supraclavicular incision with clavicle resection, a left anterolateral thoracotomy, and a sternoclavicular flap (trap door). The supraclavicular incision is made one fingerbreadth above and parallel to the clavicle, extending from the sternal notch to the lateral end of the clavicle (Figure 4). Once the clavicle has been cut and removed, the underlying scalene fat pad is removed and the phrenic nerve identified. This is a key anatomic landmark that must be preserved. The nerve courses lateral to medial along the anterior scalene muscle. The nerve can be isolated with a vessel loop and gently retracted out of the way. The anterior scalene muscle should be cut as low as possible, and the subclavian artery can be found behind it. A supraclavicular incision is adequate if the injury is proximal to the vertebral.

When a supraclavicular incision is inadequate, such as in those patients with injury of the left subclavian artery distal to the vertebral, an anterolateral thoracotomy is used. A high anterolateral thoracotomy through the third intercostal space will provide access to the origin of the subclavian (Figure 5). A posterolateral thoracotomy will give even better exposure to the distal subclavian artery, but the patient will need to be in right lateral decubitus position. The preferred sequence of steps to obtain control of the left subclavian artery in an injury that has not been identified preoperatively is to begin with a supraclavicular incision and quickly move to a thoracotomy if the necessary exposure is not obtained. If exposure is still inadequate, as a last resort, the supraclavicular and thoracotomy incisions can be connected with a median sternotomy, completing the trap

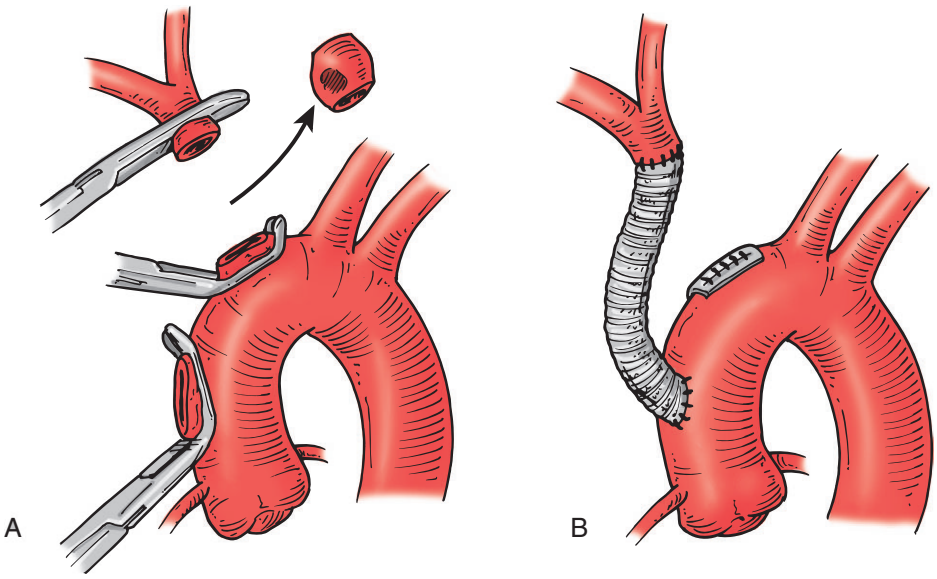

FIGURE 2 **A,** Injuries to the innominate artery require repair via the bypass exclusion technique. **B,** The stump is oversewn, and bypass grafting is from the ascending aorta to the distal innominate artery.

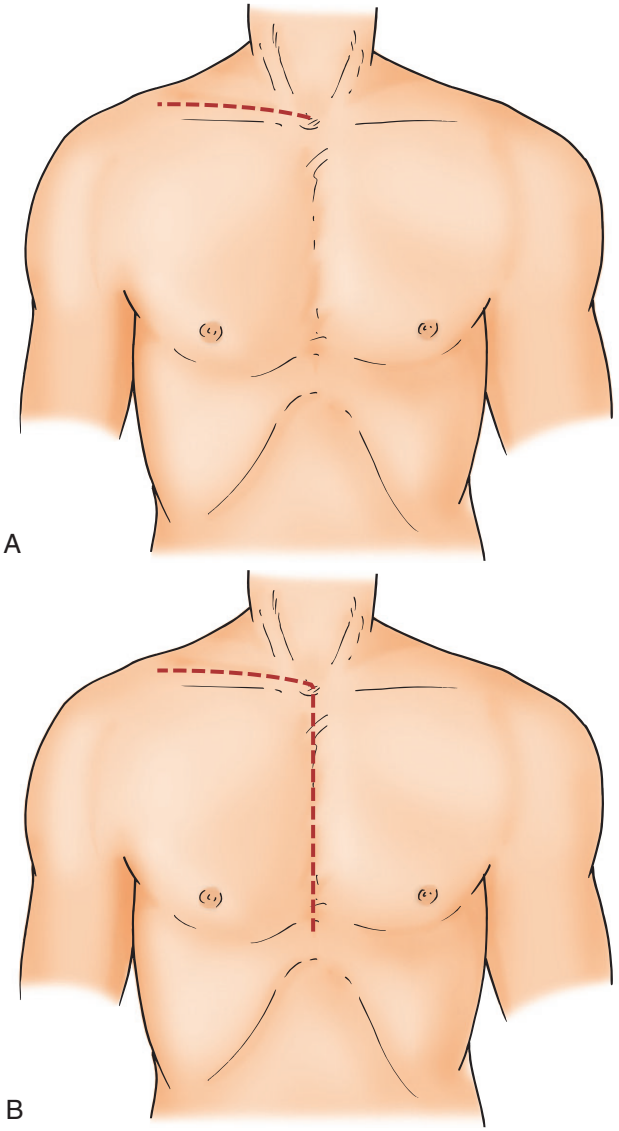

FIGURE 3 **A,** The right supraclavicular incision provides exposure to the right subclavian artery. **B,** In some instances, a median sternotomy is added to obtain more proximal control.

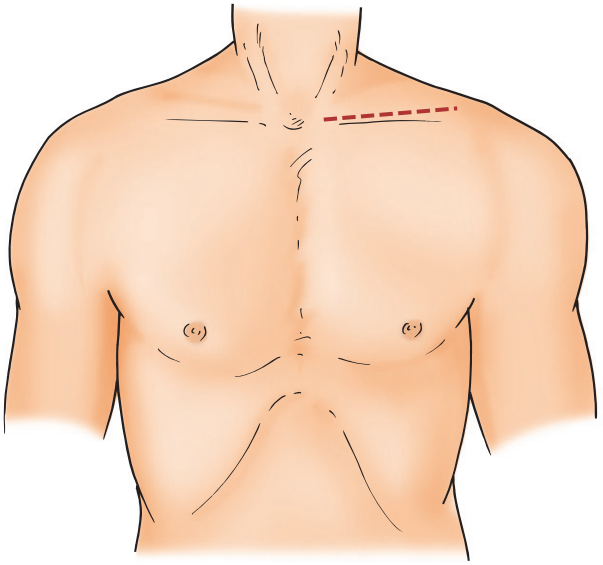

FIGURE 4 The left supraclavicular incision will provide exposure to a portion of the left subclavian artery. Resection of the medial clavicle will improve exposure.

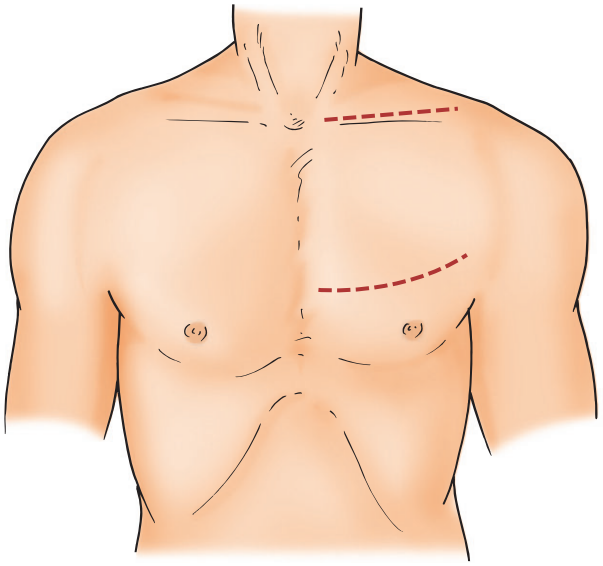

FIGURE 5 A high anterolateral thoracotomy through the third intercostal space will provide access to the proximal left subclavian artery.

door (Figure 6). This incision has a high rate of postoperative morbidity.

A small laceration in the subclavian artery may be repaired primarily, but usually the injury requires an interposition graft. For extensive injuries, an interposition graft should be performed using vein or PTFE. A proximal and distal Fogarty thrombectomy is performed, and the artery is repaired with saphenous vein from the leg. Vein is preferred, particularly in an infected field. If the patient is unstable and time does not permit vein harvest, then PTFE is acceptable. A completion angiogram should be performed. Attempting to mobilize the soft and friable subclavian artery to gain enough length for an end-to-end repair is rarely successful.

Although subclavian artery injuries should be repaired if possible, there are some patients who will need damage control. For the patient in extremis, the subclavian artery can be ligated. If possible, ligation of the subclavian artery proximal to the vertebral artery is preferred because this allows for retrograde flow to the extremity through the vertebral and collateral circulation of the shoulder. At the first suspicion of ischemia after subclavian artery ligation, the patient should undergo heparinization followed by prompt arterial reconstruction, and if necessary, fasciotomy.

A few individuals with injuries to the chest will arrive at the hospital with no obvious clinical signs of vascular compromise. These patients are best served with a CTA of the chest. The patient with blunt injury to the descending thoracic aorta is typically hemodynamically stable and has a contained hematoma. Endovascular treatment offers an effective alternative to operative repair of these injuries. The long-term effects of having an endograft in the aorta for 50 or more years has yet to be determined. As a person ages, the shape of the aorta changes, which may result in future incidences of endoleaks. For subclavian artery injuries, endovascular options, including balloon tamponade and stent grafting, can be life and limb saving. Arterial access is commonly approached percutaneously through the femoral artery. The size of the stent graft to be implanted

is determined with intravascular balloons of known length and diameter.

Abdomen

Major abdominal vascular injuries result more commonly from penetrating trauma rather than blunt trauma. Patients with penetrating abdominal wounds who do not respond adequately to initial resuscitation are considered to have a major vascular injury until proven otherwise. These injuries are very challenging for surgeons. Even for the experienced surgeon, it is sometimes difficult to determine which cavity to enter first. There may be bleeding from the chest and abdomen. If the patient arrives profoundly hypotensive or experiences cardiopulmonary arrest in the operating room, an immediate left anterolateral thoracotomy with aortic cross-clamping, pericardiotomy, and open cardiopulmonary resuscitation should be performed before proceeding with the laparotomy. A midline incision is made from the xiphoid to the pubic symphysis. With free intraperitoneal bleeding, the first maneuver is to pack all four quadrants. Solid organ injuries with active bleeding are best managed with packing until definitive control can be obtained. For patients who decompensate during laparotomy, the abdominal aorta can be controlled by cross-clamping at the aortic hiatus. Retroperitoneal hematomas are classified according to their location: zone 1 (central), zone 2 (lateral), and zone 3 (pelvic). This classification helps with surgical planning (Figure 7). All zone 1, some penetrating zone 2, and all penetrating zone 3 should be explored. Blunt zone 2 and blunt zone 3 hematomas should not be explored unless they are ruptured, pulsatile, or rapidly expanding.

If a hematoma or hemorrhage is above the transverse mesocolon, injury to the suprarenal aorta, celiac axis, superior mesenteric artery, or renal artery should be suspected. Injuries to the suprarenal aorta are difficult to access. To obtain proximal control of the aorta at the hiatus of the diaphragm, a left-sided medial visceral rotation is best. This is performed by taking down the left colon, kidney, spleen, tail of the pancreas, and fundus of the stomach to the midline (Figure 8). One alternative is to leave the left kidney in place while the rest of the viscera are mobilized. Either way, the end result will be exposure of the aorta from the diaphragm to the aortic bifurcation. In our

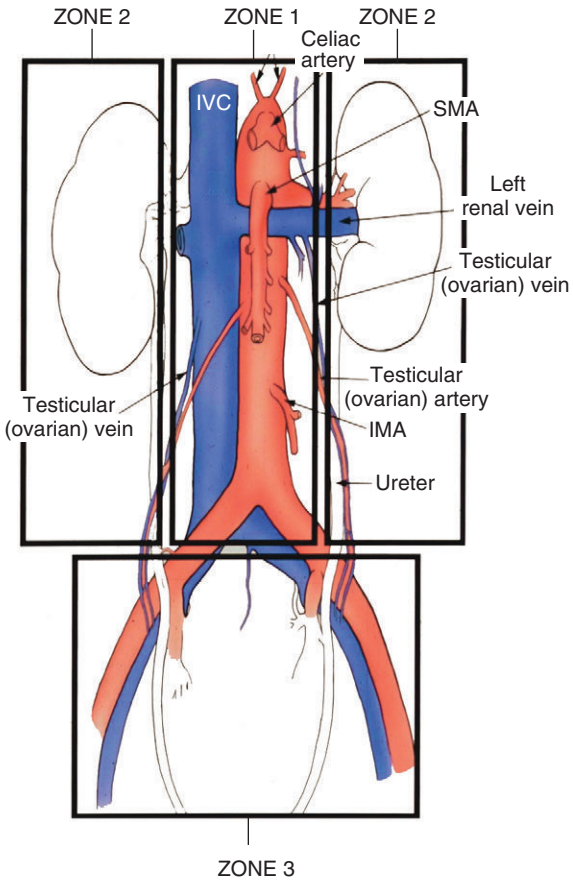

FIGURE 7 The retroperitoneal zones. Zone 1 is central. Zone 2 is lateral. Zone 3 is pelvic. *IMA,* Inferior mesenteric artery; *IVC,* inferior vena cava; *SMA,* superior mesenteric artery.

experience, the injured aorta in the suprarenal position seems to have a higher survivability than those below the renal arteries. This may be due to the celiac and superior mesenteric ganglia that are very fibrous and tend to control the bleeding. The most devastating wounds are those caused by shotgun blasts, high-velocity missiles, and large-caliber missiles. Most survivable injuries are those that can be closed with sutures. Injuries to the infrarenal aorta can be approached from the left side of the abdomen as noted earlier, or a right-sided medial visceral rotation can be performed for injuries to the right renal artery or the right common iliac artery and vein (Figure 9).

Injury to the celiac axis is extraordinarily rare, and ligation is the treatment of choice. Very few successful complex repairs of the celiac axis have been reported. If the splenic artery is transected or has a partial tear, it is prudent to remove the spleen and possibly the tail of the pancreas in order to get rapid control. Splenic and left gastric artery injuries are best treated with ligation. Hepatic artery injuries can be ligated if they are proximal to the gastroduodenal branch, but repair should be performed if possible.

The superior mesenteric artery (SMA) is similar to the subclavian artery in that it has very little elastic tissue. Sharp partial transections of the SMA can be managed with lateral arteriorrhaphy using 6-0 polypropylene suture. Because mobilization of the SMA is restricted, it is rarely repaired by end-to-end anastomosis, particularly if it is under tension. It may be better to do an aorto-SMA bypass with saphenous vein graft or PTFE. Autogenous tissue is preferred if there is small bowel or fecal contamination. SMA ligation is associated with ischemia to the small bowel and right colon. In the hemodynamically unstable patient with hypothermia, acidosis, and coagulopathy, the

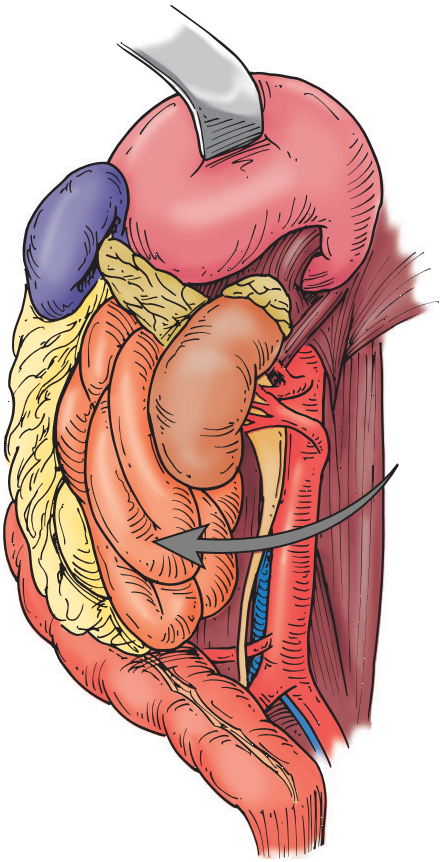

FIGURE 8 Medial rotation of left-sided viscera. This will expose the aorta from the diaphragm to the aortic bifurcation.

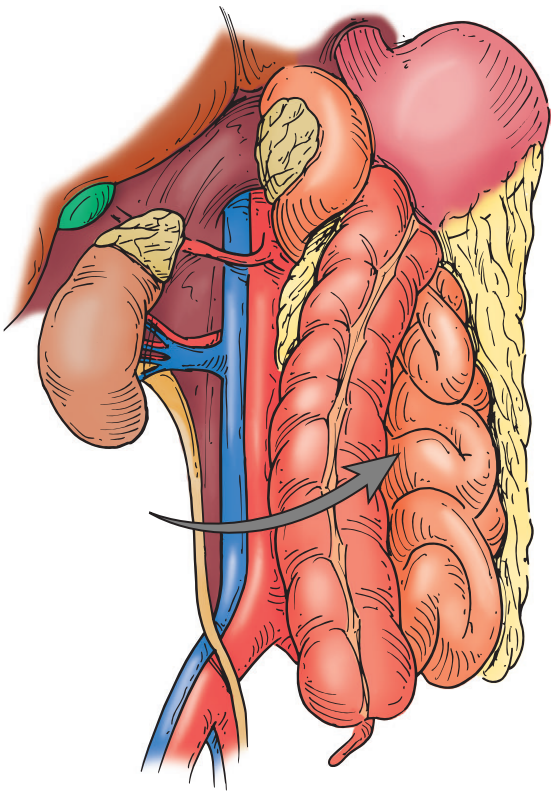

FIGURE 9 Medial rotation of right-sided viscera. This will expose the right renal artery, right common iliac artery and vein, and inferior vena cava.

insertion of a temporary intraluminal shunt into the débrided ends of the SME is appropriate.

The kidney does not tolerate prolonged ischemia. In some cases, small perforations of the artery can be repaired, but, in most cases, nephrectomy is a better choice. Arterial repairs of the renal artery have a high incidence of thrombosis. The surgeon should perform intraoperative palpation, an intravenous pyelogram, or both, to confirm a functioning contralateral kidney. Those patients with bilateral renal artery injury or solitary kidney should be considered for revascularization. When dealing with an ischemic kidney after blunt trauma in a stable patient, an endovascular repair is optimal treatment since it can be placed rapidly, minimizing the effect of ischemia on the kidney.

If the iliac artery requires only a simple lateral repair, then this can be done primarily. If definitive repair is not possible, iliac artery injuries can have a temporary shunt placed. Extensive injury to the common or external iliac artery in the presence of significant fecal contamination is a serious problem. End-to-end anastomosis or insertion of a synthetic conduit in a contaminated field often leads to postoperative pseudoaneurysm formation and potentially a blowout of the anastomosis. A safe treatment of these injuries is ligation of the common iliac artery, closure of the abdomen with appropriate washout and drainage, and an extraanatomic femorofemoral bypass graft. The external iliac artery also needs to be repaired when possible. If it cannot be repaired, a femorofemoral bypass graft using a synthetic conduit can be performed. The internal iliac artery can be ligated with impunity. Definitive repair is not necessary unless it is a small wound that can be repaired with simple sutures. Most arterial pelvic bleeding is best treated with embolization.

Pelvis

Pelvic fractures are quite common after blunt trauma. Pelvic vascular injury and hemorrhage are responsible for many deaths. The appropriate use of a pelvic binder, along with the recent evolution of earlier pelvic stabilization with external fixation, angiographic embolization, and preperitoneal pelvic packing, has decreased some of these deaths. Packing has been an important part of damage control in Europe for many years and was reintroduced in the United States recently. The procedure involves opening the anterior fascia beneath the umbilicus, retracting the rectus muscles laterally, and placing three laparotomy sponges on each side of the bladder deep in the pelvis without opening the peritoneum (Figure 10). This technique may be useful in a patient with pelvic bleeding who is too unstable to transport to the angiography suite or if an angiography suite is not present in your hospital. In a hypotensive patient with negative FAST results and pelvic fracture, embolization should be considered. A hemodynamically labile patient with a contrast blush is best served in the angiography suite. The superior gluteal artery is the most commonly injured artery after a pelvic fracture. There is an extensive network of veins in the pelvis that is often destroyed with a pelvic fracture, and bleeding from these veins is more frequent than arterial bleeding. Venous bleeding can be controlled by external fixation.

Extremity

Any hard sign of vascular injury, such as active or pulsatile hemorrhage, expanding hematoma, or absent pulse, warrants surgical exploration, ideally in a hybrid operating room so that an on-table arteriogram can be performed. Although an open operation is still the preferred treatment for many extremity vascular injuries, endovascular stenting of extremities is becoming more common. Injury to vessels in the upper extremity can result from shoulder dislocation, elbow fractures and dislocations, lacerations, and gunshot wounds. Reducing the fracture or dislocation should precede any repair to the vessel. The axillary artery is usually disrupted by blunt trauma when

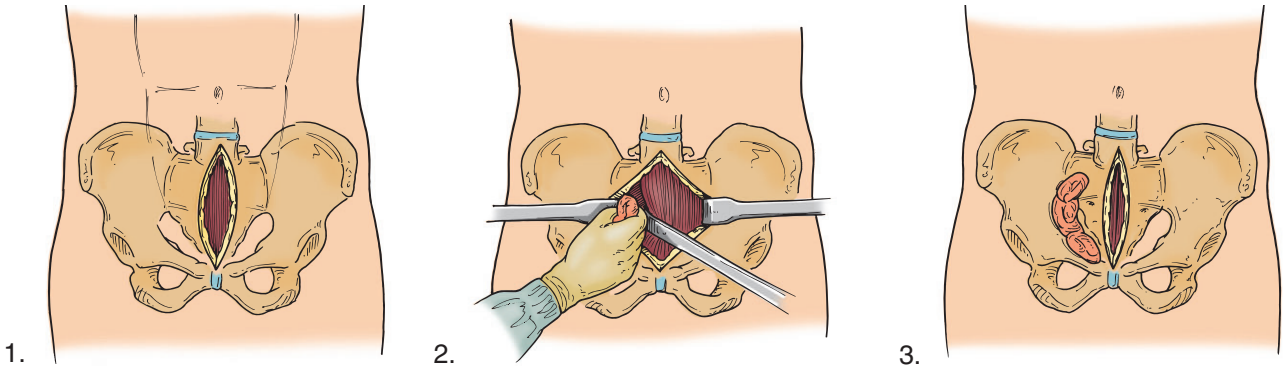

FIGURE 10 Preperitoneal packing. This involves packing three lap sponges in the preperitoneal space on each side to contain pelvic bleeding. Useful in those patients who are too unstable to go to an angiography suite or if angiography is not available. *(From Cothren CC, Osborn PM, Moore EE, et al: Preperitoneal pelvic packing for hemodynamically unstable pelvic fractures: a paradigm shift,* J Trauma *62:834–839, 2007.)*

there is tearing of the shoulder girdle. The axillary artery can sometimes be repaired with a simple suture, but it may require a saphenous vein interposition graft. If there is damage to the brachial plexus, repair of the axillary artery may not be indicated, but this is difficult to assess in the acute setting. If the expertise to repair the vessel is not available, a damage control option is shunt insertion. Only in rare circumstances are ligation and fasciotomy needed. Although collateral circulation usually prevents critical ischemia in axillary artery injury, reconstruction is the preferred treatment. The brachial artery is frequently injured. It can be exposed with an incision in the groove between the biceps and triceps muscles. The median nerve should be identified and protected. Like the axillary artery, the brachial artery can be ligated in some settings, but the preferred treatment is simple suture, if possible, or a saphenous vein interposition graft. If injured separately, the radial artery and ulnar artery do not need to be repaired since there is excellent collateral circulation in the hand. If both are injured, at least one must be repaired.

The common femoral artery should be repaired if possible. Exposure is with a vertical incision over the inguinal ligament halfway between the anterior superior iliac spine and the pubic tubercle. Approximately one third of the incision should be above the groin crease. The use of a temporary arterial shunt is an acceptable option until the patient can get to a center that can provide definitive arterial reconstruction. If bypass is needed, saphenous vein or PTFE can be used. It is rarely necessary to do a repair of the profundus artery. Most of the time the profunda will do well with ligation since there is adequate collateral blood supply around the upper hip.

The superficial femoral artery should also be repaired. In contrast to arteriosclerosis of the femoral artery, the injured femoral artery has not had time to establish collaterals. The superficial femoral artery can be exposed by the slight flexion and external rotation of the leg. An incision over the anterior border of the sartorius muscle allows retraction of the muscle and identification of the fascia directly underneath. This is Hunter's canal. Opening of the canal reveals the superficial femoral artery. Although simple repair may be possible, most require an interposition graft. Reversed autologous saphenous vein from the uninjured leg should be used if possible. If the superficial femoral vein cannot be easily repaired, then ligation should occur. Fasciotomy of the lower leg after superficial femoral artery repair should be considered. Orthopedic surgeons often perform bone alignment before definitive repair of the vessel to avoid disruption of arterial reconstruction, although occasionally the arterial injury is completed first.

The popliteal artery is injured following posterior dislocation of the knee or penetrating injuries of the leg. The collateral flow around the knee is poor. Popliteal artery injury should be repaired in a timely manner or there will be a high incidence of amputation. Fasciotomy is strongly encouraged after popliteal repair. A posterior knee dislocation merits a CTA of the leg, even if distal pulses are present. The popliteal artery can be exposed from either the medial or posterior approach. The medial approach occurs by making an incision along the medial leg between the vastus medialis and sartorius muscles. The popliteal artery will be adjacent to the posterior aspect of the femur. The popliteal artery is repaired by harvesting a piece of reversed saphenous vein from the other thigh and inserting it as an interposition graft between the proximal and distal popliteal artery, excluding the injured segment. PTFE has been used when autologous conduit is not available, but it has a high late failure rate. Endovascular repair of popliteal aneurysms has been used successfully, particularly in patients with no available conduit. To avoid an open operation in a high-risk patient, a popliteal artery injury could be treated with an endovascular approach.

Injury to one infrapopliteal artery rarely results in limb ischemia. The foot remains viable as long as there is adequate flow through the remaining vessels. When in doubt, an intraoperative arteriogram should be obtained. The anterior tibial and posterior tibial arteries may be repaired in stable patients without other significant injuries. The best reconstructive option is a size-matched reversed saphenous vein. Severely injured patients are best treated with ligation of single vessel injuries distal to the popliteal artery. The peroneal artery rarely requires repair, except in the elderly or diabetic with poor collateral circulation. Patients who undergo repair to their extremities should have a completion angiogram, be maintained on aspirin, and be followed long-term for postoperative surveillance.

Veins

Venous injuries are a common cause of bleeding from penetrating neck wounds. Small veins and the external jugular vein are best treated with ligation. Simple lacerations of the internal jugular vein may be repaired, but, if extensive, they can be ligated without consequences. The facial vein can be ligated if injured and should be ligated when an attempt is made to expose the carotid bifurcation beneath it.

The innominate and azygous vein may be ligated without consequence. For subclavian vein injuries, thrombosis often results from the low-pressure venous system. These injuries are repaired only if the patient remains stable and repair can be done without producing stenosis and without the need for an interposition graft. If this is not possible, ligation of the subclavian vein should be performed. Besides transient edema, no significant long-term complications result from its ligation.

In many ways, IVC injuries are potentially more lethal than abdominal aortic injuries. In theory, one can ligate any injury below

the renal veins; however, there is an approximately 30% morbidity rate from venous hypertension in the lower extremities. The infrarenal IVC has several lumbar veins that are posterior on the IVC, and rotation of the IVC during repair can be problematic. Initial control is another issue and can be achieved with a side-biting Satinsky clamp; however, this must be carefully handled to avoid torsion and iatrogenic tear of the thin and friable IVC. Our personal recommendation is to use sponge sticks initially to control the bleeding. Alternatively, the surgeon's index and middle finger can be placed on the hole, and a running stitch of 3-0 polypropylene can be started with gentle traction to avoid stenosis of the vessel.

The portion of the IVC from the renal veins to the heart can be treacherous. There are 12 to 15 small veins that enter the cava directly from segment 1 of the liver. In some instances of deceleration injury, all of these veins are avulsed from the superior surface of the cava, giving the appearance of a laceration. This can be a real challenge to control. Proximal control of the IVC should be attempted where it pierces the diaphragm. In some instances, it can be done superior to the liver as the IVC goes through the diaphragm. This has to be done carefully since both the right and left hepatic veins join the anterior portion of the cava at this juncture. Alternatively, the IVC can also be identified in the right chest, and supradiaphragmatic control can be achieved with a Rummel tourniquet. The final alternative is a sternotomy in which the pericardium is opened longitudinally and the IVC can be dissected inside the pericardium as it joins the right atrial portion of the heart. Again, a Rummel tourniquet can be placed around this portion of the vessel.

Branches of the superior mesenteric vein can usually be ligated if they are injured since there are adequate collaterals within the mesentery. A portion of the superior mesenteric vein as it exits through the mesentery joins with the splenic vein to form the portal vein. Ligation of the superior mesenteric vein may lead to postoperative edema of the mesentery and small bowel. This edema resolves with time, and there are usually no sequelae. A few days of vigorous postoperative fluid resuscitation in these patients helps with the transient peripheral hypovolemia that occurs.

Avulsion of the renal vein can occur following deceleration injury. Gunshot and stab wounds can cause penetrating injury to the renal vein. Both can lead to exsanguination. Venorrhaphy remains the preferred technique. If extensive damage to the hilum of the kidney occurs, nephrectomy may be indicated. The surgeon must verify that the kidney on the other side is present and functional.

Portal vein injuries can be very difficult to manage since there are often other associated arterial injuries. These include injuries to the SMA, splenic artery, or the right and left hepatic arteries. Surgical transection of the neck of the pancreas exposes the retropancreatic portal vein. Injury to the portal vein should be primarily repaired whenever possible. If portions of the vein are under tension or are retracted or severely injured, it is possible to harvest the saphenous vein and do an end-to-end repair. Alternatively, the jugular vein can also be used as a conduit for repair. If the patient is acidotic, hypothermic, and coagulopathic, the portal vein can be ligated. One of the authors has experience with portal vein injuries in San Francisco, and the postoperative mortality rate was approximately 25%. Two patients had their portal vein injuries ligated and, although both survived, the patients experience splanchnic hypervolemia and systemic hypovolemia.

Trauma to the confluence of the common iliac veins is particularly difficult to control because of its location. This confluence of iliac veins lies just behind the right common iliac artery. The right common iliac artery can be divided between clamps in order to give access to the confluence of veins (Figure 11). The divided right common iliac artery should be repaired when the venous repair is complete. Injuries to the iliac veins, in most instances, can be achieved with simple sutures. If this is not possible because of loss of tissue, ligation is an option, as it has been well tolerated. There may be postoperative swelling of the leg.

Almost all extremity veins can be ligated if necessary. Ligation of the superficial femoral and popliteal veins has some disadvantages. In the absence of near exsanguination and sequelae of shock, these two vessels ideally should be repaired. With venous congestion, there is a risk of affecting arterial inflow. The patient may also develop chronic edema of the leg. If there are extensive injuries to these veins, however, ligating them is an option, as it has been well tolerated in young trauma patients.

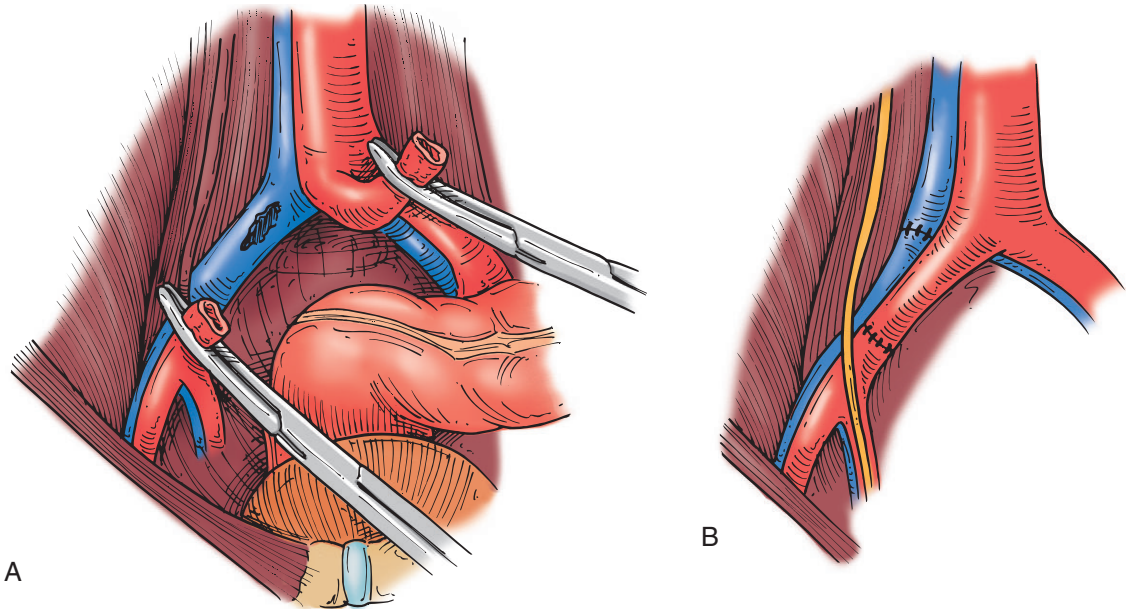

FIGURE 11 **A,** Deliberate division of the right common iliac artery to repair an injury to the right common iliac vein. **B,** Once the vein has been repaired, the artery can be reanastamosed. *(From Salam AA, Stewart MT: New approach to wounds of the aortic bifurcation and inferior vena cava,* Surgery *98:105–108, 1985.)*

SUMMARY

Vascular injuries are associated with high morbidity and mortality rates depending on the vessels injured. Although the unstable patient with a vascular injury still needs an open operation, many stable patients are being evaluated with CTA to assess the injury and are being revascularized with an endovascular approach. All stable patients with penetrating and blunt neck injuries should get a CTA. There are some injuries to the neck that are difficult to expose and may be better served with an endovascular approach. Injuries to the great vessels are usually fatal. For most individuals who suffer an aortic injury, the result is death. Those who survive are assessed for all other potential life-threatening injuries before they undergo endograft repair of their aorta. There are a few patients who present in extremis and undergo a thoracotomy with open repair, but these are extremely rare cases. Open repair of descending aortic injuries in stable patients is now occurring largely when endovascular repair is not technically feasible. The right and left subclavian arteries are exposed differently depending on the location of injury. The left subclavian artery is usually more difficult to expose, and the choice of incision is more controversial. Many subclavian artery injuries are treated with endovascular stents. Deciding if hemorrhage is coming from the chest or abdomen is sometimes difficult, and occasionally it is coming from both. To access either the suprarenal aorta or the infrarenal aorta, alternate techniques of mobilization are used. Extensive iliac injury with fecal contamination is best treated with extraanatomic bypass. Bleeding in the pelvis is common after pelvic fracture. Most of this bleeding is venous and will stop with external fixation. Arterial bleeding in the pelvis is best treated with embolization. Definitive open repair of extremity artery injuries is more common, but endovascular treatment is increasing. If definitive repair is not possible, a temporary shunt can be placed. Most veins can be ligated without long-term sequelae. Superior mesenteric vein ligation is an option, but hypovolemia is a common occurrence. Portal vein and IVC injuries should be repaired. The retrohepatic IVC is particularly difficult to access and is often a lethal injury. To repair the confluence of the iliac veins, the right iliac artery must be divided and repaired after the vein has been repaired.

Endovascular Management of Arterial Injury

Nyali Taylor, MD, and Joseph V. Lombardi, MD, FACS

Endovascular interventions have been described in the vascular surgical literature since the 1980s and debuts in the trauma literature for vascular repair in the early 1990s. Since that time, with the improvement and implementation of newer endovascular technology, the application of endovascular therapies to iatrogenic and traumatic vascular injuries has expanded significantly. Operators can have a diagnostic or therapeutic modality to intervene on lesions from the extracranial cerebrovascular arteries to the extremities. Adjunctive endovascular measures have been utilized in open procedures as well, which have aided in delineating injuries and controlling hemorrhage. These "hybrid" approaches have now become very commonplace in the management of patients with multiple injuries among high-volume centers. This chapter discusses some of the endovascular techniques employed to repair arterial injuries in the cerebrovascular, upper extremity, aortic, pelvic, and lower extremity vascular trees.

There are several generic points to be aware of when planning an endovascular therapeutic intervention: patient preparation, operating room (or interventional suite) equipment, staffing, endovascular instrumentation, and available medications. Once it has been determined that the surgeon is going to perform an endovascular intervention or adjunct, the correct operating room or interventional suite should be booked. It needs to contain a fluoroscopy-compatible bed. The side rails need to be removed for compatible armboards to be inserted if the upper extremity or cerebrovascular region is the area of interest. As part of planning, knowing the necessary access sites and having the patient adequately exposed is the key because your first choice of access is not always going to work. Depending on the institution, you may need to have fluoroscopy technologists called in to assist if the case is done in the operating room. Make sure the available staff has a working knowledge of the sheaths, catheters, wires, and medications that will be requested.

Once prepped and draped for the planned procedure, you will need to gain either percutaneous access via a 21-gauge micropuncture needle and 0.018-inch Mandril wire or cutdown for open exposure and employ an appropriate-gauge needle (19-gauge introducer for femoral or common carotid, 21-gauge for upper extremity or infrageniculate vessels). We would suggest utilizing ultrasound guidance for percutaneous access because it reduces the number of attempts and likelihood of complications. Utilize a basic braided 0.035-inch wire to maintain access, and exchange for the smallest-circumference introducer sheath that is appropriate for the chosen access site. Prior to insertion of large-circumference, near-occlusive sheaths, or any intervention (other than embolization), approximately 5000 units (or 80 units/kg) of heparin should be given, unless contraindicated. In the event that a contraindication exists, the surgeon can decide if she or he is comfortable with heparinized saline

flushes of the access vessel for local anticoagulation. If there will be any carotid sinus manipulation, consider the use of prophylactic atropine. Atropine (0.5-1.0 mg) is given prophylactically at our institution. It may be prudent to have several medications on hand: vasodilator of the operator's choice, tissue plasminogen activator, and protamine. Completion imaging should be obtained for documentation of the adequacy of the intervention. In the following sections, we discuss the major anatomic regions' indications for repair, the basic techniques, and outcomes.

EXTRACRANIAL CEREBROVASCULAR INJURY

No system is infallible, and even in the era of ultrasound-guided access, there is a less than 1% incidence of iatrogenic trauma to the carotid or subclavian arteries during percutaneous central venous catheter insertion, and specifically arterial dilation with catheters 7 Fr circumference and larger. These patients may endure significant sequelae of this injury—hematomas, pseudoaneurysms (PSA), or stroke—so rapid identification and intervention are important. If immediate repair is not possible, anticoagulation must be initiated to prevent thrombus formation and potential embolus. The literature does not support the pull and compression method if a large-bore needle or dilator was inserted because the morbidity appears to be significantly greater than repair. Guilbert and colleagues (2008) have suggested a treatment algorithm that recommends percutaneous intervention in poorly accessible areas. Employing the use of covered or overlapping bare metal stents in the carotid arteries has been described. It is important to image patients who had a pull and hold technique to assess for PSAs or arteriovenous fistulae (AVF) as late as 2 weeks post event.

Technique

Before the endovascular repair of a carotid lesion is undertaken, either computed tomography angiography (CTA) or magnetic resonance angiography with three-dimensional reconstruction should be obtained to assess the arch anatomy: type, variants, tortuosity of great vessels, and preexisting disease. To begin with a percutaneous approach, the patient is placed in the supine position with both arms tucked at the sides for femoral access or with the left arm extended for brachial access. For open access, a standard longitudinal incision anterior to the sternocleidomastoid muscle will provide exposure to the carotid sheath. Expose and control each of the vessels, taking care to preserve the vagus nerve.

Once access is obtained, advance an appropriate length 0.035-inch wire into the aorta. If the approach was retrograde from the femoral artery, allow the wire to retroflex off of the aortic valve. Advance a 6Fr guide catheter proximal to the innominate artery. Using an angiographic flush catheter, a digital subtraction arteriogram (DSA) of the arch should be taken in 30 to 45 degrees anterior oblique (AO) orientation. Use the guide catheter to engage the common CA (CCA). The guide catheter will be advanced over a stiff angled guidewire into the mid-CCA if the lesion is in the internal or external carotid. For lesions in the CCA, the sheath should be placed proximal to the lesion. At this point, a 0.014-inch wire can be exchanged for the guidewire and advanced past the lesion into the petrous portion of the internal CA or into the external CA. Once the wire is in place, advancement of an embolic protection device (EPD) is dependent on the type of injury and concomitant disease. Select an appropriately oversized (10% to 15%) covered stent based on the normal artery, and deploy this across the lesion. Postdilate the stent with a nominal-diameter balloon. Retrieve the EPD, and remove all sheaths and wires. One should document anterior cerebral circulation *both* preintervention and postintervention**.** Note that this technique can help balloon occlude a hostile injury to assist open repair or be an option for repair alone (Figures 1 and 2).

UPPER EXTREMITY INJURY

As with the iatrogenic carotid arterial injury, subclavian arterial (SCA) injuries can occur via traumatic or iatrogenic mechanisms as well. The algorithm for repair would be the same as for carotid arterial injuries, discussed previously. The SCA is a prime vessel for endovascular repair due to its difficult exposure behind the clavicle and very straightforward endovascular access via the brachial artery.

Trauma to the subclavian and axillary arteries occurs in 5% to 10% of arterial trauma, most often by a penetrating mechanism and

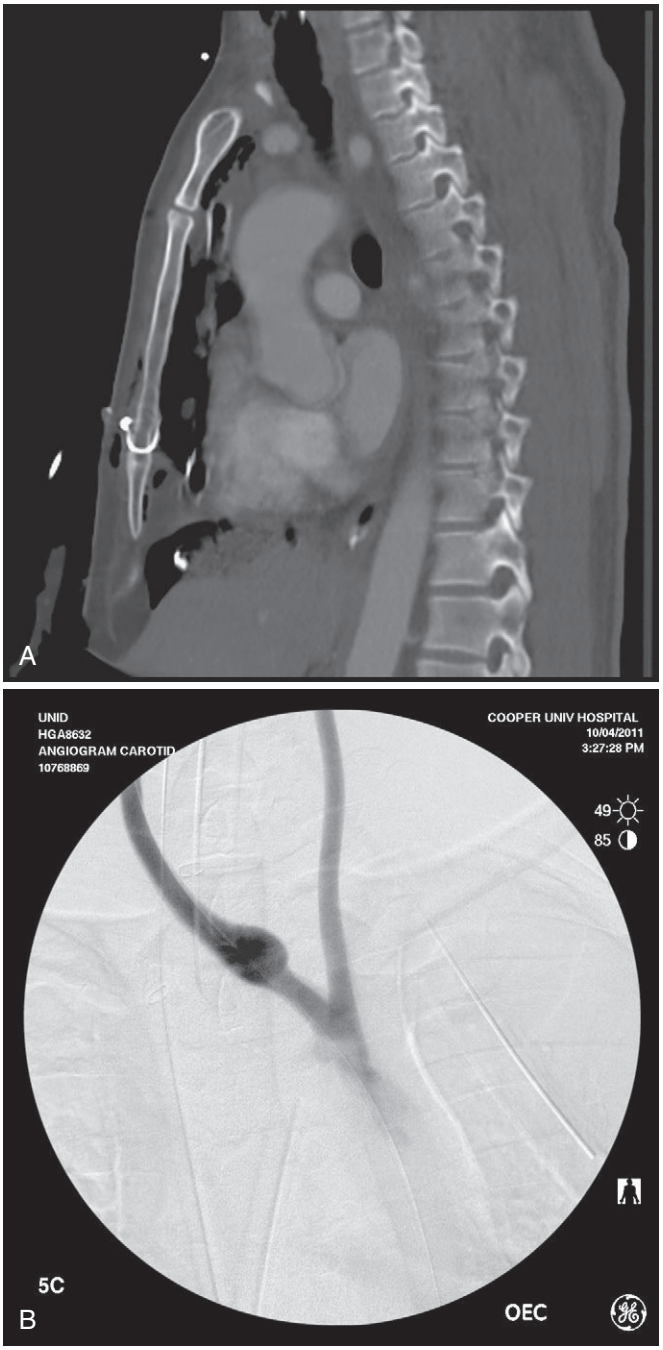

FIGURE 1 **A,** A sagittal reconstruction of the CT arteriogram image demonstrates a right common carotid pseudoaneurysm after a gunshot to the chest. **B,** The follow up digital subtracted arteriogram in AP orientation confirming the right common carotid pseudoaneurysm prior to endovascular repair.

FIGURE 2 Repair of right common carotid pseudoaneurysm with a covered stent from a retrograde open carotid approach.

frequently forming PSAs and AVFs. These patients may have multiple associated injuries, and the associated mortality is 5% to 39%. There are several considerations when selecting the appropriate candidates: lesion length, ability to cross the lesion, brachial plexus injury, and other concomitant injuries. The appropriate types of lesions for treatment are PSAs, focal lacerations, AVFs, avulsions, or dissections. The lesion should be focal, and a guidewire must be able to cross it or an intervention cannot be performed. At the very least, if a lesion cannot be traversed, insufflate a balloon catheter to control hemorrhage when arriving from the inflow vessel. The location of the injury is also important. For instance, one must consider the possibility of compressing a rigid stent as it passes through the thoracic outlet. Also, one must preserve the vertebral and internal mammary arteries when there is a proximal injury. Overtly avulsed first- or second-order branches can be controlled via balloon occlusion and/or embolization.

One feasibility study found that nearly 50% of these injuries should be amenable to endovascular repair. In an underpowered study, short-term results from retrospective reviews show patency at 1 year. Du Toit reports long-term results that noted that 5% of patients had early (<30 days) endograft occlusion, whereas 12% and 20% developed late occlusions and significant stenoses, respectively. There were no amputations in the cohort followed over 4 years. Although further investigation needs to be done with this subgroup, the data suggest that endovascular intervention is safe with reasonable long-term patency.

Technique

The patient is placed in the supine position with the ipsilateral arm abducted. Percutaneous common femoral arterial access and the DSA imaging of the aortic arch and branch selection should be obtained utilizing a similar wire and catheter combination as described in the prior section. After characterization of the lesion, decide what type of intervention is indicated: stent, embolization, or balloon tamponade. If the injury is in the distal SCA or axillary arteries, advance the catheter into the mid-SCA and obtain another image in an anteroposterior (AP) orientation. Size the vessel and choose the correct type and size of balloon, stent, or coil for the given intervention. If embolizing branch vessels, consider the use of a microcatheter system.

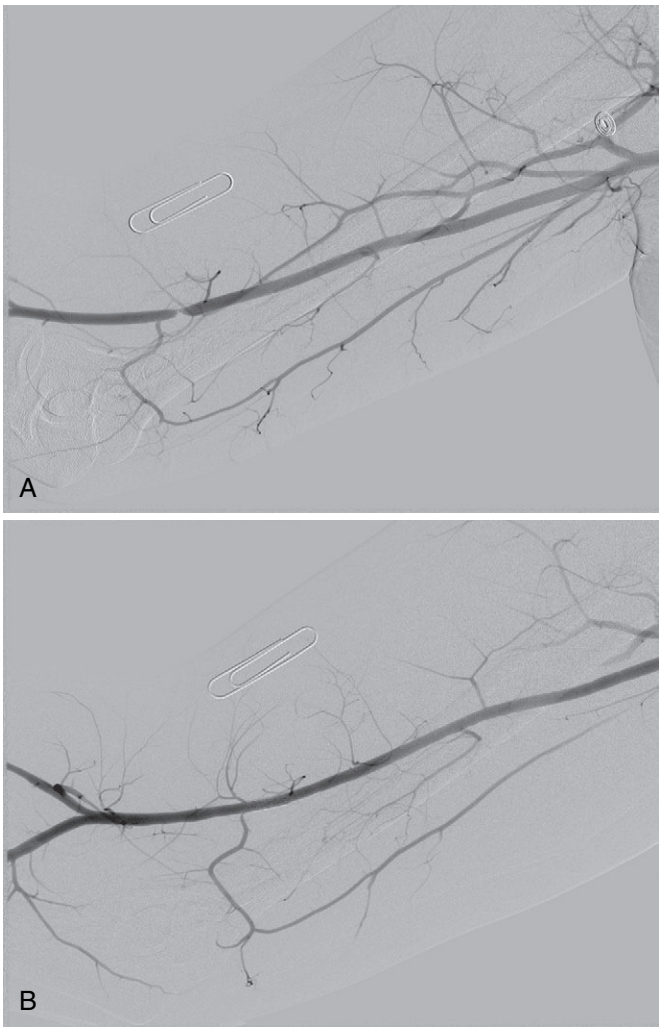

FIGURE 3 **A,** A focal intimal flap in the distal right brachial artery after gunshot to the right arm. **B,** An arteriogram after angioplasty of the lesion shows no evidence of residual defect and contrast in the radial and ulnar vessels.

Retrograde brachial arterial access is useful in the setting of an SCA occlusion. We would suggest the use of ultrasound guidance. Access the brachial artery no more than 1 to 2 cm proximal to the antecubital fossa with a 21-gauge micropuncture needle. Obtain access with a sheath that is not greater than 6 Fr in circumference. Vessel selection and intervention will be accomplished in the same manner as previously described (Figures 3 and 4).

AORTOILIAC INJURY

Descending Thoracic Aorta

Traumatic injury of the thoracic aorta has been a growing area of interest since Parodi reported endovascular repair in 1991. Open repair was the standard at that time, and it continues to have significant associated morbidity and mortality. Thoracic endovascular aortic repair (TEVAR) in the current literature has been shown to have a mortality rate from 5% to 20% in some series. The reported

FIGURE 4 **A,** A selective arteriogram of the right axillary artery after a gunshot injury. The arrows highlight extravasation from the artery. **B,** A selective arteriogram of the right axillary artery after treatment with a covered stent. There is good opacification of the distal vessel without extravasation of contrast.

morbidity is also significantly less when compared to open repair. Interestingly, many series report no paraplegia and low rates of endoleak. The Society for Vascular Surgery (SVS) clinical practice guidelines support the urgent repair of traumatic aortic injury after stabilization of other injuries without routine use of spinal drainage. Commonly seen injuries are PSAs, dissection, and transaction occurring at the ligamentum arteriosum. Penetrating injuries with a contained process also provide an opportunity for these techniques. Coverage of the left SCA is acceptable with selective revascularization based on clinical symptoms, except in the cases of left internal mammary artery (IMA) bypass, stenotic or occluded right vertebral artery, left vertebral arising from the arch, or left vertebral terminating in the posterior inferior cerebellar artery. Important caveats to understand are related to the arch anatomy and variants as mentioned above; appropriate device selection for a small-diameter aorta to prevent stent collapse (oversize no more than 10%); and utilizing retroperitoneal exposure of the common iliac artery (CIA) for difficult access or for a short device.

Technique

The patient is placed in the supine position with arms abducted over the patient's head in an AP orientation or tucked at the patient's sides. General anesthesia is preferred in order to control respirations for clear imaging. The access vessel (femoral or iliac) is exposed surgically, and a 19-gauge introducer needle is utilized to puncture the vessel under direct visualization. Exchange the access wire for a stiff wire, advancing it until it retroflexes off the aortic valve. Percutaneous access will be obtained on the contralateral side as previously described. A marker flush catheter can be advanced through the contralateral side, and a DSA of the arch employing 30 to 60 degrees of left anterior oblique (LAO) can be obtained proximal to the innominate artery. Imaging of the vertebral anatomy must be documented (either by CTA or on-table DSA). Once the anatomy has been adequately delineated and decisions made regarding coverage of the left SCA, then the device can be deployed per the specific instructions for use. Molding balloons in this setting are optional. A completion arteriogram must be obtained to evaluate for patency of the great vessels and endoleak. Repair the access vessels with 5.0 Prolene suture in a standard fashion (Figure 5).

ABDOMINAL AORTA AND ILIAC VASCULATURE

Penetrating injuries of the abdominal aorta or the visceral vessels are unlikely to be repaired in an endovascular fashion because the patients undergo laparotomy for exploration in the current practice algorithm. There are sparse case reports that discuss the use of endovascular management in this setting. Where the endovascular interventions may become important are for missed injuries in a stable patient identified at a point remote from the time of injury. For the purposes of this chapter, we focus here on blunt injuries for which there is a small body of evidence.

Although blunt abdominal aortic injury (BAAI) is a rare entity, endovascular intervention lends itself to the types of injuries sustained (PSA, AVF, acute occlusion, intimal flap +/– dissection). These injuries occur most often as a result of motor vehicle collisions. A review of the National Trauma Data Bank found that 10% of those with BAAI underwent surgical repair, and 69% of that subgroup were treated endoluminally. Recently, Shalhub characterized BAAI in a retrospective review, describing the most common site of injury as Zone III (infrarenal aorta to the aortic bifurcation), with the morphology of injury ranging from intimal tears (21%) to free rupture (29%.) Twenty-one percent of the patients were repaired via endovascular methods, with mortality approaching 32% overall. Small intimal tears appear to remain stable or resolve with medical management. Data across multiple sources demonstrate that the patients with free rupture have 100% mortality. Therefore, the lesions to consider for repair in the hemodynamically stable patient are a PSA or large intimal tear, symptomatic dissection, or extension of dissection.

Technique

The technique will be altered depending on whether the surgeon is using an aortic cuff or bifurcated stent graft. In both cases, the patient is placed in the supine position with arms tucked at the sides. General anesthesia is preferred but not required. For a bifurcated stent graft, bilateral (or ipsilateral external iliac artery with a conduit) femoral arteries are exposed surgically. The access wires are exchanged for stiff wires. Advance a marker flush catheter on the contralateral side to obtain a DSA of the abdominal aorta in an AP orientation. Once the anatomy has been adequately delineated and the injury distinguished, the device can be deployed. Deploy the stent graft in a stepwise fashion, ensuring its position below the level

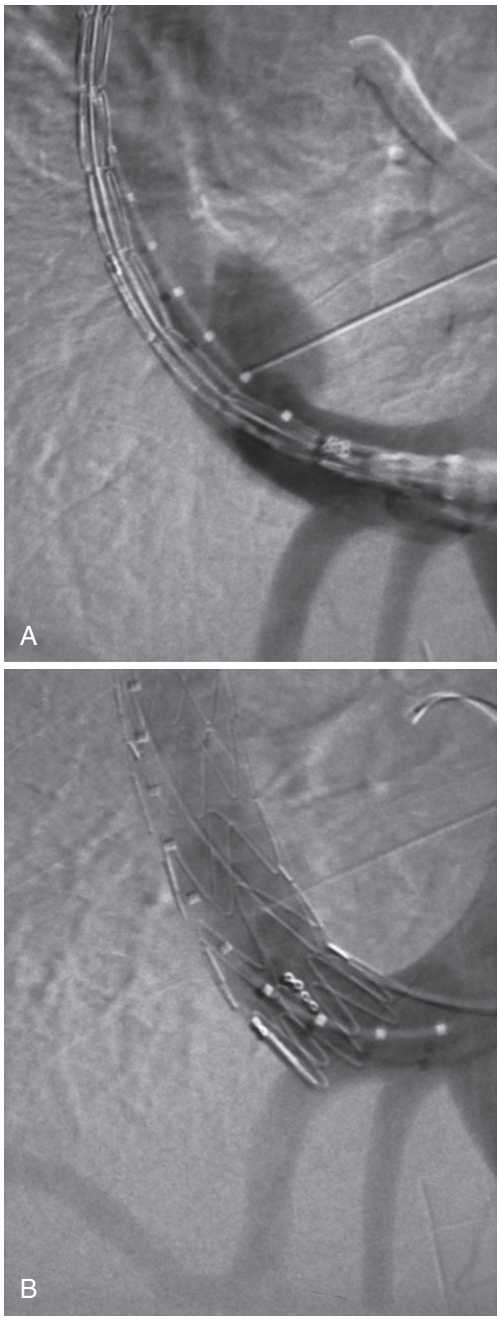

FIGURE 5 **A,** An arteriogram of the thoracic aorta in a patient with blunt thoracic aortic injury (BTAI) caused by a motor vehicle collision. There is a large pseudoaneurysm distal to the left subclavian artery. **B,** An arteriogram of the aorta after deployment of an aortic stent graft across the injury, successfully excluded the pseudoaneurysm. The left subclavian artery is preserved.

of the renal arteries. For an aortic cuff, the ipsilateral vessel is exposed surgically. Percutaneous access will be obtained on the contralateral side as previously described in other sections. A third option may be to employ an aorto-uni iliac device with contralateral iliac occlusion in conjunction with a femoral-to-femoral bypass. In a stable patient this is rarely preferred. After successful device deployment, repair the access vessels with 5.0 Prolene suture in a standard fashion. If images of the abdominal visceral vessels are needed, advance the flush catheter to T12-L1 to opacify them. Due to the more anterior takeoff of the celiac and superior mesenteric artery (SMA) axis, it will be useful to place the image intensifier in a lateral orientation (Figure 6).

ILIAC ARTERIES

In an era in which endovascular intervention is employed for a broad scope of medical comorbidities, the iliac vessels will inevitably sustain iatrogenic injuries. These lesions can range from dissections to perforation. Fernandez defines the incidence of iliac arterial rupture during endovascular aortic repair (EVAR) as 4% overall. When the group is subdivided into EVAR and TEVAR interventions, the rupture rates are 3% and 9%, respectively. The injury was typically sustained distal to the origin of the hypogastric artery and identified from extravasation during the arteriogram. Most injuries were successfully repaired with stent grafts in 94% of patients with primary and primary-assisted patency of 88% and 94%, respectively, after a median follow-up of 40 months.

There are other mechanisms that include the misplacement of femoral intravascular catheters and orthopedic and spine procedures. Based on the National Surgical Quality Improvement Program (NSQIP) database, the incidence of injury associated with orthopedic procedures is less than 1%. In a small series of patients who had undergone lumbar spine surgery, the lesions were characterized as lacerations, AVFs, and PSA, which were successfully treated. The patients had no morbidity or mortality and 100% patency at a median follow-up time of 9 years.

In terms of traumatic injuries, iliac arterial injuries are uncommon. During laparotomy for penetrating mechanisms 2% to 10% of patients will have an iliac arterial injury. A retrospective review of the National Trauma Database (NTDB) demonstrated that of the injuries repaired, 45% were penetrating and 55% were blunt. Injury associated with blunt trauma is rare and usually affects branches of the hypogastric artery. Limb-threatening ischemia is an unusual presentation, so the repair can often be managed in a more elective fashion. The outcome data are limited in this subgroup.

Technique

Percutaneous, open, antegrade, or retrograde access can be obtained as previously described. The iliac arteries and pelvic collateral vasculature can be visualized by bringing a flush catheter down to L4-L5 and obtaining a DSA in an AP orientation.

Advance a guidewire across the injured segment into healthy artery. Choose a stent, stent graft, or coils, depending on the goals of the therapy. Balloon-expandable stents are appropriate for the proximal common iliac artery where precision placement is required. Self-expanding stents will be better able to accommodate tortuosity. If there is a flush occlusion of the iliac, an endovascular approach may not be possible (Figures 7 and 8).

LOWER EXTREMITY INJURY

Iatrogenic injuries of femoropopliteal arteries are not uncommon. With the vast number of percutaneous procedures undertaken, complications are encountered in as many as 5% of all patients. Arteriovenous fistulae, PSAs, dissections, and intimal flaps are all injuries that are incurred. Danetz and collegues (2005) note the incidence of AVF and PSA to be 0.1% and 0.5%, respectively. These injuries are typically managed at the time of injury with balloon angioplasty or stenting, depending on the complication.

In the trauma literature, the NTDB was queried and found to have a penetrating mechanism in 66% and blunt mechanism in 33% of lower extremity injuries. Lesions were characterized as occlusions, transection, laceration, or dissection/intimal injury. The popliteal artery and superficial femora artery (SFA) were the most frequently

FIGURE 6 **A,** An intraoperative arteriogram demonstrates a contained AAA rupture. The arrow highlights the region of rupture along the lateral wall. The left renal artery is patent. **B,** An arteriogram showing the deployed stent graft excluding the aneurysm sac. There is no active extravasation of contrast or evidence of endoleak. The left renal artery is preserved.

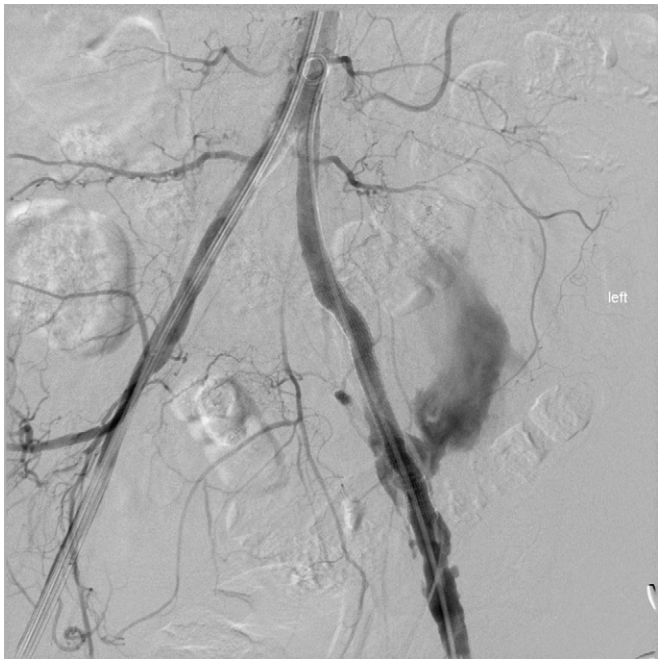

FIGURE 7 Iatrogenic perforation of the left external iliac artery with extravasation of contrast into the retroperitoneum.

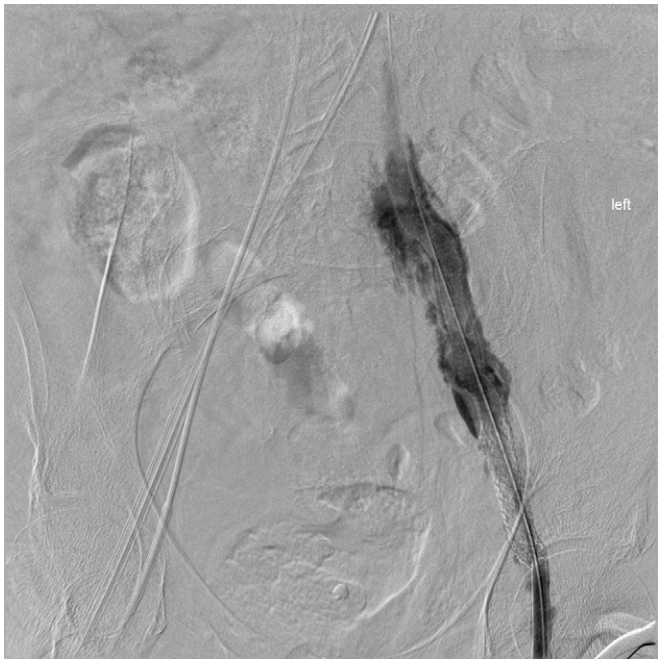

FIGURE 8 Repair of the injury with a nitinol, self-expanding stent. Residual contrast is present without active extravasation.

affected (16% to 35% and 24% to 28%, respectively). Mortality was 3% overall but was greatest within the common femoral artery (CFA) subgroup. Amputation occurred in 8% of popliteal/tibial arterial injuries, and 9% of injuries occurred by a blunt mechanism. In one small series, endovascular stent grafts and coil embolization had been utilized to manage 7% of femoral injuries. The literature points to the need for intervention in both blunt and penetrating injuries. Endovascular intervention may be best if there are soft signs present and an ankle-brachial index of less than 0.9, suggesting a potential major injury.

Technique

The technique is the same as described for iliac arterial access. Once the wire and catheter traverse the level of the injury, obtain a DSA in 25 degrees of anterior oblique angled to the ipsilateral proximal femoral trifurcation. For the remainder of the evaluation, the image intensifier can remain in an AP orientation. If accessing tibial vessels, exchange for an 0.018-inch or 0.014-inch wire. Utilize a self-expanding stent or stent graft, or embolize as indicated for the injury (Figures 9 and 10).

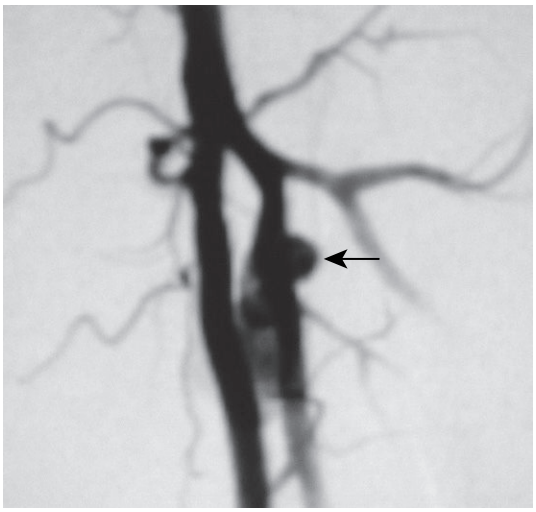

FIGURE 9 Gunshot to the left profunda femoris artery, creating a pseudoaneurysm with contrast extravasation *(arrow)*.

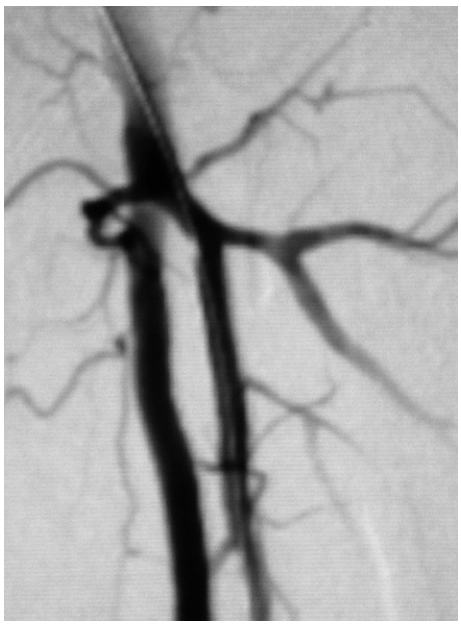

FIGURE 10 Completion arteriogram demonstrating the pseudoaneurysm repaired with a covered stent. No contrast extravasation is present.

ADJUNCTIVE TECHNIQUES

Two endovascular techniques are discussed briefly here because they are useful adjuncts either to open repair, as a bridge to definitive repair, or as the definitive repair itself to manage hemorrhage in stable or unstable patients. Serial balloon inflations can also be employed for flow-limiting antegrade dissections at locations for which stents may have a relative contraindication.

Embolization

In 1985, Panetta and colleagues described the usefulness of embolization in different anatomic locations, determining that it was a superior method to control hemorrhage over open surgery in the pelvis. In the past 25 years, this has become a standard maneuver for controlling hemorrhage in a multitude of regions that are difficult to access, such as intercostal arteries.

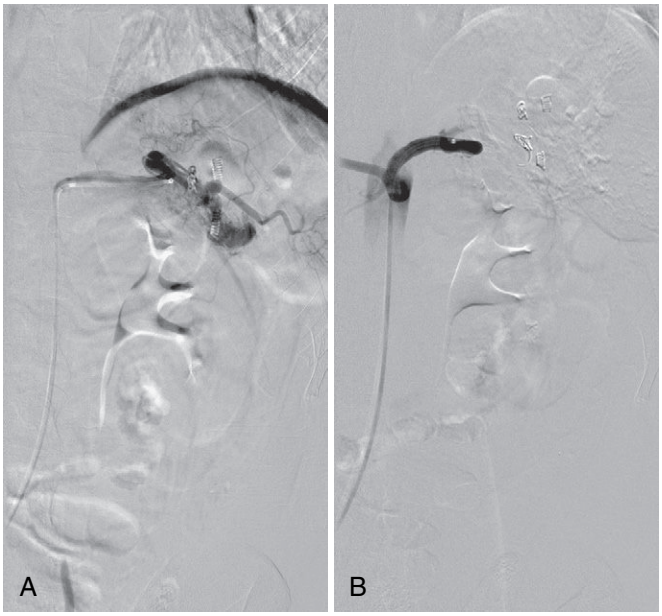

FIGURE 11 **A,** A selective arteriogram of the splenic artery demonstrates extravasation of contrast at the hilum. **B,** After embolization, endovascular coils are present at the splenic hilum with no evidence of contrast in the distal vessel or any further extravasation.

Access is obtained according to the vessel to be embolized (see the previous sections). Caution should be taken to select appropria te-sized coils and wire as recommended by the manufacturer in order to reduce the risk of distal embolization or faulty deployment. Once the vessel of interest is selected, obtain a DSA to confirm the presence and level of the injury. Position the delivery catheter distal to the injured segment. Deploy enough coils to fill the lumen and demonstrate minimal retrograde flow. Withdraw the catheter proximal to the injured segment and repeat deployment. Complete a DSA to evaluate for minimal contrast extravasation and continued patency of named or collateral vasculature (Figure 11).

Balloon Tamponade/Inflation

With wire access obtained across the vessel of interest (as previously described), choose a balloon circumference with a balloon-to-arterial ratio of 1.2:1. Serial inflations should be performed with the balloon below the nominal pressure. Maintain each inflation for 2 to 3 minutes. Obtain an angiographic image between inflations to determine whether hemostasis has been achieved. If hemostasis cannot be attained or if there is hemodynamic instability that cannot be corrected, the balloon can be used to occlude the vessel temporarily until the patient is stabilized and definitive care instituted.

The Management of Extremity Compartment Syndrome

Anna M. Ledgerwood, MD, and
Charles E. Lucas, MD

An extremity compartment syndrome develops from swelling of muscle in a confined space. This swelling may increase the tissue pressure within an anatomically contained space above capillary hydrostatic pressure, thereby compromising arteriolar inflow and leading to muscle and nerve ischemia and ultimately necrosis.

PATHOPHYSIOLOGY

Recognition of compartment syndrome began with Bywaters and Beall's (1941) descriptions of the crush syndrome in World War II. They reported on a small number of patients who were entrapped by collapsing buildings during the London Blitz. After extrication by their neighborhood civil defense workers and delivery by horse-drawn vehicles to the nearest hospitals, these initially stable and oriented patients deteriorated. The subsequent life-threatening events included hypotension from extravasation of fluid into the crushed limb, ischemia of the crushed limb as a result of high tissue pressure, rhabdomyolysis with myoglobinemia, renal failure, and death from inadequate volume replacement. Prevention of this fatal outcome requires an understanding of the pathophysiology of each step of this lethal sequence. Regardless of whether the increased tissue swelling and tissue pressure results from increased interstitial and intracellular fluid from reperfusion or crush injury or from external compression from a cast or a tourniquet, the subsequent pathophysiology of the compartment hypertension is comparable (Box 1).

The venous system is the primary egress for the extremity. When tissue pressure rises, venous outflow is impaired. This compromises the lymphatic flow, which empties locally into small veins leading to larger veins. The resultant rise in the interstitial fluid space (IFS) causes an elevation of the pressure in the intracellular fluid (ICF) spaces. Cellular hypertension compromises the nutrient flow from the capillaries through the IFS to the cells, which impairs cellular perfusion and leads to cell swelling as a result of intracellular sodium and water retention. The combination of increased pressure in the IFS and ICF shuts off transcapillary movement. The resultant cellular ischemia leads to acidosis and muscle necrosis with myoglobinemia, which is exacerbated when the restriction causing the compartment syndrome is corrected. When the insult is prolonged, extensive tissue injury and necrosis of entire muscles results, so that alleviation of the compartment syndrome must be followed by extensive débridement and occasionally amputation to remove dead tissue in order to salvage life.

ETIOLOGY

There are myriad conditions that can lead to an extremity compartment syndrome (Box 2). Tightly placed plaster casts or bandage wraps placed soon after injury can cause external compartment compression and fail to allow normal soft tissue swelling. Likewise, a circumferential third-degree burn with eschar decreases the volume of the underlying compartment and prevents the expected swelling that would occur with burn resuscitation.

Most compartment syndromes result from an internal compartment expansion that causes increased tissue pressure. The classic example is ischemia with reperfusion. Arterial occlusion from injury, thrombosis, or prolonged application of a tourniquet leads to cellular ischemia, with extensive cellular swelling once flow is restored. Patients with injury involving the femoral artery trifurcation or the popliteal artery are especially prone to severe ischemia of the leg muscles when reconstruction is delayed beyond 6 hours. The likelihood for compartment syndrome increases when the ischemic insult is combined with severe soft tissue injury, typically associated with long bone fractures and venous injury that necessitates ligation. Extensive combined injuries of bone, vessels, and soft tissues are seen after pedestrian/motor vehicle collisions and high-velocity rifle wounds. Arterial shunting, external fixation of fractures, rapid vascular reconstruction, and extensive fascia decompression are usually needed to salvage the involved limb. Burns without eschar and swelling caused by frostbite and generalized sepsis rarely increase muscle tissue pressure to the point that it impedes capillary flow. Internal compartment expansion may occur from a direct cellular insult with subsequent swelling. Classic examples include crush injury, most commonly seen today from mechanical compression of the extremity in an industrial accident. Other causes include excessive exertion or exercise and direct cellular insult from an electrical injury.

Accumulation of blood and edema with soft tissue injury are common features of fractures, particularly in the lower extremity. Alternatively, blood could accumulate spontaneously from minor trauma in a patient with a coagulopathy such as hemophilia or with the use of anticoagulants. Venous occlusion caused by iliofemoral thrombosis or venous return impaired by external pressure may lead to compartment syndrome. In the latter case, it may occur when an intoxicated patient lies on the extremity for a prolonged period of time. Miscellaneous causes of compartment syndrome include intramuscular injection of illicit drugs into the muscular compartment, which causes infection with subsequent abscess formation, cellulitis, and tissue ischemia. In rare cases, infiltrations of intravenous fluids cause compartment syndrome, inasmuch as these are usually in the subcutaneous tissue and not the muscle compartment.

DIAGNOSIS

Documenting a history of any of the many conditions that may lead to a compartment syndrome requires a careful examination of the involved extremity. An alert and cooperative patient should be assessed for the six *P*s associated with compartment syndrome (Box 3). Pain is the first and most important symptom and is usually described as a deep throbbing, unrelenting pressure. *Pain* out of proportion to physical findings is common. *Pressure* is the earliest and only truly objective finding of a compartment syndrome and is manifested as swelling, hardness, and tenderness of a muscle. This is most commonly appreciated in the anterior compartment of the lower extremity. *Pain with stretch* of the involved muscles is common but difficult to assess if there is a fracture or contusion. *Paresis,* or weakness of the muscle, is also difficult to interpret and may be secondary to nerve involvement or guarding secondary to pain. *Paresthesia* is the most reliable physical finding. Each compartment of the forearm and leg has at least one nerve coursing through it, and so careful sensory examination of the hand or foot may help confirm the compartment involved. For example, the deep perineal nerve is located in the anterior compartment and innervates the web space of the great toe. Decreased sensation in this area is indicative of an anterior compartment syndrome. The *presence of pulses* does not exclude a compartment syndrome. The increased compartment

BOX 1: Pathophysiology of compartment syndrome

1. Increased tissue pressure
2. Venous hypertension
3. Lymphatic blockade
4. Interstitial space hypertension
5. Intracellular hypertension
6. Reduced capillary perfusion
7. Tissue ischemia
8. Tissue death

BOX 2: Etiology of compartment syndrome

External Compartmental Compression
Cast/ACE wrap
Military antishock garments
Burn eschar

Internal Compartment Expansion
Ischemia and reperfusion
- Arterial injury, thrombosis, tourniquet
- Burns, frostbite

Cellular insult and swelling
- Crush injury
- Exercise/exertion
- Electrical injury

Blood accumulation and edema
- Fractures
- Hemophilia
- Anticoagulants
- Venous occlusion

Miscellaneous
- Intravenous infiltration
- Drug injection

Pain	Paresis
Pressure	Paresthesia
Pain with stretch	Pulses present

FIGURE 1 The Stryker pressure monitor is a handheld solid-state transducer device that can be used to directly measure muscle tissue pressure. The syringe and manometer are housed in a special chamber, and the directions for use are engraved on the back of the chamber.

FIGURE 2 A fasciotomy was performed for muscle ischemia of the calf after repair of a popliteal artery injury with ligation of the injured vein. There are areas of ischemia of the muscle that are allowed to demarcate with superficial débridement at 2 to 3 weeks. Early débridement leads to loss of muscle that probably would have survived.

pressure may cause muscle and nerve ischemia, but rarely is it elevated sufficiently to occlude a major artery.

Objective confirmation of a compartment syndrome requires direct monitoring of tissue pressure. Compartment decompression may be performed on the basis of clinical examination findings and does not require monitoring of tissue pressure. However, certain patients cannot be assessed clinically, such as those under anesthesia, those inhibited by alcohol or street drugs, or those suffering a head injury. There are a number of techniques available to monitor tissue pressure or, more specifically, intramuscular pressure. The direct needle puncture with a handheld solid-state transducer device (STIC catheter; Stryker Surgical, Kalamazoo, Mich) allows for repeated pressure measurements and is the technique most commonly used to measure tissue pressure (Figure 1). Alternatively, the authors have used a central venous pressure manometer, which is filled with sterile saline and attached to an extension tube, and a regular 18-gauge needle, which is inserted directly into the muscle compartment. The manometer is set so that its top is level with or slightly below the compartment, and the stopcock is opened. The manometer is gradually raised until the meniscus is seen to fall. The measurement is expressed in centimeters of water or divided by 1.4 to equal millimeters of mercury. Muscle compartmental pressure is normally less than 20 mm Hg. The authors tend to perform compartment decompression in a patient with suspected compartment syndrome whose muscle compartment pressure is greater than 35 mm Hg.

TREATMENT: COMPARTMENT DECOMPRESSION

The definitive treatment of compartment syndrome is release of the constricting tissue. Nonoperative therapies have no role in the treatment of compartment syndrome. Release of the constricting tissues almost always requires a long incision that involves the skin, subcutaneous tissues, and underlying fascia. Subcutaneous fasciotomy is best avoided. Débridement of ischemic muscle should be conservative because many segments of muscle that appear necrotic actually survive, and the negative or detrimental systemic effects of ischemic muscle are avoided once the compartment is decompressed and the products of dead muscle escape onto the dressing (Figure 2).

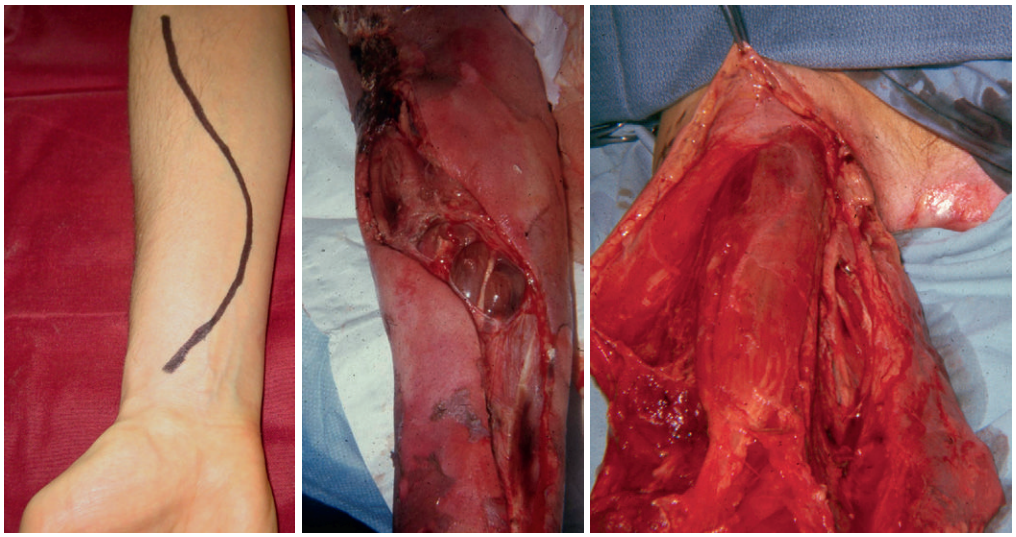

FIGURE 3 Street drugs were injected inadvertently into the subcutaneous plane of the forearm, and the extensive soft tissue necrosis and fasciitis that developed led to compartment syndrome. Extension of the forearm fasciotomy incision up to involve the anterior compartment of the arm, followed by extensive soft-tissue débridement *(left)* resulted in limb salvage and reasonable function.

The upper extremity, or arm, has two compartments containing primarily the deltoid and biceps brachii muscles anteriorly and the triceps muscle posteriorly. Anterior compartment syndrome of the arm may occur after the inadvertent subcutaneous injection of street drugs such as heroin when the intended vein is missed. The resultant extensive cellulitis compromises perfusion, necessitating a long incision beginning just distal to the deltoid to just above the elbow, staying lateral to the brachial artery and median nerve.

A compartment hypertension of both the anterior and posterior arm compartments is more likely to occur with crush injury or as a result of long-term venous occlusion caused by the patient's sleeping on the arm while intoxicated. The posterior incision extends over the triceps muscle in the midline to approximately 3 cm above the elbow. If necessary, decompression of the deltoid muscle can be achieved by extending the anterior incision proximally to the rotator cuff.

Forearm Compartment Syndrome

The forearm has three muscular compartments. The volar compartment contains the flexors of the wrist while the dorsal compartment contains the extensors to the wrist. The lateral compartment contains the brachial radialis and the extensor carpi radialis longus and extensor carpi radialis brevis. Isolated volar compartment syndrome of the forearm occurs after subcutaneous injection of street drugs, extravasation of intravenous infusions, insect bites, or crush injury. Decompression of the volar compartment is achieved through an incision that begins laterally near the elbow and descends medially in a curved manner for the first proximal half of the forearm and then curves laterally down to just above the wrist (Figure 3). This incision also decompresses the lateral compartment.

When all three forearm compartments are compromised—whether after severe burns or as a result of extensive trauma with long bone fractures and ischemia that necessitate vascular reconstruction—a posterior decompression should be added. This incision extends just distal to the radial head to the midportion of the wrist.

Above-the-Knee Compartment Syndrome

A thigh compartment syndrome is rare but may result from crush injury, venous outflow occlusion, or extensive bone and soft tissue disruptions caused by explosions, mines, or high-velocity rifle wounds (Figure 4). Compartment syndrome of the thigh is likely to involve all three compartments and to necessitate total decompression. The thigh has three compartments. The anterior compartment contains the sartorius and the quadriceps femoris muscles; the medial compartment contains the gracilis and three adductor muscles; and the posterior compartment contains the biceps femoris, semitendinosus, and semimembranosus muscles. Decompression of the anterior and posterior compartments can be achieved with an incision that extends from the greater trochanter posterior laterally to just above the knee. The fascia overlying the vastus lateralis muscle is identified so that the anterior compartment can be exposed throughout the length of the incision by an incision in the intramuscular septum separating the anterior and posterior compartments. The fascia from the vastus lateralis and its attachments on the femur are divided, thereby giving access to the lateral muscle fibers of the posterior compartment. Decompression of the medial compartment is achieved by a medial incision that stays posterior to Hunter's canal and opens the fascia of the gracilis and adductor muscles, including the adductor longus, brevis, and magnus.

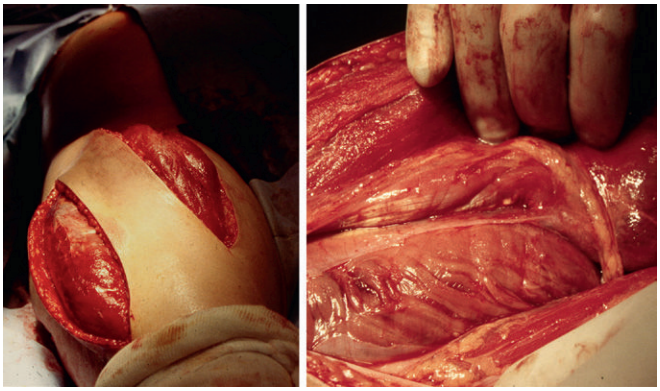

FIGURE 4 A patient who was admitted for a drug overdose was seen in consultation in the medical intensive care unit for a swollen right thigh. The thigh was hard and tense, and the patient excreted 40 mL of black urine. Medial and lateral thigh fasciotomies revealed pale muscles *(right)*. In spite of aggressive resuscitation, he developed oliguric acute renal failure and required dialysis for 3 weeks before urine output recovered. All muscle groups survived, and the wounds were treated with split-thickness skin grafting.

Below-the-Knee Compartment Syndrome

Most compartment syndromes occur in the lower leg, or calf, and are caused by ischemic reperfusion injury associated with elective or emergency vascular reconstruction or with crush injuries involving fractures and soft tissue injury.

The lower leg has four compartments. The anterior compartment contains the tibialis anterior, the extensor hallucis longus, the extensor digitorum longus, and a portion of the peroneus tertius muscles. The lateral compartment contains the peroneus longus and peroneus brevis muscles, and the posterior compartment contains the soleus, gastrocnemius, and plantaris muscles. The deep posterior compartment contains the flexor hallicis longus, tibialis posterior, flexor digitorum longus, and popliteus muscles. Although the lateral compartment contains the peroneal nerve, the peroneal artery runs deep in the posterior compartment along with the posterior tibial artery. The deep peroneal nerve runs in the anterior compartment, whereas the superficial peroneal nerve is in the lateral compartment.

Anterior Compartment Syndrome

An unusual entity is the stress-induced anterior compartment syndrome. Affected patients uniformly have a history of increased physical activity and exercise for an extended time. The patients state that the anterior calf tightened and became extremely painful; massage did not help. The severe constant pain is localized to the anterior compartment. The diagnosis is made clinically by noting that the anterior compartment is very hard. This is a surgical emergency, and immediate anterior compartment decompression as described previously is required.

Four-Compartment Syndrome

Patients presenting with ischemic reperfusion injury or severe trauma with concomitant injury to bone and muscle are more likely to have a four-compartment syndrome. The most common way of decompressing the four compartments is to use bilateral incisions (Figure 5). The medial incision is made just distal to the medial tibial condyle and extends inferiorly between the superficial posterior muscle group and the posterior ridge of the tibia. This incision should be approximately 1 cm posterior to the tibia and then carried through the superficial fascia. This decompresses the superficial posterior compartment. In order to decompress the deep posterior compartment, the fibers of the soleus muscle must be detached from the posterior tibial attachments (Figure 6). The lateral and anterior compartments are decompressed by a lateral skin incision along the anterior margin of the fibula between the muscle fibers of the lateral compartment and the lateral portion of the anterior compartment. The skin must be retracted anteriorly to expose the fascia of the anterior compartment muscles and then inferiorly to expose the fascia of the lateral compartment, both of which are incised the full length of the earlier incision (see Figure 6). Care must be taken to be certain the lateral incision includes the anterior compartment muscles. Likewise, the soleus muscle must be taken off the tibia if the deep posterior compartment is to be decompressed. On occasion, decompression of three compartments lowers the pressure in the deep posterior compartment. Tissue pressures can be obtained after a three-compartment fasciotomy; if the deep posterior compartment pressures are below 25 mm Hg, no further decompression is needed.

POSTOPERATIVE MANAGEMENT

The extremities are dressed with dry gauze and a soft wrap and elevated. A vacuum-assisted closure device can be applied if drainage is extensive. A posterior splint of the lower extremity is strongly recommended to prevent footdrop. Some fasciotomy incisions can be closed in 5 to 7 days with closure of the skin. The fascial incision should be left open because closure will lead to recurrences of compartment syndrome. If extensive muscle bulging precludes skin approximation, full-thickness skin grafts can be performed. Sometimes there is a delay to compartment decompression, which leads to superficial muscle ischemia. The superficial layer of muscle may appear necrotic. In most cases, the underlying muscle is compromised but does survive. A superficial layer of necrotic muscle can be débrided at 2 to 3 weeks (see Figure 2). The patient is monitored for

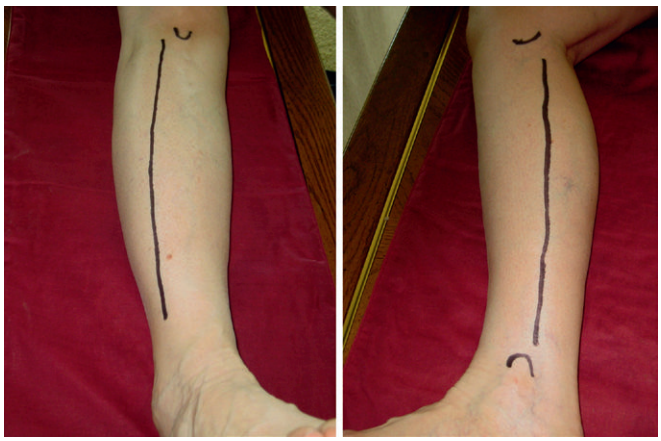

FIGURE 5 Four-compartment fasciotomy of the calf is made by a lateral skin and fascial incision made along the anterior margin of the fibula between the muscle fibers of the lateral compartment and the lateral portion of the anterior compartment. The medial incision is made just distal to the medial tibial condyle and extends inferiorly between the superficial posterior muscle group and the posterior ridge of the tibia.

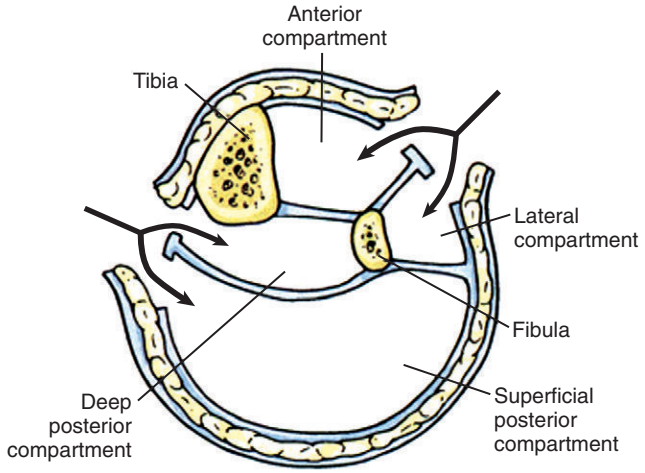

FIGURE 6 To decompress the anterior compartment, it is crucial that the skin of the lateral incision be retracted anteriorly and the fascia of the anterior compartment muscles be exposed and incised. Likewise, to decompress the deep posterior compartment, the gastrocnemius muscle needs to be retracted inferiorly in the medial wound and the soleus muscle taken off the posterior tibia. Unless the soleus muscle is taken down from the tibia, only a three-compartment fasciotomy has been performed.

myoglobinuria and, if it is present, treated with alkalinization of the urine and hydration.

Burn Wound Management

Stephen M. Milner, MBBS, BDS, DSc (Hon), FRCS (Ed), FACS, and Malachy E. Asuku, MBBS, FWACS

OVERVIEW

Although the etiology and mechanism that lead to burn injury remain diverse, the common pathway to tissue damage involves sustained exposure to temperatures outside the physiologic range. The resultant injury is dependent on the magnitude of the temperature and the duration of the exposure. Whereas the cellular damage induced by heat and ischemia is localized in minor burns, large surface area burns induce additional systemic effects mediated by inflammatory cytokines that cause generalized capillary endothelial dysfunction. The severity of the ensuing metabolic and endocrine disturbance is determined by the percentage total body surface area (TBSA) burn and the patient's age. Concomitant injuries, such as inhalation injury and patient comorbidities, have equally been shown to contribute to the overall outcome.

The strategy in the management of the burn patient as enshrined in the mission statements directs attention to life-threatening concerns before focus on the burn wound (Box 1). Therapy demands prompt attention to Advanced Trauma Life Support (ATLS) workup, fluid resuscitation, pain control, prevention of wound infection, and pharmacomodulation of the hypermetabolic state. Nutritional support by way of supplemental tube feeds has been shown to enhance epithelialization, granulation tissue formation, and immunocompetence. The consolidation of the multidisciplinary resource in the modern burn center incorporating invasive continuous cardiac monitoring, ventilator support, and renal replacement therapy (RRT) has led to improved survival in the last few decades. However, it is the preponderance of early burn wound excision and closure with skin graft that has contributed most to survival of the burn patient (Figure 1).

BOX 1: Mission statement in the management of burns

Mission Statement in the Management of Burns: The Big Picture at a Glance

1. Institution of adequate airway and breathing
2. Prevention and treatment of burn shock
3. Prevention and treatment of infection
4. Provision of permanent and durable skin cover
5. Correction of functional disabilities
6. Correction of cosmetic concerns
7. Rehabilitation and reintegration into society

THE BURN WOUND

The effective treatment and ultimate healing of the burn wound remains the sine qua non of successful treatment of the burn patient. Survival with good quality of life is contingent on complete closure of the burn wound, a feat that requires adequate understanding of the peculiar pathophysiology of the burn wound. The local effect of burn injury is depicted by the three-dimensional Jacksonian model of three concentric zones. The zone of necrosis, which is in the center, is the part exposed to the highest intensity of insult. The tissue is irreversibly damaged as the cellular protein is denatured by intense heat or cold. In the periphery lies the zone of inflammation, where injury is minimal as it is most remote from the inciting agent. The tissue is expected to make complete recovery within 7 to 10 days. In the middle is the zone of ischemia, where massive release of inflammatory cytokines lead to increased capillary permeability (Figure 2). This injured tissue has a tendency to progress to a deeper wound within 24 to 48 hours in a process described as conversion.

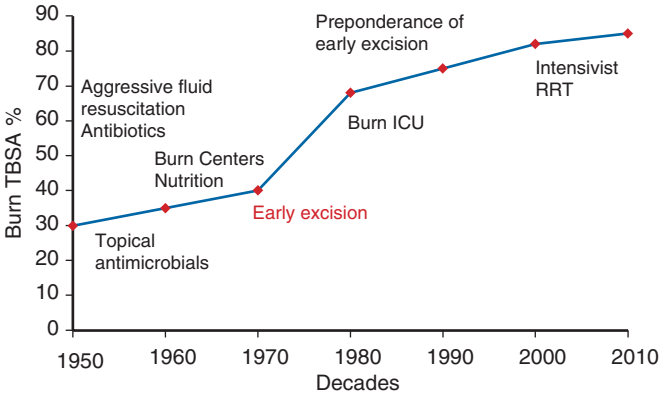

FIGURE 1 Line graph depicting burn lethal total body surface area *(TBSA). ICU,* Intensive care unit; *RRT,* renal replacement therapy. *(From Kasten KR, Makley AT, Kagan RJ: Update on the critical care management of severe burns,* J Intensive Care Med *26(4):223-236.)*

The objectives of treatment of the burn wound are therefore to rescue the tissue in the zone of ischemia, hasten the recovery of tissue in the zone of inflammation, and surgically facilitate removal of eschar in the zone of necrosis. Clinically, this translates into burn wound excision, wound dressing to provide moisture and prevent infection, and the resurfacing of epithelial defects with skin grafts where indicated. The depth of burn injury is the most important variable in determining the degree of complexity necessary in its management (Table 1). This places a high premium on the accurate assessment of burn depth, a science that has remained an enigma. Sophisticated techniques for determination of burn depth have included color temperature mapping, injection of vital dyes such as India ink and fluorescein, and ultrasound scan. The laser Doppler imaging that uses a color-coded map dependent on tissue perfusion may be the most reliable technique at this time. For the most part, however, the judgment remains a clinical one that requires a measure of experience.

The principles of the reconstructive ladder may be effectively applied to the management of the burn wound. Superficial burns have minimal requirements; provision of moisture and protection against infection allow spontaneous reepithelialization within 14 to 21 days. Topical antimicrobial ointments or other occlusive dressings have been used with great success. In deeper burns, healing is accelerated with excision and split-thickness skin graft coverage of the excised wound bed. However, composite tissue losses may necessitate the use of full-thickness skin grafts, flap coverage including free flaps, use of synthetic skin substitutes, tissue expansion, and interval use of negative-pressure therapy to facilitate granulation tissue formation preparatory to skin grafting.

MANAGEMENT OF SUPERFICIAL BURNS

Débridement of the burn wound facilitates assessment of extent of injury and serves as the first step in wound care. Intravenous narcotic analgesia provides adequate pain control and allays patient's anxiety. The core body temperature must be maintained above 36°C in patients with large surface area burns. The exposure of limited areas at a time, use of warm cleansing solution, and use of an overhead heating shield have been helpful in this regard. The wound surface is cleansed with an antiseptic solution such as 5% chlorhexidine. Nonviable tissue and blisters are excised with sharp dissection to rid the body of proinflammatory cytokines contained in blister fluid. Furthermore, débridement accords topical antimicrobial agents adequate contact with the wound bed.

Topical antimicrobial ointments have continued to play a role, albeit nominal, in the management of superficial burns. Silver sulfadiazine, marketed under different trade names across the globe (Silvadene, [Monarch Pharmaceuticals Inc., Bristol, Tenn]; Dermazene, [Silvestre Laboratorios Quimica and Farmaceutica, Brazil]; Thermazene, [Kendall Healthcare Products, Mansfield, Mass]; and Flamazine [Smith and Nephew Pharmaceuticals Ltd., Hull, UK]), remains the most widely used of these agents. Its antimicrobial properties include bactericidal activity against gram-positive and gram-negative organisms including *Pseudomonas* species and yeast. It is readily available, painless, and easy to apply. Drawbacks include infrequent hypersensitivity in individuals with sulfa allergy, transient neutropenia with prolonged use over large surface areas, and the formation of pseudoeschar capable of interfering with assessment of burn depth. Other widely used antimicrobial creams and ointments in the care of superficial burn wounds include Bacitracin (E. Fougera & Co., a division of Nycomed U.S. Inc., Melville, NY), Neosporin (Johnson and Johnson Consumer Co., Inc., NJ), and Polymyxin B

TABLE 1: Classification of burn wounds: superficial versus deep burns

Depth	Traditional	Characteristics	Significance
Superficial	1st and 2nd degrees. Superficial partial-thickness burn.	Wet, pink, blistered; blanches with pressure; and painful.	Sufficient epithelial appendages to allow healing within 3 weeks. Scarring is minimal.
Deep	3rd degree. Deep partial and full-thickness burns.	Ranges from cherry red, mottled, white, and nonblanching to leathery brown and insensate.	Insufficient epithelial appendages; healing is slow with resultant unstable scar, scar hypertrophy, and contractures. Best treated with excision and skin grafting.

(Cayman Chemical Co., Ann Arbor, Mich). In Europe and other parts of the world, fine meshed fabric described as tulle is widely used as dressing for superficial burns. The fabric is usually impregnated with Vaseline (Tulle gras, Smith and Nephew Healthcare Ltd., Hull, UK), chlorhexidene acetate (Bactigras; Smith and Nephew Healthcare Ltd., Hull, UK), or framycetin sulfate (Sofra- tulle; Hoechst Marion Russel Ltd., Uxbridge, England). The ideal dressing remains one that is inexpensive and comfortable and requires minimal dressing changes. It should provide a suitable environment for reepithelialization and protect against microbial colonization.

MANAGEMENT OF DEEP BURNS

Full-thickness circumferential extremity and trunk burns in which eschar constitutes a leathery nonyielding band are indications for escharotomy. Early recognition of the need for escharotomy or fasciotomy on an injured extremity is vital to prevention of loss of limb. Close surveillance must be extended to circumferential partial-thickness burns and full-thickness noncircumferential extremity burns in patients who need large volumes of fluid for resuscitation. Excruciating pain on passive movement and palpable firmness of the compartment precede the ominous signs of distal neurovascular compromise, such as pallor and loss of pulse. Direct measurement of compartmental pressures with the need for escharotomy established at a threshold of 30 mm Hg with a wick catheter technique has been widely adopted.

Escharotomy may be performed by the patient's bedside with minimal doses of analgesics and anxiolytics. Electrocautery is preferred to the use of scalpel blade because this minimizes bleeding. It is safe practice to outline and carry out incisions with the limbs in anatomic positions to avoid damage to neurovascular structures (Figure 3). The longitudinal decompressing incisions must traverse the depth of the eschar until the subcutaneous tissue spouts and should extend to nonburned tissue proximally and distally. It is vital to immediately ascertain the adequacy of an escharotomy by demonstrating softness of previously firm compartments and improved distal perfusion. The absence of these signs should be considered an indication for fasciotomy, which is best performed in the operating room with general anesthesia. This procedure is aimed at relieving of pressure within the well-defined fascioosseous compartments of the limbs. High-voltage electrical burn injury is a frequent cause of extremity compartment syndrome that necessitates fasciotomy. The high incidence of limb amputations associated with this injury is indicative of a need for higher index of suspicion for compartment syndrome at presentation. It is customary to explore all the fascial compartments of a limb and allow the skin incision to heal by secondary intention or delayed primary closure with split-thickness skin graft.

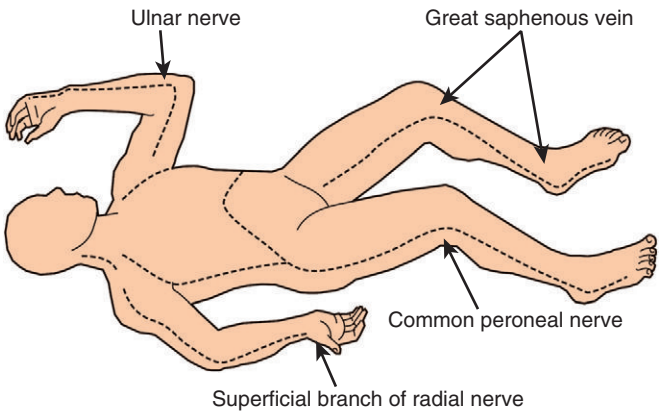

FIGURE 3 Escharotomy incision sites and neurovascular structures at risk of injury.

EXCISION OF BURN WOUNDS

Basic science and clinical research have shown that early excision of burned tissue that serves as nidus for bacterial proliferation and invasive burn wound sepsis attenuates the systemic inflammatory response in patients with major burn injury. The pioneering work of Zora Janzekovic and other researchers has proven that early burn wound excision and closure improve survival, shorten length of hospital stay, improve the quality of scarring, and enhance early return to work. Tangential excision entails serial layered excisions of the burned tissue until punctate capillary bleeding indicative of healthy bed is encountered. The handheld Weck knife mounted with a Goulian guard is most suited for this purpose. Availability of the guard in sizes ranging from 8 to 12 (representing 1/1000 of an inch) allows caution and precision at excision to be tailored to the thickness of the skin in different parts of the body. The Humby knife and the powered dermatome have also been used in the excision of larger burn surfaces. Tangential excision is associated with significant blood loss in the magnitude of 0.75 to 1 mL/ cm^2 excised. Proponents of immediate excision of burn wounds argue that the blood loss is reduced to 0.40 mL/cm^2 if excision is done within the first 24 hours of injury. Strategies aimed at minimization of blood loss include use of nonadherent Telfa pads (Telfa AMD, Covidien, Mansfield, Mass) soaked in epinephrine 1:10,000 to 1:50,000 solution applied for 7 to 10 minutes, use of topical thrombin solutions, preexcision tumescence with 1:500,000 epinephrine solution, and limb elevation/suspension from the ceiling. The use of tourniquets inflated above the systolic pressure after exsanguination is most effective in controlling blood loss in extremity excisions; however, experience is required to determine viable versus nonviable tissue in this setting.

Fascial excision, which refers to the excision of burned skin along with the underlying subcutaneous tissue with preservation of the deep fascia, is reserved for patients with limited donor skin as a result of full-thickness large surface areas burns. It is also suitable in elderly patients with multiple comorbidities in whom reducing operative time and blood loss and obtaining early wound closure are most desirable. The procedure that is undertaken with the aid of electrocautery is faster and entails less blood loss compared with tangential excision. However, the major disadvantages include long-term contour deformity as a result of loss of subcutaneous tissue.

CLOSURE OF EXCISED BURN WOUNDS

Split-thickness autograft coverage of the burn wound is the ultimate goal in the management of the burn wound. The benefits of early excision are realized only when the excised wound is covered with skin or its substitute. For the burn patient, closure of the wound with durable skin represents a major landmark on the way to recovery. Favored donor sites include the thighs, the buttocks, the back, and the scalp. Donor skin is harvested with either the powered dermatome or the handheld dermatomes such as the Humby knife. The usual thickness of split-thickness skin graft is 10/1000 to 12/1000 of an inch. The donor site is usually covered with a protective dressing to minimize pain and facilitate reepithelialization. Meshing the graft to ratios of 1:1, 2:1, 3:1, and 4:1 permits egress of blood and serum and allows coverage of larger surface areas at the expense of durability and cosmetic appearance. Survival of widely meshed autograft (3:1 and 4:1) and healing of the wide interstices is enhanced by an allograft overlay in a sandwich technique. In patients with inadequate donor skin, recropping previously harvested skin may become necessary. The interval to recropping is dependent on the thickness of the

residual dermis, which determines the rate and quality of donor site healing. Generally, a minimum of about 3 weeks may be necessary, and usual practice is to harvest thinner grafts, such as 10/1000 of an inch, when recropping skin.

Several options are available for dressing the grafted wound bed. The ideal is a comfortable dressing that provides moisture to keep the graft alive, adequate pressure to prevent collection under the graft, and immobilization to prevent shearing. Revascularization of the split-thickness skin graft is achieved through the processes of plasmatic imbibition, inosculation, and neovascularization. Reattachment, however, depends on fibrin clot on the wound bed providing the scaffold for the deposition of collagen to form fibrous adhesions. The use of full-thickness skin grafts and flaps in the coverage of acute burn wounds is limited to very small deep burns and such procedures as early correction of ectropion. Aside from being limited in supply, the full-thickness skin graft has more stringent requirements for survival. The graft is harvested with the scalpel blade, and the donor site is usually closed primarily.

Cultured epithelial autograft (CEA), which provides sheets of in vitro cultured keratinocytes, is an additional means of obtaining skin cover in patients with limited donor skin. The inadequacy of use of an epidermal component to replace full-thickness skin loss has been a major drawback to this technique. Attempts at enhancing the durability of CEA have included engrafting the cultured cells over widely meshed autograft or vascularized allogeneic dermis obtained by excising the epidermis and upper dermis of engrafted allograft. The expense, stringent requirements, and suboptimal outcome of CEA are generally accepted to only be justified by an overwhelming burn wound size in which options are limited.

Cadaver allograft represents the best option for temporary burn wound coverage. Its immediate "take" sterilizes the wound bed and prepares it for autograft placement. Allograft serves as an expendable bridge in patients with hemodynamically unstable conditions in which vasopressors known to jeopardize graft take may be necessary. It is also useful in tangentially excised wounds where the adequacy of excision is questionable. It is, however, best substituted before the onset of the process of rejection, which may set in as early as in the third week. Several cycles of allograft coverage may be required while waiting for autograft to become available. Allograft is usually meshed to a ratio of 2:1 or 1:1, depending on the site to be covered. It may be used as a sheet graft in the temporary coverage of facial and hand excisions where bleeding precludes the immediate use of autograft.

Integra (Life Sciences Laboratory Corp., Plainsboro, NJ) is a bilaminar dermal regeneration template approved by the U.S. Food and Drug Administration (FDA) for use in patients with limited donor sites as a result of massive life-threatening burns. Its outer layer is an impermeable polymeric silicon sheet, and the dermal component is a highly porous matrix composed of cross-linked coprecipitate of bovine collagen and chondroitin-6-sulphate derived from shark cartilage. Within 3 weeks of grafting, the dermal template is incorporated into the recipient bed, forming a neodermis at which stage the polymeric silicon layer is replaced by an ultrathin autograft. Integra has been found most useful in resurfacing the hands and face where it restores normal texture and elasticity. It has also shown success in the coverage of small relatively devascularized areas, such as exposed tendons and bone. Its major disadvantage remains its prohibitive cost and its limited ability to engraft in the presence of wound colonization and infection.

The negative-pressure wound therapy (NPWT) device has since its introduction continued to feature prominently in burn wound management. Its ability to splint skin grafts while allowing range of motion exercises of adjacent joints has been most useful in the patient with large surface area burns. With its control of drainage, it has been shown to equally contribute to bacteriologic control and enhance skin graft take even in areas of unfavorable contours such as the axilla and groin. Although it is not a panacea for inadequate surgery, the technique has led to significant reduction in length of hospital stay.

COMPLICATIONS OF BURN WOUND HEALING

Despite concerted efforts, a scientific tool capable of accurately determining burn depth and directing decisions on the need for surgery or otherwise has continued to evade the burn community. Consequently, complications that result from protracted healing of the burn wound abound. These complications include burn scar hypertrophy, burn scar contractures and unstable scars, and chronic wounds with their long-term potential for malignant transformation into Marjolin's ulcers. The management of these complications constitutes the bulk of the work in the realm of burn reconstruction and rehabilitation.

Practical Management of the Burn Patient

Rob Sheridan, MD

INTRODUCTION

The outlook for burn patients continues to improve both for survival and for quality of life. Current expectations include eventual return to community, school, family, and work for the large majority. Realization of these results in patients with serious injuries requires a coordinated response by a multidisciplinary group over an interval of time that can span years. This care strategy has four overlapping phases (Table 1). The initial evaluation and resuscitation phase begins at presentation and generally is complete by 48 hours. This first phase includes an accurate fluid resuscitation and through evaluation for nonburn injuries and comorbid conditions. The initial wound excision and biologic closure phase begins during or immediately after and is ideally completed in 5 to 7 days. This second phase is characterized by a series of staged operations in which deep burns are identified and excised and the resulting viable wounds are biologically closed. The definitive wound closure phase immediately follows. This third phase varies in duration with donor skin availability and involves replacement of temporary wound membranes

TABLE 1: Phases of burn care

Phase and rough time course	Objectives
One: Initial evaluation and resuscitation Injury through about 72 hours	Complete evaluation for injuries and comorbid conditions Accurate fluid resuscitation
Two: Initial wound excision and biologic closure Days 1 through 7	Identification and excision of all deep wounds Achievement of permanent or temporary biologic closure
Three: Definitive wound closure Days 1 through acute discharge (depending on donor availability)	Replacement of all temporary membranes with permanent closure Refined functional closure of face, hands, feet, and genitalia
Four: Rehabilitation and reconstruction Day 1 through first year (depending on injury severity)	Independence in activities of daily living Return to family, work, school, and community

with autografts and acute reconstruction of areas of small surface but high complexity (particularly the face and hands). The rehabilitation phase blends into the prior phase and also varies with injury severity. This fourth phase focuses on rehabilitation, reconstruction, and reintegration. In individuals with severe burns, this phase can last for years, with staged interventions, timed to minimally interfere with recovery.

PHYSIOLOGIC CHANGES WITH BURN INJURY

Like major trauma, burn injury induces a stereotypical sequence of physiologic changes that increase in magnitude and duration with injury severity and concomitant complications. A variety of efforts to modify potentially harmful elements of this physiology has been trialed but not been widely adopted. Fortunately, purposeful support of these changes is reliably successful.

Hypodynamic Phase

Postburn physiologic changes are biphasic and follow a predictable time course. Support requirements are different for each phase, as are the complications associated with inadequate support. From injury to approximately 72 hours is a hypodynamic phase, "ebb phase" or "burn shock," that is characterized by hypoperfusion and a diffuse capillary leak that roughly increases with injury size and depth. The diffuse capillary leak is assumed to be to the result of wound-released mediators and causes extravascular extravasation of fluids, electrolytes, and moderate-sized colloid molecules. Support of this phase requires individualized fluid resuscitation, which is detailed subsequently. Consequences of inadequate support include splanchnic ischemia, acute tubular necrosis, and other consequences of systemic hypoperfusion. Adverse sequelae result from overresuscitation as well, including compartment syndromes, intra-abdominal hypertension, and pulmonary edema. A timely and accurate individualized resuscitation minimizes the adverse consequences of this early postburn physiology.

Hyperdynamic Phase

In patients who have been successfully resuscitated, the early hypodynamic period is followed by a protracted phase of hyperdynamic physiology. Volume requirements fall to between 100% and 150% of a calculated maintenance rate, and cardiac output gradually increases. This physiology is characterized by fever and increased protein catabolism and is thought to be a consequence of released inflammatory mediators, cortisol, catecholamines, and glucagon. Bacterial colonization and infection exacerbate this hyperdynamic catabolic state. Support of this hyperdynamic physiology includes accurate fluid repletion, provision of adequate quantity and quality of substrate, control of environmental temperature, removal of eschar before infection, wound closure, and control of pain and anxiety.

PHASE ONE MANAGEMENT: INITIAL EVALUATION AND RESUSCITATION

The initial management of a patient with serious burns should be structured similar to that of a patient with complex trauma. In addition to the trauma considerations, a number of common pitfalls should be avoided. This is often called the burn-specific secondary survey and occurs in conjunction with fluid resuscitation.

Burn-Specific Secondary Survey

A detailed burn-specific secondary survey begins with a history. Important points include injury mechanism, initial neurologic status, extrication time, and tetanus immune status. These findings often drive subsequent imaging and management decisions.

Progressive mucosal edema can compromise airway patency over the first few postinjury hours, particularly in small children. Semiemergent intubation is indicated in the presence of worrisome facial edema, stridor, or progressive hoarseness. The presence of inhalation injury is not an absolute indication for intubation in the absence of looming airway obstruction or respiratory failure. Many patients with inhalation injury and small surface burns can be managed without intubation. Patients with coincident nonburn trauma or a large surface burn are likely to have edema develop; this should be considered in the decision for early intubation. Unplanned extubation in the patient with a burned face can be life-threatening and is best avoided though careful attention to tube security.

The head and face should be inspected for nonburn trauma. The globes should be inspected before the development of facial edema that can limit adequate examination. Burns of the globe usually impart a clouded appearance to the cornea; subtle injuries are detectable with fluorescein staining. Acute tarsorrhaphy is virtually never indicated because edema ensures globe coverage initially in the vast majority of patients, even in the presence of periocular burns. Rarely, decompression of the orbit is needed for intraocular hypertension pressures secondary to intraocular edema; this is easily effected by lateral canthotomy. Ear burns are noted, and pressure is avoided while topical mafenide acetate is applied to minimize the

development of subsequent chondritis. Signs of inhalation injury should be sought, including carbonaceous oral debris and singed nasal hairs.

Neurologic status is accessed with history and examination. Imaging of the head and spine generally depends on the mechanism of injury. Pain and anxiety should be managed judiciously with small repeated intravenous doses of opiates and benzodiazepines. Obtunded patients with inhalation injury should be assessed for carbon monoxide exposure and treated with 6 hours of 100% normobaric oxygen or hyperbaric oxygen.

The chest should be assessed for symmetric air movement and compliance. Small children exposed to irritating smokes can have significant bronchospasm develop. Deep eschar should be sectioned if it interferes with ventilation.

Burned extremities must be assessed for nonburn trauma and monitored for turgor and perfusion. Tense extremities should be decompressed with escharotomy or fasciotomy. Imaging may be necessary for diagnosis of some fractures in obtunded patients. Fractured and burned extremities are initially stabilized with external splints. Progressive edema during resuscitation can result in the late development of profound limb ischemia, as a result of swelling within circumferential eschar or inelastic muscle compartments. Extremity perfusion should be monitored throughout the resuscitation period.

The burn wounds should be assessed roughly for size with the "rule-of-nines" or a Lund-Browder chart, for depth generally with physical examination, and for the presence of near-circumferential components that may require decompression (Figure 1).

Very few laboratory or imaging studies are useful initially. Carboxyhemoglobin and arterial blood gas determinations are helpful in patients with respiratory issues or inhalation injury. Chest radiographs are appropriate to ensure proper placement of lines and the

endotracheal tube and the absence of chest trauma. The mechanism of injury dictates the need for other radiographs and laboratory studies.

All patients should be screened for abuse. In many studies, up to 20% of burns in young children are reported to state authorities for investigation, but abuse occurs in all age groups. Careful documentation of the history and injury, ideally photographic, is useful (Figure 2).

Fluid Resuscitation

In the first hour or two after even large burns, patients experience little change in intravascular volume, which explains the common observation that patients can be quite alert for the first couple of hours after injury. However, as wound-released mediators and pain-triggered hormones are absorbed, a diffuse loss of capillary integrity occurs that results in the extravasation of fluid and electrolytes. For unknown reasons, this leak abates between 18 and 24 hours later in well-resuscitated patients. Increased leakage is routinely seen in patients whose resuscitations are delayed and in those with inhalation injury, possibly contributed to by a whole-body ischemia-reperfusion reaction.

A variety of body and burn size adjusted burn fluid resuscitation formulas have been promulgated over the past 50 years. None are universally accurate in light of the inherent variability of burn wounds and patients. A common consensus is based on the modified Brooke formula, which recommends administration of 2 to 4 mL/kg/percent burn of Ringer's lactate solution over the first 24 postinjury hours (half in the first 8 postinjury hours) and a small dose of colloid (5% albumin solution) from hour 24 to hour 48 (Table 2). However, numerous publications have described the widely varying individual needs of burn patients. No formula is accurate enough to be relied on in actual practice. Quality resuscitation requires an hourly reevaluation of physiologic endpoints with adjustment of infusions accordingly. Markers of adequate resuscitation include normal vital signs, urine output, and peripheral perfusion (Box 1).

The role of colloid in burn resuscitation is increasingly controversial. The trauma literature shows that many practitioners use colloid early during resuscitation. This author's routine practice is to administer a maintenance rate of 5% albumin to most patients with burns in excess of 30% from the beginning of resuscitation, subtracting this from the calculated crystalloid rate. The crystalloid rate is weaned as tolerated based on serial measurement of resuscitation endpoints. In small children, a maintenance rate of 5% dextrose in lactated Ringer's solution substitutes for an equal portion of calculated Ringer's lactate solution. The practice of early colloid administration seems to be associated with reduced overall fluid requirements and a reduced incidence of morbidity related to edema. Patients with burns smaller than 15% generally do not need a calculated resuscitation; they are well managed with 150% of maintenance needs and careful clinical monitoring of hydration.

FIGURE 2 Flexor sparing suggests possible immersion of a flexed body part and is seen here in the popliteal fossa.

TABLE 2: Consensus resuscitation formula

First 24 Hours
Adults and children >20 kg
Ringer's lactate solution: 2-4 mL/kg/% burn/24 h (first half in first 8 h)
Colloid: None*
Children <20 kg
Ringer's lactate solution: 2-3 mL/kg/% burn/24 h (first half in first 8 h)
Ringer's lactate solution with 5% dextrose: maintenance rate (approximately 4 mL/kg/h for the first 10 kg, 2 mL/kg/h for the next 10 kg; and 1 mL/kg/h for weight >20 kg)
Colloid: None*
Second 24 Hours
All patients
Crystalloid: To maintain urine output. If silver nitrate is used, sodium leeching mandates continued isotonic crystalloid. If other topical is used, free water requirement is significant. Serum sodium should be monitored closely. Nutritional support should begin, ideally via the enteral route. Total input generally approximately 140% maintenance, depending on injury severity.
Colloid* (5% albumin in Ringer's lactate solution):

0-30% burn:	None
30%-50% burn:	0.3 mL/kg/% burn/24 h
50%-70% burn:	0.4 mL/kg/% burn/24 h
70%-100% burn:	0.5 mL/kg/% burn/24 h

*An increasing body of clinical practice favors earlier institution of colloid. This author routinely substitutes 100% maintenance rate of calculated Ringer's lactate solution with equal volume of 5% albumin beginning at start of resuscitation in patients with larger injuries.

BOX 1: Burn resuscitation endpoints

Sensorium: Arousable and comfortable
Digital temperature: Warm peripherally
Systolic blood pressure: For infants, 60 mm Hg systolic; for older children, 70 to 90, plus 2× age in years, mm Hg; for adults, mean arterial pressure over 60 mm Hg
Pulse: 80-180 per minute (age-dependent)
Urine output: 0.5-1 mL/kg/h (glucose-negative)
Base deficit: <2

PHASE TWO MANAGEMENT: WOUND EXCISION AND BIOLOGIC CLOSURE

If fluid resuscitation reduces morbidity and mortality from otherwise inevitable burn shock, early wound excision and closure reduces morbidity and mortality from otherwise inevitable burn wound sepsis. "Early" has been variably defined but implies excision is complete before heavy wound colonization and infection has occurred, generally within the first few days after injury. The definition of "early" varies with the severity of the wound, the stability of the patient, and the resources available for surgery and critical care support. Although conceptually logical, a relative paucity of data remains to support the strategy. Serial physical examination by an experienced surgeon remains the most reliable method of determination of need for wound excision. When carefully planned, appropriately staged, and expeditiously performed with hemostatic techniques, these operations are well tolerated by most patients.

Determination of the Need, Timing, and Extent of Operation

Burn size and depth drive the need for and timing of burn wound excision. Patients with small superficial burns rarely have systemic sepsis develop and can be safely treated with topical therapy, with only grafting of small nonhealed areas subsequently. Very deep dermal and full-thickness burns are best identified early and excised and grafted promptly, to minimize septic morbidity, patient suffering, hypertrophic scarring, and hospital length of stay.

Patients with large injuries benefit from a more aggressive surgical approach because the injury size alone presents a physiologic threat. The objective of operation is to identify, excise, and achieve biologic closure of all full-thickness components. When the wounds are very large, this may necessitate staged procedures. If autograft is temporarily exhausted or if patient conditions are not stable, temporary biologic closure of excised wounds can be achieved with human allograft Integra (Integra Life Sciences, Plainsboro, NJ), or other temporary wound closure materials.

Techniques of Burn Wound Excision

Wounds that are superficial require no excision and are simply cleansed and treated with topical medications or temporary biologic dressings. Middermal wounds can be similarly addressed. Topical proteolytic enzymes can be useful in such wounds but have not been widely adopted because currently available formulations débride over days rather than hours. Very deep dermal wounds are often excised and grafted because healing is generally quite prolonged with a high incidence of hypertrophic scarring. Deep dermal excisions should only be done when they quite clearly will give better results than those obtained with protracted topical care. Full-thickness wounds are ideally excised with a layered technique to viable subcutaneous fat to optimize function and contour. It is important to conform grafts to the small irregularities of such wound beds and to prevent exposure and desiccation of subcutaneous fat because this results in compromised engraftment.

Fascial excisions are much less frequently done today than in prior decades because they may exacerbate aesthetic and functional deformities. However, they are still indicated if burns involve subcutaneous fat or if patients have massive full-thickness burns and the risk of graft loss on extensive wounds excised to subcutaneous fat is life threatening. Fascial excisions can be hemostatically performed with coagulating electrocautery, which provides excellent hemostasis and a clear viable plane that reliably accepts autograft. The plume from these excisions can be controlled with a high-efficiency suction device. Subfascial excisions are infrequently necessary in high-voltage electrical injuries or remarkably deep thermal burns. Exploration of muscle compartments can readily be done through decompressive fasciotomy incisions. Definitive closure may require delayed grafting, local flaps, or free tissue transfer.

Hemostatic Excision Techniques

Historically, burn wound excision was associated with substantial blood loss because free capillary bleeding was used to ensure tissue viability. Several very simple maneuvers, when practiced, minimize blood loss during these operations. Careful planning before excision reduces operating time, which itself can markedly reduce blood loss. Performing extremity excisions after inflation of a pneumatic tourniquet and wrapping the extremity in a hemostatic dressing before tourniquet deflation reduce blood loss. Layered torso excisions and donor skin procurement after dilute epinephrine clysis is very effective in reducing bleeding. Use of coagulating cautery to perform fascial excisions keeps these fields dry. Tissue viability can be determined with the practiced eye looking for bright moist yellow fat, patent small blood vessels, the absence of thrombosis of small vessels, and the absence of extravascular hemoglobin. Maintaining patient euthermia enhances innate coagulation mechanisms and is best done through operating room heating. Minimized blood loss in burn excision is an essential element in successful management of large wounds.

BURN CRITICAL CARE

Critical care is an integral component of all aspects of burn care, but it is a particularly prominent component of the period of wound excision and closure. An imbedded or seamlessly integrated critical care unit is an essential element of a successful burn program. Although many burn patients need additional temperature support and wound care, they can be well managed in trauma or general surgical intensive care units with the proper coordination.

Inhalation Injury

Inhalation injury complicates care of those injured in structural fires; it causes variable degrees of upper airway edema from direct thermal injury, bronchospasm from aerosolized irritants, small airway occlusion from sloughed endobronchial debris and loss of the ciliary clearance mechanism, increased dead space and intrapulmonary shunting from alveolar flooding, decreased lung and chest wall compliance from interstitial and alveolar edema and swelling or burn of the chest wall, and secondary infection of the denuded tracheobronchial tree (tracheobronchitis) or pulmonary parenchyma (pneumonia). The diagnosis of inhalation injury is usually clinical, based on a history of closed space exposure, burns of the face or nasal hairs, and carbonaceous debris in the mouth or sputum. Routine early diagnostic or therapeutic bronchoscopy has no clearly demonstrated value. Patients with inhalation injury usually have 2 to 5 days of relatively normal gas exchange before endobronchial slough with associated infection and respiratory compromise. Use of this window of relatively normal pulmonary function to effect large initial excisions is important.

Carbon monoxide (CO) binds avidly to heme-containing enzymes, most notably hemoglobin and mitochondrial cytochromes, interfering with oxygen delivery and utilization, respectively. Such patients can be treated with 6 hours of normobaric 100% oxygen. If patients have stable conditions and have no contraindications (particularly mucous plugging or bronchospasm), hyperbaric oxygen may diminish a small incidence of long-term neurologic sequelae. However, these treatments are not without risk, and not all studies support the efficacy of hyperbaric oxygen in this regard.

Pneumonia, tracheobronchitis, and respiratory failure occur in approximately 30% of those with inhalation injury, as a result of loss of the ciliary clearance mechanism and sloughed endobronchial debris. Antibiotic therapy is directed by sputum gram stain and cultures and should not be prolonged beyond a 7-day to 10-day therapeutic course. Vigorous pulmonary toilet is an important component of therapy. When gas exchange failure requires mechanical support, patients should be managed with the same low-volume strategy widely practiced in general surgical intensive care units today. Tracheostomy is useful if prolonged ventilation or difficult weaning is anticipated. It is ideal if neck edema has subsided so that the procedure is not technically difficult. Tracheostomy in small children may be associated with a higher incidence of prolonged cannulation and long-term complications and is ideally avoided when possible.

Neurologic Issues

Peripheral neuropathies develop in about 5% of patients with serious burns. These are secondary to direct thermal injury, metabolic derangements, compartment syndromes, or pressure. Some may be avoided with tight control of electrolyte disturbances, prompt decompression of ischemic extremities, and attention to the fitting of splints and intraoperative position.

Multidisciplinary management of treatment-related burn pain and anxiety enhances short-term and long-term outcomes. Opiate and benzodiazepine synergy facilitates good control with modest drug doses. Newer agents, such as dexmedetomidine, can further help control symptoms while minimizing morbidity related to higher opiate and benzodiazepine dosing. Nonpharmacologic interventions and wound membranes are playing an increasing role in control of the inevitable treatment-related burn pain and anxiety.

Postresuscitation Hemodynamic and Electrolyte Issues

After resuscitation, burn patients predictably have hyperdynamic hemodynamics develop, with a high cardiac output and low peripheral resistance. This physiology is exacerbated by wound colonization and sepsis. Intravascular volume is best judged with serial physical examination, intravascular pressures, urine output, serum osmolality, base deficit, and serum sodium concentration.

Cerebral edema and seizures have been reported with rapid development of hyponatremia during burn resuscitation with hypotonic fluids. Overly rapid correction of hyponatremia is associated with demyelinization. Many patients have development of derangements of serum potassium, magnesium, and phosphate. These issues are best avoided through careful control of serum electrolytes. Patients with large open wounds are at particular risk because evaporative free water loss and transeschar electrolyte flux are impossible to predict with accuracy.

Most patients with large burns require protracted central vascular access. Rotation of catheters to diminish the incidence of catheter sepsis is variably practiced. The author is convinced that a weekly rotation of catheters is a reasonable compromise that minimizes both catheter-related sepsis and the mechanical complications. If antiseptic catheters are used, durations out to 2 weeks seem safe.

Nutritional Support

The hypermetabolic response to burns is characterized by fever, increased metabolic rate, increased minute ventilation, increased cardiac output, decreased afterload, increased gluconeogenesis, insulin resistance, and increased skeletal and visceral muscle catabolism. Patients remain hypermetabolic for a variable period after wound closure. Modification of the catabolic component of the response is desirable and may be aided with anabolic steroids or beta-blockade. Most patients do very well if the physiology is supported through accurate nutritional support. Overfeeding is associated with hepatic steatosis, dysfunction, and increased CO_2 production. Underfeeding results in inanition and poor wound healing.

Basal metabolic rate can be calculated with a number of formulas. Resting energy expenditure can be roughly measured with expired gas indirect calorimetry. Most authors advocate provision of 150% of basal energy needs for burn patients managed with prompt wound excision and closure. Protein administration of 2.5 g/kg/d adequately supports the needs of most burn patients. Most patients can be supported enterally, beginning coincident with resuscitation. This author generally begins with nasogastric sump tubes because these tubes facilitate assessment of gastric residuals. These are subsequently changed to a soft enteral feeding tube. Occasional patients with very large wounds or septic complications do not tolerate enteral feedings; supplemental parenteral nutrition is a safe and useful adjunct.

Septic Complications and Multiple Organ Failure

Burn patients have immunosuppression, compromised epithelial barriers, and multiple invasive devices. They are prone to a host of septic complications until wound closure is complete. Infection control measures should be rigorously followed to prevent cross contamination. Multiple organ dysfunction is a manifestation of uncontrolled systemic inflammation, infection, or tissue hypoxia. Successful management requires identification and treatment of any septic foci, including excision of infected eschar, hemodynamic support, and management of failing organ systems.

PHASE THREE MANAGEMENT: DEFINITIVE WOUND CLOSURE

Phase three involves replacement of temporary membranes and completion of closure of physiologically small but functionally important areas, such as the face and hands. At this point, most patients are extubated and have bulk physiologic wound closure and hemodynamically stable conditions.

Skin Substitutes

Most deep burn wounds are best closed as quickly as possible with split-thickness autograft. Currently available skin substitutes are designed to be temporary or permanent. A large number of temporary membranes are designed to provide a vapor and bacterial barrier and enhance pain control as underlying wounds epithelialize. These membranes minimize the need for dressing changes and are particularly useful in the outpatient setting. A very limited number of membranes are designed to become incorporated into the wound as permanent dermal or epidermal elements. For now, these membranes are useful only in a very small minority of patients with massive injuries. When a practical permanent skin replacement becomes available, it will profoundly change the nature of acute and reconstructive burn care.

Face and Head

Burns of the face are physiologically small but aesthetically and functionally critical. Patients with larger burns are ideally approached in a thoughtful manner after bulk wound closure has been achieved and

conditions are stable. Skin of the nose and central face is thick and rich in sweat and sebaceous glands; even deep second-degree burns often heal with quite a nice result when they are managed with good topical wound care. Anatomy of the skin in this area makes a conservative initial approach physiologically sound. No topical or membrane is clearly superior to another for facial burn management. Common practice is to apply petroleum-based ointments containing antibiotics on superficial burns and silver sulphadiazine on deeper wounds. Burns around the eyes can be dressed with topical ophthalmic antibiotic ointments. Those facial wounds that need to be grafted should be resurfaced with thick split-thickness grafts of optimal color match in cosmetic units as long as this does not require the sacrifice of significant areas of healed burn or unburned skin (Figure 3). Excisions are done in a layered fashion. The operations can be bloody, but subeschar dilute epinephrine clysis and elevation of the head of the operating table reduce blood loss. After the grafts have vascularized, massage and pressure therapy should begin.

External ear burns are best managed with avoidance of pressure on the burned auricle and prevention of auricular chondritis with application of topical mafenide acetate, which penetrates the cartilage. Subsequent management is based on depth of injury. Wounds generated by débridement of necrotic skin and cartilage can generally be closed with thin split-thickness grafts with good aesthetic results.

If eyelid burns are present, globe protection from edema is generally good for the first 1 to 2 weeks. An acute tarsorrhaphy is almost never necessary. This can be followed by contraction and globe exposure. When this is relatively mild, no intervention beyond globe lubrication and monitoring is necessary. Should exposure keratitis occur, early lid release should be performed to prevent corneal desiccation, ulceration, and infection (Figure 4).

Hands and Feet

During the first 72 hours, hand perfusion should be optimized with escharotomy and fasciotomy as needed and hemodynamic support. Seriously burned hands should be ranged twice daily and at other times elevated and splinted in a position of function. Deep dermal and full-thickness burns should undergo excision and grafting as soon as practical and splinted; ranging can generally commence a few days later. Burns of the feet are managed similarly. Neutral ankle position is important to maintain in bedridden patients.

FIGURE 3 Facial grafting does not require sacrifice of well-healed wounds or unburned skin to complete aesthetic units.

PHASE FOUR MANAGEMENT: RECONSTRUCTION AND REINTEGRATION

Expectations for the quality of burn recovery are now high. Patients are surviving serious burns more routinely. These facts have quietly increased the need for and complexity of burn rehabilitation and reconstruction. High-quality functional and aesthetic outcomes are most effectively delivered by a coordinated burn aftercare program, rather than isolated physical therapists and surgeons.

Burn Rehabilitation

Attention to this issue should start early during the acute hospitalization. Ranging and antideformity positioning and splinting minimize the otherwise inevitable capsular contraction and shortening of tendon and muscle groups, which complicate later rehabilitation efforts (Table 3). As the patient with serious burns is weaned from the critical care environment, rehabilitation efforts begin to focus on active ranging and strengthening, reduction of edema, and activities of daily living. A good program of passive ranging during critical illness pays great dividends here.

In the outpatient setting, the rehabilitation focus moves toward strengthening, work-hardening, postoperative therapy after reconstructive operations, and scar management. The number of tools available to manage scar maturation has increased in recent years. Pruritus, discomfort, contraction, and thickening are not inevitable. In wounds destined to become hypertrophic, a marked increase in neovessel formation and erythema is seen 2 or 3 months after healing. Optimally, these areas are identified and become the focus of efforts to modulate scar development. Available methods include scar massage, compression garments, topical silicone, steroid injections, serial casting, tunable dye and fractional carbon dioxide lasers, and surgery. No one of these tools is usually successful alone. They must be applied within a multimodality program, best coordinated in a burn aftercare program.

FIGURE 4 If lid contracture leads to exposure keratitis, early lid release should be performed to prevent corneal desiccation, ulceration, and infection.

TABLE 3: Common burn unit contractures and prevention strategies

Common contracture	Splinting and positioning strategy
Neck flexion	Daily ranging and extension splinting and conformers, split mattress
Shoulder adduction	Daily ranging and abduction splinting with axillary splints or troughs
Elbow flexion and extension	Daily ranging and alternating extension and flexion splints
Wrist flexion and extension	Daily ranging and splinting in functional position (20 degrees of extension)
Metacarpophalangeal (MCP) joint extension	Daily ranging and splinting in functional position (MCP joints at 70-90 degrees with interphalangeal joints in extension)
Hip flexion	Daily ranging and extension splints and prone positioning (if tolerated)
Knee flexion	Daily ranging and knee splints and knee immobilizers
Ankle extension	Daily ranging and neutral splints
Metatarsophalangeal joint extension	Daily ranging and splinting in functional position, rocker bottom shoes

Early Burn Reconstruction

A plan of acute burn reconstruction should be made collaboratively with the patient, family, therapists, and surgeon. A list of surgical needs should be balanced with the patient's reintegration plans. Woven into the plan should be ongoing scar management and rehabilitation efforts. Early facial reconstruction primarily involves function. Lip eversion, microstomia, thickened nasolabial bands, canthal webs, and obstruction or distortion of the nares may develop, depending on the severity of the initial burn and efficacy of initial treatment. Hand and upper extremity deformities should also be addressed on presentation if they significantly limit function. Most common are dorsal hand and web spaces. Burn boutonniere deformities are difficult to treat if they become established and should also be addressed early. On occasion, heterotopic ossification develops early, most commonly forming in the soft tissues around the triceps tendon of deeply burned elbows. This may resolve with resolution of systemic inflammation; but when it is severe, it usually requires surgery. Axillary contractures are usually amendable to simple reconstruction and should be addressed if they limit activities of daily living. Lower extremity contractures that limit ambulation and sitting should also be addressed in the early postacute period. The most common issues are dorsal foot, popliteal, and flexion hip contractures. All are generally amenable to simple stellate release and graft reconstruction.

Outpatient Burn Care

Most burn patients can be managed as outpatients. Those who need hospitalization receive major parts of the overall care in the outpatient setting. Ideally, a seamless interface occurs between the inpatient and the outpatient setting. Quality outpatient burn care is neither simple nor easy, and if done poorly, it results in significant pain and morbidity. Key components of a successful program are elaborated in Table 3 and include prudent patient selection, caregiver identification and teaching, simple wound hygiene and topical care, judicious pain management, specific hospitalization and follow-up teaching, and long-term follow-up.

CONCLUSION

A number of other issues, including high-voltage electrical injuries, chemical and tar burns, cold injuries, toxic epidermal necrolysis, and soft tissue infections, are commonly managed in burn programs and are addressed in other chapters. The burn unit offers a critical care and wound management resource useful for many of these patients. Patients with burns or complex wound needs are best managed in an organized program of care that seamlessly spans the continuum from resuscitation through reintegration. An increasing body of data supports the efficacy and cost effectiveness of this concept. Ultimately, it is the happiness and success of our patients that provides the most important endorsement.

Cold Injury, Frostbite, and Hypothermia

Colleen M. Ryan, MD, and Philip H. Chang, MD

OVERVIEW

Localized cold injuries can be classified according to the temperatures that produce them, either freezing or nonfreezing temperatures. Trench foot, immersion hand and foot, and chilblains (pernio) are all produced by exposure to nonfreezing temperatures. Freezing temperatures produce frostbite. Generalized cold injury presents as hypothermia. Hypothermia can be from environmental exposure or can be medically induced for treatment of anoxic conditions.

NONFREEZING COLD INJURIES

Trench Foot, Immersion Foot (Cold)

Prolonged exposure (as little as 13 hours) to nonfreezing cold temperatures (32°F to 60°F) in the presence of moisture can result in trench foot. Cold immersion foot (or hand) is seen after prolonged exposure to cold but not freezing water. Trench foot was a significant public health issue during World War I, when soldiers spent days in the wet mud of the war trenches in ill-fitting shoes. It resulted in tremendous suffering and often required amputation for gangrene. These injuries involve alternating arterial vasospasm and vasodilation, with the affected tissue first cold and numb. After 24 to 48 hours of exposure, hyperemia occurs, accompanied by dysesthesias and severe burning pain. Tissue damage is evidenced by edema, blistering, redness, ecchymosis, and ulceration. Complications include cellulitis and gangrene. Late findings can include tissue cyanosis with increased sensitivity to cold. Pain, paresthesias, and nerve paralysis can be seen after all types of cold injuries.

Prevention consists of keeping feet warm and dry and prevention and management of hyperhidrosis. In World War I, the requirement for soldiers to carry extra pairs of socks and the pairing of soldiers to inspect each other's feet prevented trench foot. Treatment consists of immediate removal of the extremity from the cold wet environment and exposure of the feet (or hands) to warm dry air. The extremity should be elevated to minimize edema and protected from pressure injuries from ill-fitting shoes. Local and occasionally systemic measures to combat infection are indicated. Massage, soaking of the feet, and rapid rewarming are not indicated. Demyelination of nerves, muscle atrophy, fallen arches, and osteoporosis may all present as long-term complications, and a tendency toward marked vasospasm during subsequent exposure to cold develops in some patients.

Chilblains (Pernio)

Repetitive exposure to cold and damp, but not freezing temperatures, can result in chilblains, also known as pernio, perniosis, or blain. These terms are descriptive for the consequences of local cold injury. Acute chilblains is characterized by pruritic red-purple papules, macules, plaques, or nodules on the skin, usually the face, the anterior surface of the tibia, or the dorsum of the hands and feet, and can occur within hours of the exposure. Chronic chilblains can also occur and persist long after the cold exposure. The lesions can blister and ulcerate, making them susceptible to secondary infection. Women, infants, and the elderly are at risk. Medical conditions such as chronic myelomonocytic leukemia, lupus, and anorexia nervosa can be associated with chilblains.

Treatment consists of sheltering the patient, elevating the affected part, and allowing gradual rewarming at room temperature. Rubbing and massage are contraindicated because they can cause further damage and secondary infection. Severe itching can be treated with topical steroids, and open lesions with topical antibiotics. Nifedipine promotes faster healing and prevents recurrence. Lesions usually subside in 2 to 3 weeks, but hypersensitivity can persist. Depigmentation and scarring can result.

FREEZING COLD INJURIES

Frostnip

Frostnip occurs with brief exposures to freezing temperatures when ice crystals, appearing as a frost, form on the surface of the skin, usually on the exposed skin of the face. An intense local vasoconstriction occurs, which results in numbness and pallor. By definition, ice crystals do not form in the tissue nor does tissue loss occur in frostnip. The numbness and pallor resolve quickly with rewarming, and no long-term damage occurs. The appearance of frostnip signals conditions favorable for frostbite, and appropriate action should be undertaken immediately to prevent injury.

Frostbite

Tissue injury from freezing temperatures, frostbite, evolves through four overlapping processes. First, during the prefreeze stage, vasoconstriction and ischemia occur devoid of ice crystallization. Paresthesias and pain are associated with neuronal cooling. Second, ice crystals form intracellularly (during a more rapid-onset freezing injury) or extracellularly (during a slower freeze) during the freeze-thaw stage. This causes alteration in proteins, lipids, and intracellular electrolytes, resulting in intracellular dehydration, membrane disruption, and cell death. The thawing process brings ischemia-reperfusion injury and inflammation. Third, a vascular stasis stage occurs in which blood vessels constrict and dilate. Blood coagulates within the vessels or leaks into the tissues. Fourth and finally, the late ischemic phase results from progressive tissue ischemia, infarction, and inflammation from continued reperfusion injury, microemboli, and thrombus formation. The microcirculation is destroyed, resulting in further cell death.

CLASSIFICATION OF FROSTBITE

Frostbite has been historically classified into degrees of injury depending on the depth of damage, paralleling the classification of burn injuries. Often, several degrees of injury are seen in the same extremity. These classifications are based on the physical examination after rewarming.

First-degree frostbite is a superficial skin injury that is characterized by numbness, edema, and erythema. A white or yellow firm, slightly raised plaque develops in the area of injury. The injury heals spontaneously, usually within 1 to 2 weeks. Superficial desquamation can occur (Figure 1).

Second-degree frostbite injury results in numbness, edema, erythema, and vesiculation. Blisters can contain a clear or milky fluid and are surrounded by erythema and edema (Figure 2). This partial

FIGURE 1 First-degree and second-degree frostbite. Epidermal skin loss and peeling are seen.

FIGURE 3 Third-degree and fourth-degree frostbite with tissue death; note demarcation beyond the interphalangeal joint.

FIGURE 2 **A,** Second-degree frostbite in the fingers. Vesicles and swelling are seen. **B,** Second-degree frostbite in the feet. Vesicles and swelling are seen.

thickness injury heals in 2 to 4 weeks. The healed skin is atrophic and has a reduced number of skin appendages.

Third-degree frostbite creates deeper hemorrhagic blisters, which indicate full-thickness loss. Nonviable skin can present initially as a gray-blue patch, or death of the skin may follow an initial period of reactive hyperemia after 24 to 72 hours. Eventually, a black eschar forms and generally separates slowly in 1 to 3 months (Figure 3).

Fourth-degree frostbite injury results in necrosis that extends completely through the dermis and into muscle and to the level of bone. The black, mummified tissues are present with the initial episode. If infection develops, the mummified tissue softens and adjacent viable margin becomes swollen and macerated.

A simpler classification scheme is used in the field and before rewarming. Superficial injuries have no anticipated tissue loss (corresponding to first-degree and second-degree injuries), and deep injuries have anticipated tissue loss (corresponding to third-degree and fourth-degree injuries).

PREVENTION OF FROSTBITE

Frostbite is typically preventable. The risk of frostbite is related to underlying medical problems, and prevention must address both the environmental and the medical issues that put the person at risk. When tissue heat loss exceeds the ability of local tissue perfusion to maintain the temperature of the tissues above freezing, frostbite occurs. Environmental conditions below –15°C, even with low wind speeds, increase the risk of frostbite.

Key elements to prevent frostbite include maintenance of core temperature and hydration, minimization of effects of drugs and diseases that decrease perfusion, maintenance of covering on skin and scalp, minimization of restrictive clothing, and maintenance of exercise to encourage peripheral vasodilation. Skin should be protected from moisture and wind, and clothing should be layered. The ability to respond appropriately to changing environmental conditions is often compromised by alcohol, drugs, or anoxia.

INITIAL FIELD TREATMENT OF FROSTBITE

Treatment of hypothermia or serious trauma is the first priority if present. No specific studies examine concurrent hypothermia and frostbite. Hypothermia frequently accompanies frostbite and causes peripheral vasoconstriction that impairs blood flow to the extremities. Mild hypothermia may be treated concurrently with the frostbite injury. Moderate and severe hypothermia should be treated effectively *before* treatment of the frostbite injury.

If a body part is frozen in the field, the frozen tissue should be protected from further damage. Jewelry should be removed. The affected area should be rapidly rewarmed in water heated and maintained between 37°C and 39°C (98.6°F and 102.2°F) until the area becomes soft and pliable to the touch (approximately 30 minutes). Rapid rewarming is preferred; however, if it is not available and repeat freezing is not expected, the affected area should be allowed to thaw spontaneously. Refreezing can exacerbate the injury by recycling through the freeze-thaw stage, increasing inflammatory mediators, vasoconstriction, and thrombosis.

Rewarming is painful, and opiates should be administered as needed. The affected area should be air dried, wrapped in dry bulky dressings, and elevated if possible. Topical aloe vera cream or gel can be used if available. Further trauma to the affected part should be avoided. Hydration should be administered as available.

MEDICAL THERAPY

Treatment of trauma and hypothermia remains a priority once the patient reaches the hospital. The patient should be hydrated. Rapid rewarming of the part should be undertaken as previously described unless already done in the field.

Clear or cloudy blisters contain prostaglandins and thromboxanes that may damage underlying tissue. Hemorrhagic blisters are thought to signify deeper tissue damage into the dermal vascular plexus. Common practice is to selectively drain clear blisters (e.g., with needle aspiration) and leave hemorrhagic blisters intact. Although this selective débridement is recommended by many authorities, comparative studies have not been performed and data are insufficient to make absolute recommendations. Some authors argue that unroofing blisters may lead to the desiccation of exposed tissue and that blisters should only be removed if they are tense, likely to be infected, or interfere with the patient's range of motion. Débridement or aspiration of clear, cloudy, or tense blisters may be at the discretion of the treating provider, with consideration of patient circumstances, until better evidence is available.

Wounds should be dressed with dry sterile dressings. Topical aloe vera cream or gel can be applied to the thawed tissue with each dressing change. Extremities should be splinted in positions of function, and pressure areas should be avoided. Ambulation should be initially avoided in lower extremity injuries unless it is limited to the toes. Systemic antibiotics are not indicated unless there are signs of cellulitis or sepsis. Tetanus prophylaxis should be administered according to standard guidelines.

Ibuprofen is recommended at a lower dose of 12 mg/kg divided twice daily (to inhibit harmful prostaglandins but remain safer on the gastrointestinal system) until the frostbite wound is healed or surgical management occurs (typically 4 to 6 weeks).

THROMBOLYTIC, VASODILATOR, AND PROSTACYCLIN THERAPY

The goal of thrombolytic therapy in frostbite injury is to address microvascular thrombosis. Thrombolytic therapy should be reserved for deep frostbite injuries and should be administered in settings with resources for intensive care unit (ICU) care and experienced surgical assessment. For deep frostbite injury with potential significant morbidity, angiography and use of either intravenous (IV) or intraarterial tissue plasminogen activator (t-PA) within 24 hours of thawing may salvage some or all tissue at risk. The potential risks of t-PA include systemic and catheter-site bleeding, compartment syndrome, and failure to salvage tissue. The long-term functional consequences of digit salvage with t-PA have also not been evaluated. Use of t-PA in the field setting is not recommended because detection and treatment of bleeding complications may be impossible. Published protocols include the use of heparin in conjunction with thrombolytic therapy to prevent recurrent local thrombosis, and heparin is recommended in this circumstance as adjunctive therapy. Angiography or pyrophosphate scanning should be used to evaluate the initial injury and monitor progress after t-PA administration as directed by local protocol and resources (angiography scanning for intraarterial, and pyrophosphate scanning for IV).

No evidence supports the use of low molecular-weight heparin or unfractionated heparin as a monotherapy for initial management of frostbite in the field or hospital. Vasodilators, such as prostaglandin E1 (PGE1), the prostacyclin analogue iloprost, nitroglycerin, pentoxifylline, phenoxybenzamine, nifedipine, reserpine, and buflomedil, have been used as primary and adjunctive therapies in the treatment of frostbite injuries. In addition to vasodilation, some of these agents may also prevent platelet aggregation and microvascular occlusion that occur after frostbite. Intraarterial infusion of nitroglycerin during angiography, before t-PA infusion, has been recommended. Pentoxifylline, a methylxanthine-derived phosphodiesterase inhibitor, has yielded some promising results in animal and human frostbite. Controlled-release pentoxifylline, one 400-mg tablet 3 times a day with meals, is continued for 2 to 6 weeks after injury. However, controlled studies of pentoxifylline in the management of frostbite have yet to be performed. Buflomedil is an alpha adrenolytic agent that is used widely in Europe with some preliminary and anecdotal evidence of good results; however, animal models have not replicated these findings. In addition, the medication is not approved by the U.S. Food and Drug Administration. Intraarterial reserpine has been studied in a case–control study and found not to be effective.

Certain vasodilators have the potential to improve outcomes and can be used with minimal risk. However, as discussed previously, the data that show benefit are limited. Iloprost is the only vasodilator with reasonable scientific evidence supporting its use, although it is currently not available in many countries, including the United States.

Other postthaw medical therapies, including hyperbaric oxygen, hydrotherapy, sympathectomy, and IV guanethidine, have insufficient data to support their use.

SURGICAL INTERVENTION

Significant swelling should prompt an evaluation for compartment syndrome. Thawing reperfuses ischemic tissue that, in turn, can result in the development of elevated pressures within a closed soft tissue compartment. Compartment syndrome is clinically manifest by tense, painful distension with reduction in movement and sensation. Urgent attention and consultation are necessary to evaluate compartment pressures. If elevated compartment pressures are present, urgent surgical decompression is indicated for limb salvage. After frostbite occurs, complete demarcation of tissue necrosis may take 1 to 3 months. Angiography, technetium-99 bone scan, and magnetic resonance imaging may be used to assist determination of surgical margins in conjunction with clinical findings. If the patient has signs and symptoms of sepsis attributed to infected frostbitten tissue, amputation should be performed expeditiously. Otherwise, amputation should be delayed until definitive demarcation occurs, a process that may take weeks to months. The affected limb is often insensate. Consequently, an approach that addresses both protective footwear and orthotics to provide optimal function is essential. The authors' experience has shown that early involvement of a multidisciplinary rehabilitation team produces better long-term functional results. Telemedicine or electronic consultation with a surgical frostbite expert to guide local surgeons should be considered when no local expert is available. Because significant morbidity may result from unnecessary or premature surgical intervention, a surgeon with experience evaluating and treating frostbite should assess the need for and the timing of any amputations.

CHRONIC CHANGES OF FROSTBITE

Patients with the chronic sequelae of frostbite may benefit from sympathectomy in that sympathetic overactivity (hyperhidrosis and vasoconstriction) and cold sensitivity are reduced. The symptoms represent diminished circulation and reflect pallor, vasospasm, and pain symptoms. Lubrication of atrophic skin and protection from extreme temperatures are important. The parts affected must be prevented from further cold exposure because they are more susceptible to cold injury. Degenerative joint disease may be seen in severe cases, and stiff painful joints with fibrosis may be a consequence of moderately severe frostbite. Intrinsic muscle atrophy and fibrosis has also been described as a long-term outcome of severe frostbite, and these changes might be attenuated with proper physiotherapy, splinting, and appropriate exercise. In children, even mild frostbite can cause injury to epiphyseal growth centers, resulting in short digits, deviated digits, or osteoarthritis. Parents should be advised that these sequelae are possible despite appropriate therapy of frostbite during the acute phase of injury.

ACCIDENTAL HYPOTHERMIA

Hypothermia is defined as a core body temperature less than 35°C (95°F). Primary hypothermia occurs when heat production in a healthy person is overwhelmed by the stress of excessive cold. Secondary hypothermia can occur in warmer environments when an underlying illness interferes with the body's ability to regulate temperature. Hypothermia is often seen as a result of environmental exposure from military situations, recreational activities, homelessness, or substance abuse. In healthcare settings, hypothermia can occur in surgical patients under anesthesia and lead to coagulopathy. Trauma patients may present with hypothermia, especially in the presence of brain injury. The risk of death from cardiac arrest increases significantly at a body temperature of 28°C.

CLASSIFICATION OF HYPOTHERMIA AND SYMPTOMS

Traditional classification of hypothermia includes mild, moderate, severe, and profound. Mild hypothermia (core temperature, 90°F to 94°F) is symptomatic with shivering, reports of being cold, and mild mental confusion, but the patient maintains a normal blood pressure. In moderate hypothermia (84°F to 89°F), the patient becomes more confused and is often agitated, delirious, or combative. The shivering ceases. Muscle spasticity, dilated pupils, and slow respirations are present. At this stage, atrial fibrillation and other arrhythmias commonly develop. In severe hypothermia (70°F to 84°F), the patient becomes comatose, has a flaccid paralysis, and begins to develop apnea. Eventually, this progresses to ventricular fibrillation and death. Patients with profound hypothermia (<70°F) manifest cessation of cardiac electromechanical activity with electroencephalogram (EEG) silencing and typically present with complete loss of vital signs. The lowest adult accidental hypothermia survival reported was with a core temperature of 56.7°F.

The Swiss staging system of Durrer (stages HT 1 to HT IV) is useful when the temperature cannot measured. This system classifies based on symptoms (stage HT I, conscious and shivering; stage HT II, impaired consciousness and no shivering; HT III, unconscious, not shivering, but vital signs present; and stage IV, no vital signs).

PHYSIOLOGIC EFFECTS OF HYPOTHERMIA

Basal heat production usually ranges between 40 and 60 kcal/m^2/h, which is roughly equivalent to the heat of a 100-watt incandescent light bulb. The body responds physiologically to lowered temperatures by increasing cardiac output with tachycardia. Hypotension then follows with apnea and bradycardia. Peripheral vascular resistance increases with decreased cardiac output, and then, mean arterial pressure increases. Cardiac arrhythmias and sudden death occur in this sequence after ventricular ectopy and atrial fibrillation. Cardiac standstill occurs with a body temperature of less than 21°C (70°F). The blood becomes more viscous with each drop in temperature, and hemoconcentration is seen related to cold diuresis. Cold diuresis is renal water loss from cold-induced vasoconstriction and decreased antidiuretic hormone release. Sludging occurs in the peripheral vessels. Respiratory depression follows. A decrease in the ability to clear bronchial secretions is seen, along with a diminished cough reflex that results in cold bronchorrhea. Metabolic acidosis and pulmonary edema occur with rewarming, and cold diuresis results in hypovolemia.

DIAGNOSIS AND TREATMENT

Diagnosis may be made based on history of cold exposure and measurement of core temperature. Most standard clinical thermometers lack the ability to measure the low range of temperatures seen with severe hypothermia, and peripheral vasoconstriction and low cardiac output can interfere with measurements. Jugular venous bulb and pulmonary artery catheters are the gold standard for continuous temperature monitoring. Proximal esophageal probes can be falsely high from warmed ventilation, bladder temperatures can be influenced by peritoneal lavage, and rectal temperatures can lag during rewarming. Thermister probes in contact with the tympanic membrane accurately measure brain temperature if properly insulated. When accurate measurement is not feasible, management may be based on clinical symptoms correlating with the severity of the hypothermia. Electrocardiographic (ECG) findings of dangerous hypothermia include a prolonged QRS interval and Osborn waves, positive deflections that occur at the junction between the QRS complex and the ST segment.

When the victim is identified in the prehospital setting, removal of wet clothing and replacement with dry clothing should be performed. No massage, friction rubbing, or manipulation should be performed. For HT stage I, active movement should be encouraged if possible. Patients with HT stage I can be triaged to local hospitals if they are unable to be rewarmed in the field, and any patient with mental status changes warrants transport to a hospital. Patients with HT stage II can be rewarmed with minimally invasive techniques, including thermal packs or blankets (electrical, forced hot air, or chemical) and warm IV fluids (38°C to 42°C, or 100°F to 108°F). The volume of crystalloid administered should account for fluids lost from cold diuresis plus intravascular replacement for vasodilation. Standard resuscitation markers (volume status, electrolytes, glucose, pH, and lactate measurements) should be assessed for each individual patient, and fluid infusions adjusted. In patients with hemodynamically unstable conditions, pressors should be used cautiously because of the risk of cardiac arrhythmias and the risks associated with peripheral vasoconstriction if concurrent frostbite has occurred. In patients with mental status changes, cardiac instability, or a temperature of 28°C (82°F), transport to a tertiary center with advanced invasive rewarming capabilities (cardiac bypass, dialysis, or extracorporeal membrane oxygenation [ECMO]) is warranted if possible. If ECMO or cardiopulmonary bypass is not available, such as a situation with other pressing traumatic injuries, thoracic lavage of the left pleural space with two chest tubes is an alternative method of rewarming that should be considered.

Patients who have had cardiopulmonary arrest should undergo resuscitation according to standard protocols because patients survived after rewarming with long periods of CPR. If asystole persists in a patient with hypothermia despite rewarming to 32°C, survival is

unlikely. If the serum potassium level is higher than 12 mmol/L, CPR is likely to be futile.

During transport of the patient with significant hypothermia or during therapeutic interventions such as central lines or radiologic workups, care must be taken not to precipitate cardiac arrhythmias with manipulations, sustain further cooling, or allow the patient to succumb to hypovolemic shock.

INTRAOPERATIVE HYPOTHERMIA

Surgeons should be especially cognizant of the risks of hypothermia in patients in the intraoperative setting. A slight drop in body temperature during surgery is associated with an increased incidence of postoperative respiratory failure, infections, and delays in postanesthesia recovery. Severe hypothermia can result in impaired coagulation and lead to increased blood loss. A few examples of patients at high risk of intraoperative hypothermia include patients with large burns, prolonged abdominal cavity exposure, and large blood losses. The elderly and very young are also at risk. Trauma patients also experience heat loss in the emergency department with extensive radiologic workups, and temperatures should be monitored during this process. Prevention measures include but are not limited to manipulating the room temperature, limiting exposure of the patient with use of a more selective operative field, use of reflective coverings and warming blankets, and warm fluid. Monitoring temperature during the procedure and truncating the procedure when necessary are important steps.

THERAPEUTIC HYPOTHERMIA

Therapeutic hypothermia is used to reduce mortality and neurologic complications after out-of-hospital ventricular fibrillation cardiac arrest (class Ia recommendation) and in-hospital and other rhythm cardiac arrests (class Ib recommendation). Studies are ongoing to assess efficacy in other indications, including spinal cord injury and traumatic brain injury. The American Heart Association recommends the performance of therapeutic hypothermia in a complete ICU setting with intubation, central temperature monitoring, arterial and central lines, cardiac monitoring, and EEG monitoring if available. Standard protocols are implemented rapidly for the induction of hypothermia. Length and depth of hypothermia vary depending on the indication. For mild hypothermia, these protocols might include infusion of 2 L of cold (4°C) normal saline solution and wrapping the body in cooling equipment to reach a temperature of 32°C to 34°C within 4 hours. The mild hypothermia is maintained at this temperature for 12 to 24 hours. Induced paralysis with train of four (TOF) monitoring may be indicated to prevent shivering. Angiograms and cardiac interventions have been safely performed during this period.

Rewarming occurs slowly at less than 0.5°C/h. Potassium, magnesium, glucose, and phosphorus might require attention during the process. Normal side effects of mild therapeutic hypothermia include tachycardia then bradycardia when temperature is less than 35°C, vasoconstriction with increased blood pressure, and increased central venous pressure (CVP) from venoconstriction (but decreased blood pressure from cold diuresis may also be present). Mottling of the skin is seen. Arrhythmias are rare if temperature is maintained at more than 30°C. The mild hypothermia results in a shifting of the oxyhemoglobin curve to the left, decreased metabolic rate, hyperglycemia, and changes in metabolism of some drugs. Contraindications to institution of therapeutic hypothermia include Glasgow coma scale of less than 6, other reasons for coma than sudden cardiac arrest, uncontrolled bleeding or cardiac arrhythmias, hemodynamic instability, multiple organ dysfunction syndrome (MODS) or septic state, comfort care code status before arrest, or prearrest impaired cognition. Indications in prolonged arrest (>60 minutes) or pregnancy are unclear. One of the risks of the cutaneous contact systems used to produce therapeutic hypothermia is cold injury to the skin. Treatment of such injuries is the same as for injuries detailed previously.

ELECTRICAL AND LIGHTNING INJURY

Laurie Anne Loiacono, MD, FCCP and Leigh Ann Price, MD

Electrical injury is one of the most destructive and disfiguring traumatic events a human can sustain. The injury complex is typically a combination of electrical shock, thermal injury, and blunt trauma, involving potentially devastating associated multisystem damage with high morbidity and mortality rates. Overall incidence of these injuries is low compared with other multisystem trauma injuries in the United States. Because of this, most healthcare teams have limited experience with this mechanism of injury, adding to the complexity of developing an effective medical and surgical care plan.

Optimal management of electrical and lightning injury victims necessitates: (1) a basic understanding of electrical injury mechanisms and their associated patterns of disease, (2) timely and appropriate resuscitation, (3) aggressive surgical and critical care medical management, and (4) implementation of coordinated multidisciplinary care for these patients from onset of injury through injury recovery and rehabilitation.

EPIDEMIOLOGY

Electrical burns and lightning injuries result in approximately 6000 injuries per year in the United States. Electrical burn survivors make up approximately 5% of total admissions to major burn centers, and a bimodal distribution exists with respect to age. In the majority of cases, non–lightning-related electrical injuries to children are accidental in nature and occur in the home; similar injuries to adults generally occur in the workplace. About two thirds of all non–lightning-related electrical injuries occur in the workplace; the majority of the rest occur in the home.

Electrical injuries account for 2% to 3% of all burns in children. The majority of electrical injuries in children are associated with transient, low-voltage exposure to household electrical and extension cords and wall outlets. Older children are exposed to life-threatening high-voltage injury through climbing activities. More than 200 household-related electrocutions (i.e., death by electricity) occur annually and are typically associated with consumer product misuse or malfunction.

The majority of construction and utility worker electrical injuries are related to brief, high-voltage exposure. Up to 40% of serious electrical injuries are fatal (56% of these deaths occur in the workplace). Electrical injuries represent 5% to 6% of all work-related traumatic deaths and account for an excess of 500 deaths per year. They are the second leading cause of occupation-related deaths in the United States. Short- and long-term morbidity in many electrical injury survivors is related to significant musculoskeletal and neurologic disability.

ELECTRICITY BASICS

Current

Electricity is defined as the flow of electrons through a conductor. *Electrical current* (I) is the volume of electrons between these points per second. Current exists in two forms: *alternating current* (AC) and *direct current* (DC). High-voltage utility power lines may be either AC (most common, commercial) or DC.

Alternating Current

AC is the directional flow of current in a circuit that is constantly being reversed back and forth in a repetitive pattern and is a more efficient way of generating and distributing electricity than DC current. Standard household current is AC at a rate of 60 Hz (cycles per second) and is supported by 100 to 250 amperes (A). AC can be much more dangerous than DC in certain circumstances because it causes tetanic muscle contractions that prevent a victim from releasing the electrical source. This is known as the "let-go" threshold. The bidirectional flow of AC produces cutaneous burns know as contact points; this is in contrast to the entrance and exit wounds from DC current. The "let-go" current intensity varies from 3 to 9 milliamperes (mA) depending on body size; tetany occurs at 16 to 20 mA. Although AC current is generally lower voltage and produces less direct tissue injury, prolonged contact can alter the cardiac cycle, causing arrhythmias and cardiac arrest. Ventricular fibrillation occurs at 50 to 100 mA and asystole occurs at more than 2 A. Keep in mind that although most providers speak about voltage, it is the amperage that kills.

Direct Current

DC means that the direction of electrical current remains constant. It is found in automobile electrical systems, railway tracks, batteries, and lightning. DC provides a vector directionality to the electrical current exposure, hence the typical "entrance and exit" point cutaneous wounds that identify potential current pathway. High-voltage DC injury often produces smaller, cutaneous "entrance and exit" wounds but much more significant deep tissue injury in addition to the electrical current tissue effects. DC does not produce the same contraction of the muscles that is found with AC. Although low-voltage DC current is not as dangerous as the corresponding AC current, contact with high-voltage DC is more apt to be fatal than contact with AC of the same voltage.

Voltage and Resistance

Voltage

The force that drives current (I) across the potential difference is the voltage (V), which contributes critically to the intensity of the electrical injury. Electrical injuries are classified as either high voltage (>1000 V) or low voltage (<1000 V). Typical voltage delivered to homes in the United States and Canada is 120/240 V, providing 240 V for appliances requiring high power and 120 V for general use. Low-voltage injuries tend to occur indoors and are almost exclusively AC. The AC power system in the United States and Canada operates at 60 Hz, causing the current to reverse polarity 120 times a second. Based on this fact, the terms *entrance* and *exit* should be abandoned and the resultant wounds from AC should be referred to as *contact points*. Voltage in high-tension power lines tends to exceed 100,000 V and is most commonly AC in developed areas. High-voltage mortality and amputation rates typically exceed low-voltage rates twofold to threefold.

Resistance

Resistance (R) is the hindrance to current flow and is measured in ohms. Resistance creates heat according to Joule's law. *Joule heating* is energy transfer that occurs when charged particles meet resistance and lose energy to tissues in the form of heat.

Joule's law:

$$\text{Power (J, Joule)} = I^2 \text{ (Current)} \times R \text{ (Resistance)}$$

Materials that are the best conductors (meaning they facilitate current flow) have the least resistance. With increasing resistance, more energy is expended in the form of heat and results in thermal tissue damage.

Different tissues have innately different resistances (Figure 1), and resistances will vary under different conditions. Overall resistance of a tissue depends on the surface area of contact, the tissues in the current's pathway, pressure applied, duration of exposure, magnitude of current flow, and absence or presence of moisture. For example, dry skin has a much greater resistance (approximately 100,000 ohms) than moist skin (<2500 ohms).

The relationship between the previously defined forces is described by *Ohm's law:*

$$I = V/R$$

where the current (I) is directly proportional to the voltage (V) and inversely proportional to resistance (R).

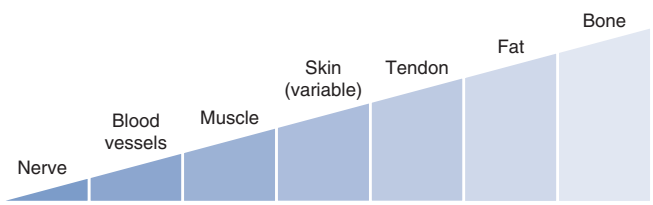

FIGURE 1 The magnitude of average electrical resistance across body tissues.

PHYSICS AND PATHOPHYSIOLOGY OF ELECTRICAL INJURY

All electrical injury involves both direct and indirect mechanisms. The direct damage is caused by the actual effect of electrical current on the body tissues or organs (e.g., brain or heart) or by the conversion of electrical to thermal energy resulting in burns. Indirect injuries are the result of associated tissue injury from severe muscle contraction, blunt trauma from falls or ejection, or associated multiorgan system dysfunction (e.g., renal failure from rhabdomyolysis).

Direct Injury (Electrical and Lightning)

The severity of direct electrical injury is determined by several critical factors:

1. Voltage (high or low)
2. Type of current (alternating or direct)
3. Intensity of current (amperage)
4. Pathway of the current through the body (vertical, horizontal, peripheral)
5. Duration of current exposure
6. Area of contact on the body
7. Resistance of the body tissues involved

Injury to the affected tissue predominantly depends on the intensity and duration of electrical exposure. For example, brief exposure to current will conduct rapidly across low resistance tissues (Ohm's law) with less heat production and structural tissue damage, but more electrophysiologic derailment of end organs (i.e., heart, central nervous system [CNS], and muscle). Hence, lightning causes little, if any, direct tissue injury.

If contact time is brief, nonthermal direct electrical damage to tissue occurs as the current disrupts the microelectrical gradient across cell membranes via electroporation and conformational changes in membrane proteins. Electroporation results in a significant increase in the electrical conductivity and cell plasma membrane permeability leading to tissue edema and possible cell injury. Muscle fibers and nerves are the most susceptible. Electroporation can induce cell necrosis or permanently, partially, or reversibly affect cell membrane function in the absence of joule heating. Damage will be relatively localized to the involved tissue cell membranes and result in functional disruption of those end organs dependent on coordinated electrical activity such as heart, brain, spinal cord, and muscle (Table 1). These cell membrane effects may progress over time and partially explain some of the delayed clinical symptoms observed following electrical injury, such as vascular thrombosis and rupture, cognitive dysfunction, and late-appearing spinal cord deficits (Table 2).

Lightning, a form of DC current, is one of the most dramatic examples of high-voltage direct electrical injury. Its injuries are a small subset of electrical injuries, but DC is responsible for an average of 300 injuries and 100 deaths per year in the United States. Estimated fatality from lightning is 30%, and 70% to 80% of survivors may have permanent disabilities. Lightning discharges can be either positively or negatively charged (Table 3).

Lightning injury can be minor, moderate, or severe.

1. Minor: often awake and alert, may have confusion or amnesia, dysesthesia, hearing or vision changes. Physical findings may be temporary, and complete recovery can occur.
2. Moderate: disorientation, combativeness, unconsciousness, paralysis, skin mottling, hypotension, respiratory failure, secondary cardiac arrest. Physical symptoms may resolve over time. Long-term sequelae, such as cognitive and sleep disorders, weakness, dysesthesias and peripheral neuropathy, can develop.
3. Severe: Serious injury or death occurs in 30% of victims. Injuries include blunt trauma, contusion from the shock wave, cardiac dysrhythmias, cardiac arrest (primary or secondary), and CNS dysfunction. Asystole may be transient and spontaneous rhythm may recover as a result of cardiac automaticity. Hypoxia related to central apnea may lead to secondary cardiac arrest. Long-term sequelae such as cognitive and sleep

TABLE 1: Examples of acute, direct electrical organ tissue dysfunction

Tissue	Acute effect
Heart	Asystole, arrhythmia, cardiac tissue necrosis (myocardium, nodal tissue, conduction pathways, coronary arteries)
CNS	Brain stem dysfunction: central apnea, loss of consciousness, seizure, confusion, amnesia, cranial nerve deficits, paralysis, spinal cord transection, visual and hearing disturbances
Muscle	Tetany (rhabdomyolysis, lactic acidosis, bone stress fracture, "locking-on" phenomenon)

CNS, Central nervous system.

TABLE 2: Examples of late electrical injury organ tissue dysfunction

Tissue	Late effect
Heart	Patchy cardiac tissue necrosis (myocardium, nodal tissue, conduction pathways, coronary arteries); late arrhythmias are rare
CNS	Cognitive deficits, spinal cord and peripheral nerve dysfunction, cataracts
Muscle	Weakness, arthropathy, nonspecific myopathy/fibrosis, limitation of joint function
Vascular	Venous thrombosis, arterial rupture

CNS, Central nervous system.

TABLE 3: Different patterns of lightning strikes

Type	Pattern
Direct strike	Lightning directly strikes victim
Splash strike	Lightning hits another object and "splashes" onto the victim
Side flash	Individual is inside a building and exposure to current occurs through a conductive source within the structure (e.g., metal object or landline telephone)
Step voltage	Lightning strikes the ground and the current is conducted along the ground to an adjacent victim

disorders, weakness, dysesthesias, and peripheral neuropathy can develop without direct evidence of initial direct anatomic brain injury.

The two most common causes of death are (1) cardiopulmonary arrest due to an interruption of the cardiac cycle by the direct current, resulting in asystole; and (2) apnea from the direct current's interference with the brain's respiratory center, which, if left untreated, will result in hypoxia, arrhythmia, and secondary cardiac arrest. There is an estimated morbidity rate of 5 to 10 times higher than the rate of casualties of non–lightning-related electrical injury (Table 4). A pathognomonic fernlike pattern called keraunographic markings or Lichtenberg figure (Figure 2) may appear on the skin of victims of lightning strike. This is not a burn and often disappears within 24 hours.

Direct Injury (Thermal)

When contact time is prolonged, heat damage will dominate as the whole cell in the pathway is compromised. Thermal burn injury caused by electricity may be classified into three categories:

- Joule heat: This is the direct effect of electrical current on tissue resistance causing heating of tissue, resulting in deep and superficial burns. The extent of specific tissue injury depends on the current path, Joule's law, and the duration of exposure.

TABLE 4: Comparison between lightning, high-voltage, and low-voltage electrical injuries

	Lightning	High-voltage	Low-voltage
Voltage (V)	$>30 \times 10^6$	>1000	<1000
Current (A)	>200,000	Variable	240
Duration	Instantaneous	Brief	Prolonged
Type of current	DC	DC or AC	Mostly AC
Cardiac effect	Arrest: asystole	Arrest: ventricular fibrillation	Arrest: ventricular fibrillation
Respiratory effect	Respiratory arrest: direct CNS injury	Respiratory arrest: indirect trauma or tetanic contractions of respiratory muscles	Respiratory arrest: tetanic contractions of respiratory muscles
Muscle effect	Single	Contraction: DC: single AC: tetanic	Contraction: tetanic
CNS effect	Early and delayed brain injury, coma, seizures, blindness, deafness, aphasia, cerebral vein thrombosis, late spinal cord deficits, cataracts	Early and delayed brain injury, coma, seizures, blindness, deafness, aphasia, cerebral vein thrombosis, late spinal cord deficits, cataracts	Paresthesias, transient neuropathy
Burns	Rare: superficial ("flashover" diverts current around the body)	Common: superficial (less) and deep (most)	Usually superficial, can be full-thickness
Rhabdomyolysis	Uncommon	Very common	Common
Blunt injury	Blast effect, shock wave	Muscle contraction, fall	Fall (uncommon)
Mortality rate (early)	Very high (about 30%)	Moderate (about 5%-15%)	Low

AC, Alternating current; *CNS,* central nervous system; *DC,* direct current.

- Arc: Direct thermal injury from arcing is caused by high-voltage current passing through the air. These injuries are most commonly seen in electricians working with metal objects close to an electrical source. These injuries occur without actual current flowing *through* tissue. Electricity arcs at a temperature up to 4000° C to 5000° C generating a "flash" type injury.
- Flame: Thermal burns result from ignited clothes or surroundings and are managed as conventional flame burns.

Most direct injuries are a combination of both electrical current conduction and heat transfer to tissues (Figure 3). Both mechanisms should be expected and fully explored in the course of the electrically injured patient's evaluation.

Importance of Current Pathways

Identification of "contact points" often helps establish the path current has taken. A path parallel or "vertical" to the axis of the body (craniocaudal) is most dangerous because it may affect all the vital organs. A "horizontal path" for example, from hand to hand, may spare the brain but may still be fatal from its effect on the heart and respiratory muscles. A path with contact points confined to a single extremity may cause extensive local damage but not be lethal (Figure 4).

Immediate cardiac arrest and life-threatening arrhythmias may occur with the conduction of current across the heart. AC current tends to cause ventricular fibrillation, whereas DC current tends to cause asystole. Actual injury to the heart or the metabolic effects from injury elsewhere in the body (e.g., hyperkalemia and rhabdomyolysis) may result in delayed cardiac arrhythmias and acute renal failure. Paralysis of the muscles of respiration can result in apnea. Effects on the spinal cord and brain can lead to immediate death or long-term neurologic abnormalities.

Indirect Injury

Additional tissue and organ injury not directly caused by, but clearly related to, the electrical insult is a significant contribution to morbidity and mortality of these patients. Many electrically injured patients fall from a height or are thrown or ejected following a blast or arc. These patients should receive a full multitrauma assessment on initial evaluation, including full spine and airway stabilization.

Respiratory failure can result from direct, blunt, or electrical lung injury; smoke or chemical inhalation; pulmonary edema; or acute lung injury. Many victims who develop muscle injury from tetany, direct electrical injury, or blunt trauma develop early acute kidney injury secondary to rhabdomyolysis or shock. CNS abnormalities can be transient, permanent, or delayed based on gross and histologic anatomic structure injury.

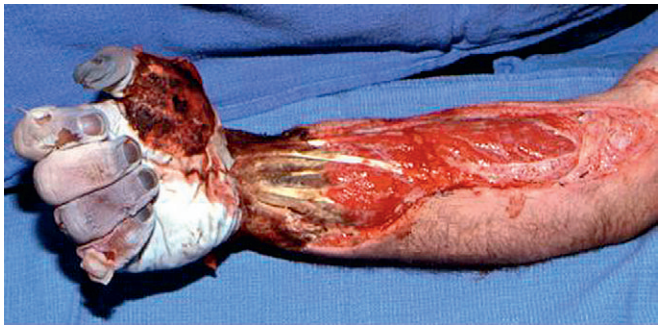

FIGURE 3 High-voltage electrical injury.

MANAGEMENT

The development of guidelines and outcome-based benchmarks requires established standards of practice; however, no specific guidelines exist at this time for electrical injuries. Due to the traumatic, multisystem nature of electrical injury (including potential associated blunt or penetrating trauma injuries), these patients should be managed according to both trauma and burn reconstruction guidelines for care and include the following.

1. Establish safe access to the electrically injured patient.
2. Rapidly assess the patient's airway, breathing, circulation, and disability (rapid neurologic assessment) and provide in-line immobilization of the entire spine (primary survey).
3. Treat life-threatening findings immediately. Control threatened airway and/or ventilation, decompress a tension pneumothorax or pericardial tamponade, control external hemorrhage, expose patient, and manage potential core-temperature heat loss (hypothermia).
4. Establish intravenous (IV; or interosseous, if in the field) access and continuous vital signs (including temperature), neurologic exam, pulse oximetry, respiratory function, electrocardiogram (ECG), and urine output monitoring (urinary catheter); central venous pressure.

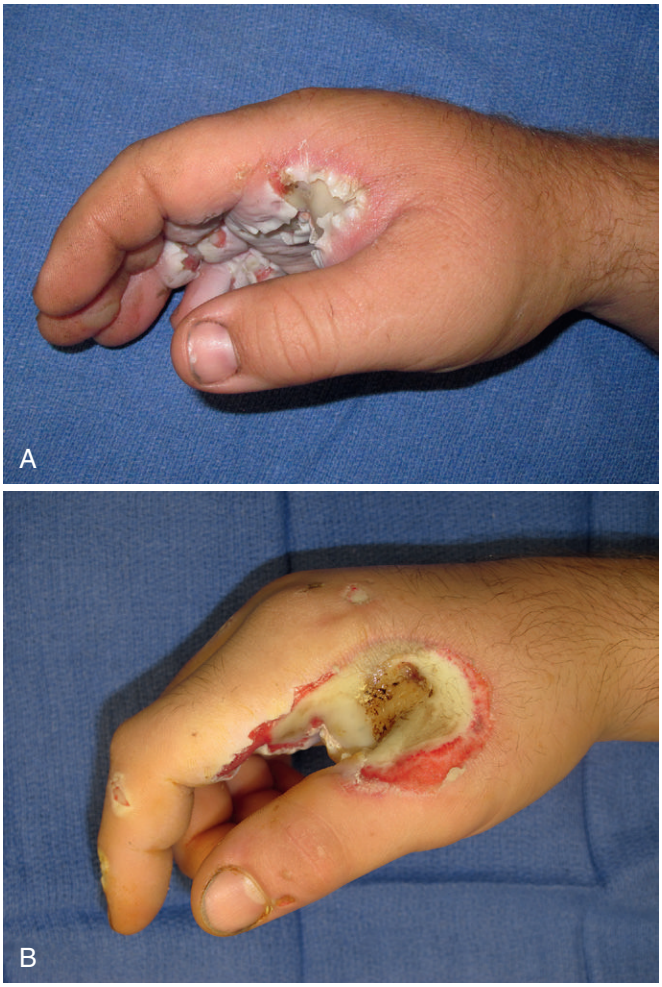

FIGURE 4 **A,** A farmer working in the field came in direct contact with a low hanging wire (7000 V). **B,** An electrician grabbed a cable (270 V, alternating current) overhead to avoid falling into a ditch.

5. Expose and cover thermal burn sites with clean, dry sheets or towels; then use appropriate topical dressing when at the hospital. Keep in mind the need for escharotomy or fasciotomy.
6. Initiate fluid resuscitation with warmed, isotonic crystalloid IV fluids (Parkland formula suggests Ringer's lactate for the burned patient) to a target urinary output (UO) of 0.5 mL/kg/hr if the patient is at low risk for rhabdomyolysis (>1.0 mL/kg/hr if at high risk for rhabdomyolysis).
7. Closely monitor physiologic response to initiated therapies, if deterioration occurs.
8. Initiate aggressive surgical and critical care medical management.
9. Implement coordinated multidisciplinary care for these patients from onset of injury through injury recovery and rehabilitation.

Prehospital Management and Special Considerations

Access to the Victim and Scene Safety

The scene of an electrical injury is unique compared to other trauma sites. The rescuer can easily become another victim.

Be aware of the following:

- Victim's existing contact with the current source. "DO NOT TOUCH," specialized nonconductive equipment is necessary to safely recover these victims.
- Active live electrical sources and confirm disconnection.
- Environment conductors to avoid (i.e., puddles of liquid, exposed metals and wires).

Victims of lightning injury may be treated immediately.

Critical Care Management

Early, goal-directed resuscitation and aggressive surgical management are cornerstones for optimal patient outcome. Targeted multiorgan system assessment and support are critical in the first hour following injury (Table 5).

Optimal surgical treatment will vary with the severity and etiology of electrical injury and the specific location of the injury site.

Multidisciplinary, System-Based Critical Care Management of the Electrical Injury Patient

Neurologic

Serial neurologic assessments, spine clearance (within 24 hours) for mobilization, pain management, early mobilization, aggressive physical and occupational therapy, cognitive/vision/hearing assessments, and rehabilitation plan.

Complications

Neurologic complications are common sequelae of electrical injuries and can affect both the central and the peripheral nervous system. Early manifestations include varying levels of unconsciousness (including coma), sensory dysfunction, memory disturbances, autonomic dysfunction, respiratory paralysis, and motor dysfunction. Deficits may be "patchy" with sensory deficits not coinciding with the motor findings. Clinical manifestations of neurologic injury may be delayed for days or even months and are not consistent with the size or location of the injury.

Cardiac

Continuous ECG monitoring for the first 24 hours. If no acute cardiac issues or arrhythmia occur, continuous monitoring can be stopped, Avoid hypotension and tachycardia. Check an echocardiogram if hypotension occurs or if acute myocardial injury is suggested based on cardiac enzyme levels.

Complications

Ventricular fibrillation is the most common fatal arrhythmia, occurring in up to 60% of patients in whom the current has taken a horizontal pathway. However, virtually any cardiac dysrhythmia can be precipitated by any electrical injury. The overall estimate of arrhythmia following electrical injury is up to 15%; most of these are benign and occur within the first few hours of hospital admission. Recent studies have shown that new onset atrial fibrillation is the most common dysrhythmia seen in survivors; it can be managed easily with medical treatment. ECG should be performed in all patients who sustain electrical injuries, whether low or high voltage. Duration of cardiac monitoring needed is generally between 24 and 48 hours, but it should continue if any underlying cardiac injury has not been completely ruled out.

Direct myocardial injury is uncommon, but it can present as a traumatic cardiac contusion. Myocardial infarction is rare.

Respiratory

Extubated patients: incentive spirometry, cough and deep breathing, early mobilization, oxygen (O_2) as needed to maintain arterial oxygen saturation level (SaO_2) above 92%.

Intubated patients: use a "lung protective" ventilator strategy, develop a weaning plan, consider the value of early tracheostomy, maintain head of bed at 30 degrees or higher, provide venous thromboembolism and ulcer prophylaxes, perform a daily sedation holiday.

Gastrointestinal

Early enteral feedings, twice-weekly acute phase protein assessment, daily bowel assessment and regimen.

Renal

Goal UO is O.5 mL/kg/hr (adjusted goal for rhabdomyolysis: UO > 1.0 mL/kg/hr).

Complications

Massive tissue necrosis associated with electrical injury can result in rhabdomyolysis and subsequent pigment-induced acute kidney injury from myoglobinuria. Mechanisms of myoglobin-induced acute renal failure include (1) renal constriction and ischemia from hypovolemia due to extravascular extravasation of fluid, (2) direct cytotoxic action of myoglobin on the proximal convoluted tubules due to tissue and muscle breakdown, and (3) myoglobin cast formation in the distal convoluted tubules.

It is essential to manage rhabdomyolysis with aggressive fluid resuscitation and increased urine output goals targeting UO at 1-2 mL/kg/hr. Osmotic diuresis with mannitol and alkalinization of urine has been proposed as adjunct strategies but are not currently supported by level I evidence.

Infectious Disease

Tetanus administration should be considered where appropriate. Systemic inflammatory response syndrome (SIRS) criteria should be monitored for sepsis for needed workup.

TABLE 5: Critical care management of patients with electrical injury (first hour)

Concern	Action	Goal
Airway (PRIORITY) Assess for • Airway patency • Altered mental status • Facial injuries • Airway obstruction • Aspiration	1. Provide manual airway support as needed (e.g., clear airway, bag-valve-mask [BVM]). 2. Intubate EARLY. Edema and multisystem organ dysfunction will progress quickly (surgical airway may be necessary). 3. Clinically confirm placement with exam and end-tidal CO_2 monitor; secure endotracheal tube in place. 4. Immobilize cervical/thoracic/lumbar/sacral spine immediately. 5. Initiate pulse oximetry.	• Secure airway
Breathing Assess for • Spontaneous effort • Pneumothorax • Hemothorax • Chest wall compromise (musculoskeletal or burn) • Smoke inhalation (if associated material ignition)	1. Treat pneumothorax immediately. 2. Initiate mechanical ventilation if needed. 3. Correct hypoxia with supplemental O_2 (start with 100% FiO_2). 4. Check ABGs. 5. CXR (confirm tube placement, identify injury). 6. Perform early escharotomy if needed.	• AVOID hypoxia. • SaO_2 >92% • PCO_2 35-45 mm Hg • Plateau pressure <30 mm Hg
Circulation Assess for • Cardiac tamponade • Distended neck veins • Shock • Cardiac arrhythmia • Cardiac dysfunction • Hemorrhage • Peripheral pulses	1. Treat cardiac tamponade immediately. 2. Establish adequate IV access. Edema and multisystem organ dysfunction will progress quickly. 3. Infuse isotonic IV fluids toward target goals. 4. Ensure continuous ECG and blood pressure monitoring. 5. Place urinary catheter. 6. Perform FAST exam and/or abdominal and pelvic CT scan. 7. Consider central venous access for resuscitation monitoring. 8. Perform early fasciotomy. 9. Complete blood count, type & cross, cardiac enzymes, lactate.	• MAP ≥ 60 mm Hg • UO ≥ 0.5 mL/kg/hr (if suspect rhabdomyolysis: UO >1.0 mL/kg/hr) • SvO_2 60-65 mm Hg • Lactic acid <2.0 • Closely monitor for development of pulmonary edema.
Disability Assess for • Acute brain injury • Acute spine injury • Musculoskeletal deformity	1. Assess consciousness, pupillary size and response, lateralizing signs, and level of spinal cord injury. 2. Assess GCS score. 3. Assess spine pain and gross function. 4. Do a full neurologic exam when possible. 5. Perform head and spine CT scan as needed.	
Exposure Assess for • Core temperature • Cutaneous injury	1. Warm IV fluids. 2. Warm room. 3. Provide insulating covers (if needed). 4. Assess the burn wound area. 5. Cover burn sites with dry, clean linen (pending definitive burn care). 6. Splint unstable fracture sites to avoid neurovascular compromise. 7. Make serial, focused neurovascular checks.	AVOID hypothermia. Core temp 98.6°F (37°C)
Comprehensive Evaluation Assess for • Efficacy of current treatment • Additional or missed injuries; identify and treat them.	1. Perform Secondary and Tertiary Surveys per ACS Trauma (ATLS) Protocol. 2. Order pertinent additional lab and radiologic studies. 3. Consider transfer to burn center.	

ABGs, Arterial blood gases; *ACS,* American College of Surgeons; *ATLS*, Advanced trauma life support; *CT,* computed tomographic; *CXR,* chest x-ray; *ECG,* electrocardiogram; *FAST,* focused assessment with sonography for trauma; *FiO_2,* fractional inspired oxygen; *GCS,* Glasgow Coma Scale; *IV,* intravenous, *MAP,* mean arterial pressure; *SvO_2,* mixed venous saturation; *UO,* urinary output.

Musculoskeletal

Radiologic studies of suspicious areas are necessary to evaluate for fractures, frequent neurovascular checks to affected extremities are necessary to monitor for evolving tissue injury, early fasciotomy is required for compartment syndrome, early carpal tunnel release may be necessary for clinical signs of tissue entrapment, and performance of early aggressive débridement of nonviable tissue should be done, including splinting the affected extremity in its position of function.

Musculoskeletal Complications

Bone has the highest resistance of any body tissue, thus generating the greatest amount of heat when exposed to an electrical current. This then causes the greatest amount of thermal damage to tissue adjacent to long bone structures and manifests as periosteal burns and possible osteonecrosis. Tetanic muscular contractions induced by AC may result in fractures or dislocation of bone or joint.

In addition, traumatic injuries resulting in fractures from blast injuries, falls, or repetitive forceful muscle contractions have also been reported. Patients with significant electrical injuries or altered mental status should have imaging studies of their cervical spine to rule out any evolving pathology.

Unfortunately, escharotomy is not of much use in patients with electrical burn because of the depth of the injury. Fasciotomies and/or carpal tunnel releases should be performed in the operating room immediately when circulation is presumed to be impaired. Initial fasciotomy should be performed in the areas of contact and conduction; for instance, the carpal tunnel may be released if the injury occurs in the wrist. The injury may be confined to the digits, the hand, or both, but if the patient has a considerable amount of pain, it may be advisable to complete a carpal tunnel release as the canal may become narrow as a result of the recent trauma and deep tissue injury, which may cause swelling leading to early signs of compression. Fasciotomy plays a major role in the early management of electrical burns and can dramatically improve the salvage of tissue, including the limb. Splinting extremities in positions of function must be accomplished for preservation of joint use in the extremities.

Skin Complications

By far, the most common manifestations of electrical injuries can be attributed to the thermal damage caused to exposed skin. Although surgeons often refer to entrance (more tissue damage) and exit wounds, with AC there is no such thing as the current entering or leaving. Instead, injuries are labeled as contact points.

Superficial, partial-thickness, and full-thickness burns can occur from any electrical injury. Estimates have shown that exposure to only 20 to 35 mA per mm^2 of skin surface for 20 seconds raises the skin temperature to 50° C, causing denaturing of protein, which leads to blistering and swelling. A crucial point to remember is that the degree of external injury cannot be used to determine the extent of the internal damage, regardless of voltage. Minor superficial burns may coexist with massive muscle coagulation and necrosis.

Of note, the incidence of superficial surface burns is high in victims of lightning injury, but deep burns are uncommon.

Surgical Management

Low-Voltage Injury Management

Low-voltage injuries (<1000 V) (see Figure 4, *B*; also see Figure 4, *A* although considered a high-voltage injury) are less devastating but can remain just as debilitating. These injuries often require close monitoring for the first few hours of admission in order to rule out evolving vascular sequelae to the limb or potential complications of myoglobin clearance. The first elective operative procedure is sharp excision of the eschar, often completed using a tourniquet, followed by initial placement of meshed allograft. The allograft is placed during the first excision even if the wound bed appears healthy and completely viable; this allows metabolic changes to alter the tissue beneath. In general, after the second débridement, sheet (nonmeshed) autograft is then applied to those wounds on the face, neck, and hands; otherwise, meshed autograft can be used at the surgeon's discretion. Again, splinting the extremity in its position of function must be accomplished for preservation of joint(s) use in the extremity. Early intervention by a rehabilitation therapist (giving occupational therapy and physical therapy) will optimize patient outcome and advance function with better range of motion and strengthening. It is considered good practice to educate patients that in the distant future they may require additional surgical therapy for burn contracture release, which may include placement of a full-thickness skin graft.

High-Voltage Injury Management

Most electrical injuries cause damage to limb tissue by generation of heat causing thermal insult and by endothelial damage with progressive tissue necrosis. These injuries are often associated with limb loss via amputation at various levels and carry a high rate of morbidity. Limb salvage and appropriate, aggressive initial resuscitation are challenging from the moment these injuries are first encountered. The American Burn Association referral criteria recommend that patients with high-voltage electrical trauma to the upper extremity be referred to specialized burn centers experienced with these injuries.

Most high-voltage (>1000 V) injuries are associated with deep tissue injury that is often underappreciated and more extensive than initially apparent. The initial management of the limb involves immediate (first 6 to 8 hours after injury has occurred) surgical exploration and decompressive fasciotomies. Fasciotomy plays a major role in the early management of electrical burns and can dramatically improve the salvage of tissue, including the limb. Escharotomy alone (incision is made into the subcutaneous fat just beyond the eschar) is of limited benefit. Although escharotomies may often be performed at the bedside, fasciotomies and carpal tunnel release should be performed in the operating room.

Indications for surgical decompression include progressive neurologic dysfunction, vascular compromise, increased compartment pressure, and systemic clinical deterioration from suspected ongoing myonecrosis. Decompression includes forearm fasciotomy and assessment of muscle compartment integrity. The decision to include a carpal tunnel release should be made on a case-by-case basis. Initial fasciotomy should be performed in the areas of contact and conduction; for instance, the carpal tunnel may be released if the injury occurs in the wrist. However, if the injury is confined to the digits, the hand, or both, and if the patient has a considerable amount of pain, it may be advisable to complete a carpal tunnel release as the canal can become narrow as the result of the recent trauma and deep tissue injury and there may be resultant swelling leading to early signs of compression. Delayed exploration and decompression in the compromised extremity may result in increased amputation rates along with increased organ failure and mortality. To date, no definitive data exist to illustrate that immediate surgical decompression reduces the need for amputation in any series.

As in Figure 3, lack of opportunity for limb salvage may be obvious early, regardless of the number of surgical débridements, because of the extent of devitalized tissue noted on presentation. However, one important consideration regarding amputation is the length of tissue able to be retained and the remaining length required to fit a prosthesis. Do not confuse nonviable tissue with minimally bleeding tissue. As a general surgical principle, surgeons are not

trained to "leave behind" nonviable tissue as there is risk for infection, but there is evidence that supports keeping some (minimally bleeding) tissue in question with multiple serial débridements and a watchful eye. Always start with débridement of devitalized tissue and continue every other day until sustainably viable tissue is apparent and the source is controlled. Leaving tendon intact that lacks its peritenon may be of use in long-term limb salvage, as there may be regeneration along the intact, viable tissue. Serial débridements can then be performed and continued in preparation for definitive reconstruction or formal amputation. Splinting the extremity in position of function must be accomplished for preservation of joint use in the extremity, and this should be commenced even prior to the first surgery.

Significant advances in extremity reconstruction have been made through the development of high-quality, functional prostheses and new advances in tissue engineering such as vascularized composite allotransplantation (VCA). VCA is an option held in reserve after all other attempts have been exhausted and the patient has survived the initial injury, as the immunosuppression necessary for graft survival can harm the patient in the acute phase prior to chimerism.

In addition to basic general surgical principles—such as débridement of nonviable tissue, protection of tissue perfusion, nutritional optimization, and control of infection—reconstructive surgery follows basic principles of the reconstructive ladder: healing by secondary intention, primary closure, delayed primary closure, grafts (split-thickness, full-thickness), tissue expansion, flaps (random, axial, and free). This organizational ladder provides a systematic approach to wound closure from the emphasis of simple to complex techniques based on local wound requirements and complexity.

In burn surgery, rarely are the first few rungs of the ladder helpful due to the nature of the injury; surgeons often jump to the rung of grafting secondary to tissue loss. There must be a healthy, vascularized wound bed for a split-thickness graft to take (i.e., if the peritenon or periosteum is lacking, the graft will not take). Allograft versus autograft is a very important tissue choice and ultimately the decision of the surgeon (keep in mind that if the allograft does not adhere, neither will the autograft). Use of allografting preserves the patient's tissue until the wound bed is ready and allows the surgeon to return to the operating room for re-débridement of areas where microscopic changes at the cellular level are noted.

Full-thickness skin grafting is often susceptible to infection if nonviable tissue is left behind as a result of the lack of adequate vascular blood supply. Rarely is tissue expansion considered in patients with acute burn injuries. Random and axial flaps are used when appropriate and are often the preferred method of reconstruction, especially in the acutely injured. However, the operating surgeon must keep in mind that during an electrical injury, significant vessel damage may occur to the media or endothelium of the vessel in which the flap is based.

Other vascular abnormalities, such as vascular occlusions, arteritis and aneurysm formation, thrombosis and segmental narrowing of major extremity vessels, and a marked decrease in the density of small nutrient vessels, have been described after electrical injuries. As a rule of thumb, the ideal tissue to be used is outside of the zone of injury; this principle should also be respected and strongly adhered to during free tissue transfer. Although free flap reconstruction is rarely indicated in patients with acute burn injuries, as the versatility and variability of the free flaps have evolved, so has their applicability to tissue reconstruction. Timing of the reconstructive procedure in relation to the injury, the age of patient, existing medical comorbidities, the length of the operative procedure, and extent of the zone of injury all have a significant impact on the success rate of a free flap reconstruction. The importance of these issues should not be minimized, as free flap coverage may be necessary for coverage of exposed joint, bone, vessels, and tendons. The failure rate of free tissue transplantation post injury is well documented as ranging from postoperative day 5 up to 6 weeks. Therefore, it is critical to optimize the burn patient's treatment from its onset, as the outcomes of these types of injuries will be life-altering.

Commissure Injuries

The American College of Surgeons has recommended that all facial burns be triaged to an American Burn Association burn center. Commissure burns typically occur in the young patient and commonly result from biting or teething on a household appliance cord. Although considered a relatively low-voltage (120 to 240 V) injury, this soft tissue injury can be devastating and lead to significant tissue loss (Figure 5). The burn is a result of the saliva permitting the local conduction and arcing of electricity. The electrical energy is generally concentrated to the oral commissure and the anterior tongue. As with any trauma, the initial management, according to the Advanced Trauma Life Support guidelines, involves a thorough assessment from head to toe. Rarely do these isolated injuries require intubation.

The contact burn wound, often a grayish-white eschar, should be cleaned gently and dressed with an ointment of choice. On examination of the vestibule of mouth, digital palpation may reveal a "woody," indurated buccal mucosa as far posterior as the tonsillar pillars. Early surgical intervention can lead to loss of potentially salvageable tissue that may be necessary for the reconstructive surgery and thus should be avoided. The goal is to maintain a clean, moist environment that allows the tissue to heal. The child should be encouraged to continue to eat and drink. Involvement of a speech pathologist can be of significant help from the onset. The use of a custom-made splint can help reduce scar formation and should be initiated between 10 and 14 days after the injury has occurred. The eschar will continue to demarcate and slough within 7 to 21 days. Based on the proximity of the labial artery to the oral commissure, vessel rupture can be expected to occur in approximately 10% of the patients. Parents and caregivers should be educated that should labial artery rupture bleeding occur, compression of the site between the index finger and thumb should be performed to minimize the hemorrhage, and they should immediately return to the hospital. Seldom do these need surgical intervention for ligation.

The continued healing from the burn can result in tissue scarring and contracture. Contracture can interfere with normal vocalization, facial expression, eating, oral hygiene (including dental care), not to mention the psychologic sequelae of the trauma. Long-term burns to the mouth can be associated with microstomia. Contracture of the angle of the mouth is generally treated approximately 1 year after the burn injury has occurred, as it takes at least 1 year for the burn to

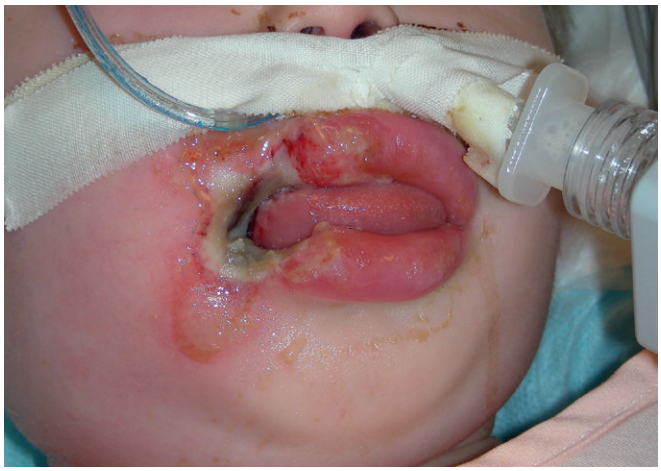

FIGURE 5 Oral commissure burn due to contact with a household electrical wire. Associated complication: labial artery rupture may occur 7 days post burn.

become stable because of the sphincteral action of the orbicularis oris muscle. Late effects of burn reconstructive surgery may include Z-plasty, tongue advancement flap, or commissuroplasty. Of note, the tongue advancement flap, often the only choice based on initial injury, may give a less aesthetically pleasing appearance, as the tongue papilla are transferred to the external orifice.

Late Complications

A multitude of late complications from electrical injuries include cataracts, increased cholelithiasis causing cholecystitis, delayed hemorrhage from blood vessel rupture, skeletal complications of fibrosis, and limitation of joint function.

Although there have been significant advances in both burn and the critical care management of these very specialized patients, prevention and safety remain the best ways to avoid or minimize the occurrence and severity of electrical injury. With the exception of lightning, electrical injuries are almost always preventable.

Preoperative and Postoperative Care

Fluids and Electrolytes

Seth Goldstein, MD, Bellal Joseph, MD, and Albert Chi, MD

INTRODUCTION

Surgical diseases affect the body's equilibrium of water and electrolytes. Surgeons must understand changes in fluid and electrolyte balance caused by different disease processes at the cellular level. This chapter discusses the normal anatomic distribution of fluid and electrolytes, resuscitation fluids, and corrective therapies for correction of fluid and electrolyte abnormalities.

FLUID COMPARTMENTS AND OSMOLALITY

Approximately 50% to 60% of an individual's total body weight is made up of water, referred to as total body water (TBW). Because the water content of muscle exceeds that of fat, TBW as a percentage of body weight is lower in obese individuals. Males, on average, have greater muscle mass than females. TBW is approximately 60% of total body weight in males and 50% to 55% of total body weight in females.

Body fluid in a healthy subject is generally contained in one of multiple compartments as shown in Figure 1. Two thirds of the body's TBW is intracellular, and one third is extracellular, which is further divided into interstitial and intravascular or plasma compartments. Three fourths of the extravascular fluid is found within the interstitium and one fourth in the plasma. Thus, a 70-kg man is predicted to have a TBW of 42 L (60% TBW). The intracellular TBW volume is 28 L, and 14 L are extracellular, of which 4 L is the estimated intravascular plasma volume.

Osmotic equilibration occurs when water moves across membranes from areas of lower to areas of higher osmolality. The membranes that separate the intracellular and extracellular compartments are freely permeable to water, resulting in equal osmolality of intracellular, interstitial, and intravascular spaces. In contrast, there are different permeabilities for various solutes, and those that cannot traverse a given membrane have the capacity to exert an osmotic force that directs water movement across that membrane; such solutes are known as effective osmoles. Such movement occurs either through intercellular junctions or via a transcellular route. Water crosses the lipid-rich cell membrane by simple diffusion, or alternatively, it passes through fenestrations and water channels known as aquaporins that are embedded in the cell membrane.

Capillary membranes are permeable to most small solutes, including sodium, potassium, glucose, and small molecular-weight proteins (less than 50,000 kDa). These small solutes have no role as effective osmoles; rather, movement of water across capillary membranes is directed by the osmotic pressure generated by plasma proteins that are too large to cross the capillary wall and by the hydrostatic pressure from blood flow. This force that is generated is known as oncotic pressure. Taken together, the oncotic and hydrostatic pressures are known as Starling's forces, and their effect on transcapillary movement can be described by Starling's law, which states that net filtration is the difference between the hydrostatic pressure and the oncotic pressure of both the capillary and interstitial fluids. The plasma proteins are effective osmoles that hold water in the intravascular space and generate oncotic pressure. This opposes the hydrostatic pressure of the plasma, which tends to force fluid into the interstitium. At the arteriolar end of the capillary, intravascular hydrostatic pressure exceeds oncotic pressure, and fluid moves out. With the net efflux of fluid along the length of the capillary, the situation is reversed at the venous end, and fluid is drawn from the interstitium back into the intravascular space.

Although small solutes do not contribute to water movement across capillary membranes, they do act as effective osmoles that direct water movement between the intracellular and extracellular spaces across cell membranes. Sodium (Na^+) and potassium (K^+) are the principal determinants of extracellular and intracellular osmolality, respectively; they are unable to diffuse passively across the lipid-rich cell membrane. The imbalance between the intracellular and extracellular concentrations of these two solutes is generated and maintained by the Na^+K^+ adenosine triphosphatase mechanism. This transmembrane transporter exchanges three Na^+ molecules for two of K^+ and generates a net negative cell membrane potential. Were the concentration of either of these ions to change, water would be forced to move from the compartment with lower osmolality to the compartment with higher osmolality to reestablish equilibrium. For example, if hypotonic saline solution (e.g., 0.45% NaCl normal saline solution) is administered, the extracellular osmolality is lowered, and water moves from the extracellular to intracellular space, causing cellular swelling. In contrast, with administration of hypertonic saline solution (e.g., 3% NaCl normal saline solution), the extracellular osmolality increases, and water moves from the intracellular to the extracellular space, causing cellular dehydration. Serum osmolality is maintained in a narrow range by the process of osmoregulation and is calculated with the following formula:

$$\text{mOsm/kg} = 2 \times (\text{Na} + \text{K}) + (\text{BUN}/2.8) + (\text{glucose}/18)$$

where *BUN* is blood urea nitrogen and *mOsm/kg* is serum osmolality. Normal serum osmolality is 275 to 290 mOsm/kg, and variations of only 1% to 2% stimulate mechanisms to restore the normal level, a

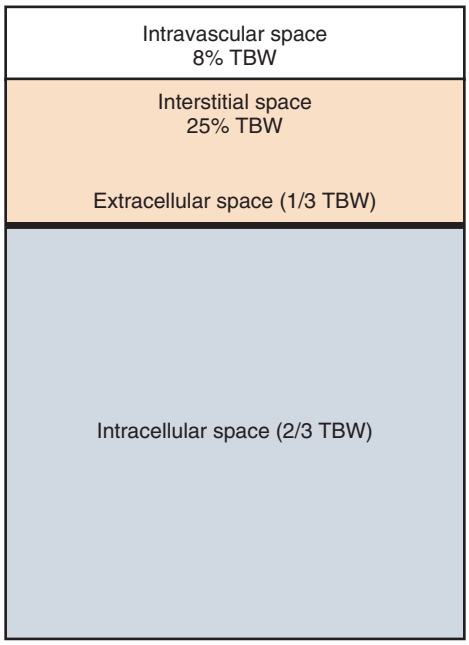

FIGURE 1 Body fluid distribution. *TBW*, Total body water.

process known as osmoregulation. Osmoreceptors in the hypothalamus detect high plasma osmolality and stimulate the thirst mechanism and antidiuretic hormone (ADH) secretion by the posterior pituitary gland. ADH then upregulates aquaporins in the distal collecting tubules of the kidney to reabsorb free water. As a result, adult urine osmolality has a wide range that can vary from 100 to 1200 mOsm/kg depending on the serum osmolality. On average, patients with a high serum osmolality and intact renal function have a urine osmolality greater than 500 mOsm/kg. Circulatory baroreceptors also stimulate ADH secretion based on detection of plasma volume, although volume is a less potent stimulus than osmolality.

Hormones that influence total body sodium content are the principal mediators of volume regulation. These include the renin-angiotensin-aldosterone axis and atrial natriuretic peptide (ANP). Renin is secreted by the juxtaglomerular cells in response to renal hypoperfusion or low sodium concentration in the macula densa region of the distal tubule. Renin secretion leads to activation of angiotensin and release of aldosterone, which both promote sodium reabsorption. ANP is a systemic hormone released in response to cardiac atrial stretch and enhances renal blood flow while inhibiting sodium reabsorption in the kidney.

DAILY REQUIREMENTS AND CHOICE OF MAINTENANCE FLUIDS

Maintenance fluids replace normal sensible and insensible losses. Replacement fluids replace abnormal or excess losses and correct for any water or electrolyte deficits. Sensible water losses can be quantified and occur primarily in urine and stool. Insensible losses cannot be measured and include evaporative losses from the skin (75%) and the upper respiratory tract (25%). Normal daily sensible losses include 800 to 1500 mL in urine and 250 mL in stool, and insensible losses are approximately 8 to 12 mL/kg/d. The insensible losses increase in various physiologic and pathologic conditions, including fever, hyperventilation, burns, tachycardia, and other hypermetabolic states. Cutaneous insensible losses increase by 10% per day for every 1°C increase in body temperature above 37°C. During a thoracotomy or laparotomy, insensible losses from the operative field can approach 1 L/h.

TABLE 1: Maintenance fluid requirements

Body mass (kg)	Fluid volume (mL/kg/h)	Fluid volume (mL/kg/d)
First 10 kg	4	100
Second 10 kg (10 to 20 kg)	2	50
Each kg >20 kg	1	20
60 kg	100	2300

The rate of maintenance fluid administration for both pediatric and adult patients can be calculated for a 24-hour period by the 100-50-20 rule or hourly by the 4-2-1 rule (Table 1). The electrolyte composition of maintenance fluids is based on daily losses. Daily sodium requirement in the postoperative period is 1 to 2 mEq/kg/d, and potassium requirement is 0.5 to 1 mEq/kg/d. Postoperative maintenance fluids may also include dextrose to maintain plasma osmolality and reduce short-term proteolysis. Specific electrolyte and carbohydrate requirements may vary with the clinical situation and should be monitored closely in all critically ill patients. The usual postoperative maintenance fluid for an adult is composed of dextrose 5% (D5) in isotonic, half-normal saline solution (0.45% NaCl) with 20 mEq/L KCl. Children older than 2 years can receive the same maintenance fluids as an adult, but younger children are usually given D5 quarter-normal saline solution (0.22% NaCl) with 20 mEq KCl. Until age 2 years, the kidney has a glomerular filtration rate (GFR) that is one quarter the adult level, and the distal nephrons are unable to effectively concentrate the urine, leading to a difficulty in excreting high sodium loads.

ASSESSMENT OF FLUID STATUS AND CHOICE OF REPLACEMENT FLUIDS

In the immediate postoperative period, patients may have fluid deficits that result from preoperative or intraoperative fluid losses. During the extended postoperative period, continued excess fluid losses in the urine, skin, and gastrointestinal (GI) tract are common. Fluid management in the postoperative period requires a close assessment of fluid status and selection of an appropriate type and rate of fluid replacement. Importantly, in an inflammatory state, it is common to have low intravascular volume despite overall positive fluid balance.

Common signs and symptoms of low effective circulatory volume include abnormal mentation, excessive thirst, dry mucous membranes, poor skin turgor, tachycardia, hypotension, orthostatic changes in heart rate and blood pressure, and oliguria. In addition to clinical signs and symptoms, daily weights, serum and urine electrolyte levels, acid-base balance, and invasive monitoring can be used to measure volume status and assess the adequacy of resuscitation. Urine output is an excellent measure of volume status and should be at least 0.5 mL/kg/h for adults and 1 to 2 mL/kg/h in children. Urine output may be an inaccurate measure if the patient has renal insufficiency, is receiving diuretics, or is hyperglycemic.

Increases in either serum or urine osmolality suggest intravascular hypovolemia. Other indicators of intravascular depletion include an elevated hematocrit value, low serum bicarbonate level with a base deficit, a BUN/creatinine (Cr) ratio of greater than 20:1 (prerenal azotemia), and a fractional excretion of sodium (FeNa) of less than 1%.

$$\text{FeNa} = ([\text{urine Na}] \times [\text{plasma Cr}] / [\text{plasma Na}] \times [\text{urine Cr}]) \times 100$$

TABLE 2: Electrolyte composition (mEq) of parenteral fluids

Fluid	Na^+	K^+	Cl^-	Ca^{2+}	HCO_3^-	Dextrose	pH
Extracellular fluid	142	4	103	5	27	0	7.4
Ringer's lactate solution	130	4	109	2.7	28	0	6.5
Normal saline solution (0.9% NaCl)	154	0	154	0	0	0	4.5
1/4 Normal saline solution (0.45% NaCl)	77	0	77	0	0	0	4.5
1/4 Normal saline solution (0.2% NaCl)	34	0	34	0	0	0	4.5
3% Saline solution	513	0	513	0	0	0	4.5
5% Dextrose in water	0	0	0	0	0	50 g	4.5
5% Albumin	145	0	0	0	0	0	7.4

As in the case of urine output, the FeNa is altered and is not a useful indicator of volume status if the patient has underlying renal dysfunction or is receiving diuretics, most commonly furosemide.

The rate of replacement fluid administration is determined by the severity of the existing deficit, presence of ongoing losses, and comorbidities. Severe fluid losses that result in hemodynamic instability should be replaced with intravenous (IV) fluid boluses of 0.9% NaCl (normal saline solution [NS]) or lactated Ringer's solution (LR) at volumes of 10 to 20 mL/kg, with boluses repeated until an adequate resuscitation is reached.

The composition of various replacement fluids is shown in Table 2. NS and LR are most commonly used for replacement because they best approach the composition of extracellular fluid. LR contains 28 mEq of HCO_3^-, whereas NS does not contain any HCO_3^- but has a greater concentration of Na^+ and Cl^- (154 mEq). Thus, NS is used preferentially in patients with a metabolic alkalosis but can cause a hyperchloremic metabolic acidosis. Colloid solutions, such as 5% albumin, are theoretically useful in restoring intravascular volume because of the oncotic pressure afforded by the protein content. However, liberal use of colloid solutions has not been consistently shown to improve patient outcomes in randomized studies.

The electrolyte compositions of different GI fluids are listed in Table 3. The optimal replacement for gastric losses is D5 half NS with 20 mEq/L KCl; for pancreatic, biliary, or small intestinal losses, LR; and for large intestinal losses, LR with 20 mEq/L KCl. If GI losses are substantial or persistent, they should be replaced on a milliliter-for-milliliter basis with the correct fluid.

TABLE 3: Electrolyte composition (mEq) of gastrointestinal fluids

Source	Daily loss (mL)	Na^+	K^+	Cl^-	HCO_3^-
Saliva	1000	30-80	20	70	30
Gastric	1000-2000	60-80	15	100	0
Pancreas	1000	140	5-10	60-90	40-100
Bile	1000	140	5-10	100	40
Small bowel	2000-5000	140	20	100	25-50
Large bowel	200-1500	75	30	30	0

DIAGNOSIS AND TREATMENT OF ELECTROLYTE DISORDERS

Sodium

Sodium is the principal determinant of serum osmolality and free-water balance. The normal range of serum sodium concentration is 135 to 145 mEq/L. Sodium is an effective osmole that stimulates free-water movement across membranes because the cell wall is impermeable to sodium.

Hypernatremia is defined as a serum sodium concentration greater than 145 mEq/L. In moderate cases, the serum sodium is 145 to 159 mmol/L; in severe cases, it is greater than 160 mEq/L. Severe hypernatremia, or acute increases in serum sodium levels, can result in central pontine myelinolysis (CPM). Other symptoms of severe hypernatremia include muscle weakness, restlessness, insomnia, lethargy, and coma.

Hypernatremia is always associated with hypertonicity and can occur in the context of hypovolemia, euvolemia, or hypervolemia. Hypovolemic hypernatremia is most often seen in dehydrated patients with limited free water intake and uncontrolled fluid losses, such as infants, the elderly, and patients with mental impairments. Patients with high GI losses from nasogastric suction, vomiting, or diarrhea are also at risk. Euvolemic hypernatremia occurs with excess loss of urinary free water in patients with neurogenic or nephrogenic diabetes insipidus. These states of low ADH secretion are characterized by low urine osmolality with hypernatremia and are differentiated by observing response to desmopressin, an ADH analog that lacks a vasoconstrictive effect. Nephrogenic diabetes insipidus results from an impaired ability of the renal tubules to respond to ADH and therefore is unresponsive to exogenous desmopressin administration. Lastly, hypervolemic hypernatremia is usually iatrogenic, the result of fluid resuscitation with hypertonic solutions or states of mineralocorticoid excess such as Conn's or Cushing's syndrome.

Treatment of hypernatremia begins with calculation of the free water deficit.

$$\text{Free water deficit (L)} = [(\text{Serum Na} - 140)/140] \times 0.6 \times \text{weight (kg)}$$

Patients with severe (>160 mEq/L) or symptomatic hypernatremia should receive D5 water, and patients with mild or moderate hypernatremia can be given isotonic half NS. The first half of the free water deficit should be corrected over the first 24 hours, and the

second half subsequently. Serum sodium levels should be frequently checked, and serum Na^+ concentration should not be reduced more than 0.5 mEq/L/h to avoid cerebral edema.

Hyponatremia is defined as a serum sodium concentration below 135 mEq/L and is classified as mild (130 to 135 mEq/L), moderate (120 to 130 mEq/L), or severe (<120 mEq/L). Hyponatremia most often occurs in association with low serum osmolality (hypotonic hyponatremia). Similar to hypernatremia, assessment of volume status is important in establishing cause, and hypotonic hyponatremia can be further categorized as hypervolemic, euvolemic, or hypovolemic.

The notable exception to the association with low serum osmolality is hypertonic hyponatremia, which occurs when BUN or glucose levels are elevated, thus increasing oncotic pressure and causing water to shift from the intracellular to the extracellular space. For each 100 mg/dL increase in glucose over normal, 2 mEq/L should be added to the reported sodium level for a truly representative value. Isotonic hyponatremia, or pseudohyponatremia, occurs when elements that do not contribute to the serum osmolality are elevated, such as triglycerides and proteins. Most laboratories now correct the sodium level for these artifacts and have eliminated cases of pseudohyponatremia.

In hypervolemic hypotonic hyponatremia, the extracellular fluid (ECF) and interstitium are expanded, but plasma volume is contracted, thus stimulating ADH release. Common clinical circumstances include congestive heart failure, chronic renal insufficiency, nephrotic syndrome, cirrhosis, and hypoalbuminemia. Hypervolemic hyponatremia is uncommon in the perioperative period and most often results from iatrogenic excessive administration of hypotonic fluids. It may occur in patients with advanced cirrhosis with development of hepatorenal syndrome or with renal insufficiency that occurs as a result of a low effective circulatory volume and renal blood flow. Patients with hypervolemic hypotonic hyponatremia are most effectively managed with a low-sodium diet (1500 to 2000 mg/d) and fluid restriction (1 L/d). In addition, spironolactone or amiloride can be added to promote a negative sodium balance.

Euvolemic hyponatremia can result from the syndrome of inappropriate ADH secretion (SIADH), hypothyroidism, or excessive water intake (psychogenic polydipsia). Increased ADH secretion occurs transiently in the early postoperative period, after trauma or with severe burns, but it can also occur with pulmonary malignancies, including carcinoid tumors and small-cell lung cancers, lung infections, and central nervous system (CNS) injuries and infections. Euvolemic hyponatremia is the most common presentation of acquired immune deficiency syndrome (AIDS)-related CNS infections. SIADH can be diagnosed by the presence of high urine osmolality (>150 mmol/kg) and high urine sodium (>20 mmol/L); it must be differentiated from adrenal insufficiency, which is accompanied by hypokalemia. SIADH is treated with fluid restriction (<1 L/d). Isotonic fluids actually worsen the hyponatremia because sodium is filtered in the glomerulus and free water is reabsorbed in the distal tubule.

Hypovolemic hypotonic hyponatremia is the most common form of hyponatremia in postoperative cases. If urine sodium is greater than 20 mmol/L, the sodium loss is primarily renal in origin. If urine sodium is less than 20 mmol/L, the sodium deficit is primarily from sequestration of isotonic fluids in the extravascular (third) space or loss from the GI tract or skin or from bleeding. Treatment of hypovolemic hyponatremia differs from euvolemic or hypervolemic cases because fluid restriction only worsens the clinical picture. Mild to moderate cases are best managed with slow correction with isotonic saline solution.

Severe cases of hyponatremia or acute changes in serum sodium concentration can result in cellular edema and cerebral swelling and produce symptoms that include headache, lethargy, seizures, and coma (Tables 4 and 5). Because of the other determinants of serum osmolality, primarily BUN and glucose, hyponatremia can occur with high, normal, or low serum osmolarity. Regardless of the serum osmolality, patients with severe or symptomatic hyponatremia should be aggressively treated with 3% NaCl hypertonic saline solution. Before treatment, it is important to calculate the sodium deficit, which is directly proportional to the TBW.

$$\text{Na deficit} = (140 - \text{serum Na}) \times \text{TBW}$$

TBW can be estimated at 0.6 times total body weight for males and 0.55 times total body weight for females.

Rapid correction of hyponatremia with hypertonic saline solution can lead to CPM, with potential for permanent spastic quadriparesis and pseudobulbar palsy. Therefore, serum sodium should not be corrected more rapidly than 0.25 mEq/L/h or 8 mEq/kg/d. Hypertonic saline solution (3% NaCl) should be given in 250-mL aliquots at a rate of 50 mL/h, with frequent serum sodium level measurements. Furosemide can also be used to minimize the volume of resuscitation and aids in correcting the hyponatremia, as furosemide-induced diuresis is osmotically equivalent to administration of half NS.

Potassium

Serum potassium is maintained in a narrow range from 3.5 to 5 mmol/L, and variations in either direction from this range have potentially significant morbidity. Of total body potassium, 98% resides in the intracellular fluid compartment. Serum potassium is tightly regulated by the renin-angiotensin-aldosterone axis. Aldosterone causes secretion of potassium in the distal renal tubule.

Hyperkalemia, defined as K^+ above 5.5 mEq/L, is cardiotoxic and can lead to ventricular arrhythmias. Electrocardiographic (ECG) findings include, in order of progression, peaked T waves, QRS widening, shortened QT intervals, and ventricular ectopy. Chronic K^+ elevations in patients with chronic renal failure are well tolerated, but acute changes are not. Acute causes of hyperkalemia include acute renal failure, acidosis, rhabdomyolysis, cell lysis, and insulin deficiency. Pseudohyperkalemia occurs when red blood cells lyse in the collection tube; if this is suspected, the K^+ level should be rechecked.

Hypokalemia, defined as serum K^+ below 3.5 mEq/L, is encountered commonly in the postoperative period. Signs and symptoms of hypokalemia include generalized fatigue and weakness, atrial arrhythmias, ileus, and acute renal insufficiency. Flat T or U waves are seen on ECG. Causes of hypokalemia include large losses from the kidney or GI tract via nasogastric suctioning, vomiting, or diarrhea; alkalosis; catecholamine secretion; and insulin administration. Because most of the K^+ is stored intracellularly, small changes in serum K^+ reflect large changes in body stores. Low K^+ is frequently associated with hypomagnesemia and acidemia. Magnesium must first be replenished before K^+ corrects in response to exogenous administration. In patients who are both hypokalemic and acidemic, K^+ administration should precede correction of acidemia with bicarbonate, to avoid a precipitous drop in serum K^+ as the pH increases. Potassium can be replenished orally or via IV administration. For treatment of mild hypokalemia, oral replacement with KCl is recommended. Because the oral form is well absorbed, IV administration should be reserved for patients who do not tolerate the oral form or for those who have severe hypokalemia.

The ischemia-reperfusion cycle poses great risk of hyperkalemia in patients who undergo reperfusion of an ischemic extremity. Severe systemic hyperkalemia may occur in response to revascularization with at least 4 to 6 hours of ischemia. The authors routinely administer prophylactic bicarbonate before reperfusion. Another cause of hyperkalemia is succinylcholine, a depolarizing paralytic agent, particularly in patients with disuse atrophy usually from prolonged bed rest, neurologic denervation syndromes, severe burns, or muscle trauma.

Hyperkalemia must be identified and treated immediately. Patients should receive at least 1 ampule of prophylactic calcium gluconate to antagonize the K^+ depolarization effect on cardiac

TABLE 4: Signs and symptoms of electrolyte disorders

Disorder	Neurologic	Cardiovascular	Gastrointestinal	Renal	Other
Hyponatremia	Confusion, seizures, coma	Hypotension, hypertension	Salivation	Oliguria	
Hypernatremia	Confusion, seizures, coma	Fluid overload (edema)	Thirst		Tachypnea
Hypokalemia	Fatigue, weakness	Atrial arrhythmias, flat T wave, U waves	Ileus	Nephrotoxicity	
Hyperkalemia	Confusion, paralysis, areflexia	Ventricular arrhythmias, peaked T wave, prolonged PR interval, wide QRS complex	Nausea, vomiting, abdominal pain		
Hypocalcemia	Paresthesia, perioral tingling, carpopedal spasm, Chvostek's sign	Ventricular arrhythmias, prolonged QT interval			Laryngospasm
Hypercalcemia	Confusion, fatigue, coma	Shortened QT interval	Abdominal pain	Renal stones, nephrogenic diabetes insipidus (long-term)	
Hypomagnesemia	Weakness, cramping, hyperreflexia	Atrial ventricular arrhythmias (torsades des pointes)	Dysphagia		Refractory hypokalemia, hypocalcemia
Hypermagnesemia	Sedation, paralysis, areflexia	Atrial, ventricular arrhythmias	Diarrhea		
Hypophosphatemia	Confusion, seizures, weakness	Heart failure, respiratory failure			Bone pain
Hyperphosphatemia	Symptoms of hypocalcemia				

myocytes. Treatment strategies to decrease the serum K^+ include shifting the K^+ intracellularly or eliminating it from the body altogether. Intracellular shift is promoted by administering 10 U of insulin along with 1 ampule of D50 to prevent hypoglycemia or giving 1 ampule of $NaHCO_3$. Potassium excretion in urine or stool is promoted with administration of a loop diuretic, such as furosemide or bumetanide, or a sodium-potassium exchange resin, such as kayexalate, either orally or as a retention enema with sorbitol. With the exchange resin, 1 mEq of K^+ is taken up in exchange for 2 mEq Na^+, and an osmotic diarrhea ensues. The retention enema should not be given to patients with immunosuppression because it can cause rectal perforation. If these measures are unsuccessful, hemodialysis may be used as a last resort.

Calcium

Calcium is the most abundant electrolyte in the body. The normal range of serum calcium is 8.5 to 10.5 mg/dL, with 99% stored in bone. Approximately 50% of calcium circulates as the biologically active ionized form, and the other 50% as the biologically inactive bound form. As most of the nonionized form is bound to albumin, the serum calcium level must be adjusted for the serum albumin level in patients who are malnourished; calcium falls 0.8 mEq/dL for every 1 g/dL reduction in serum albumin. Serum calcium concentrations are regulated by parathyroid hormone (PTH) and vitamin D. Conditions that alter PTH and vitamin D levels also indirectly alter calcium levels.

Hypocalcemia is defined as total serum concentration below 8.4 mg/dL or ionized calcium concentration below 4.5 mg/dL. Common causes of hypocalcemia include hypoparathyroidism and vitamin D deficiency. Less common causes include hyperphosphatemia, hypomagnesemia, acute pancreatitis, malnutrition, rhabdomyolysis, infusion of large volumes of fluid, and acute alkalosis from hypoventilation.

Acute hypocalcemia in the postoperative period can occur in response to rapid blood transfusions and hypoparathyroidism. In the past, stored blood contained a higher concentration of citrate, which binds to and chelates serum calcium. Now that citrate has been eliminated from blood-banking techniques, this is rarely seen. Patients who undergo thyroidectomy or parathyroidectomy may have hypocalcemia develop after surgery.

Symptoms of hypocalcemia include perioral numbness and tingling, hyperreflexia on stimulation of the facial nerve (Chvostek's sign), and spasm of muscles of the hand and forearm with inflation of a blood pressure cuff (Trousseau's sign). Prolonged QT intervals and arrhythmias may also been seen.

Hypocalcemia should be treated in symptomatic patients and also in patients with total serum calcium below 7.0 mg/dL or ionized calcium below 3.0 mg/dL. Calcium may be given orally, or

TABLE 5: Treatment options for electrolyte disorders

Disorder	Therapy
Hyponatremia	Fluid restrictions 0.9% NaCl Hypertonic saline solution ± diuretic
Hypernatremia	Free water 0.45% NaCl
Hypokalemia	Oral/IV potassium
Hyperkalemia	IV insulin + 50% dextrose 10% calcium gluconate
Hypocalcemia	IV calcium gluconate 1,25 Dihydroxyvitamin D_3
Hypercalcemia	IV 0.9% NaCl Furosemide
Hypomagnesemia	IV magnesium Magnesium sulfate
Hypermagnesemia	Sodium or potassium phosphate
Hyperphosphatemia	IV 0.9% NaCl Diuretics Acetazolamide

IV, Intravenous.

intravenously, in the form of calcium gluconate or calcium chloride. Severe hypocalcemia and symptoms such as overt tetany, laryngospasm, and seizures are indicative of IV calcium replacement. Calcium gluconate has 9 mg of elemental Ca^{2+} per mL, whereas $CaCl_2$ contains 27 mEq of Ca^{2+} per mL; hence, $CaCl_2$ contains three times more elemental Ca. $CaCl_2$ must be administered via central access and in a monitored setting to avoid associated bradycardia or hypotension. Concurrent hypomagnesemia or hyperphosphatemia must be corrected first for the calcium supplementation to be effective.

Calcium salts available for oral use include calcium carbonate and calcium gluconate. When hypocalcemia is resistant or severe, calcium salts should be supplemented with vitamin D_3.

Hypercalcemia is defined as serum calcium concentration greater than 10.4 mg/dL or ionized concentration greater than 5.6 mg/dL. It occurs most commonly with malignant diseases in hospitalized patients and with hyperparathyroidism in the general population. Breast cancer is the most common malignant cause. Other causes include vitamin A and D overdose, thyrotoxicosis, immobilization, excess exogenous calcium intake, granulomatous diseases, familial hypocalciuric hypercalcemia, and medications such as thiazide diuretics and lithium.

Symptoms of hypercalcemia include nausea, vomiting, altered mental status, constipation, depression, lethargy, myalgias, arthralgias, polyuria, headache, abdominal and flank pain (renal stones), and coma. Patients with symptoms or serum calcium above 14 mg/dL should be treated to avoid a hypercalcemic crisis. Goals of treatment include expansion of intravascular volume with normal saline solution to dilute circulating calcium and increase filtration of calcium in the kidneys. Furosemide should be administered via IV to increase renal calcium excretion and offset fluid administration.

Mild hypercalcemia (Ca < 12 mg/dL) can be managed with restriction in calcium intake and treatment of the underlying etiology. Hypercalcemic crisis usually occurs with serum calcium levels in excess of 14 mg/dL, and it requires aggressive treatment with bisphosphonates or calcitonin in addition to fluids and diuretics. Bisphosphonates, such as pamidronate (60 to 90 mg IV), inhibit osteoclast-induced bone resorption with onset of action between 24 and 48 hours. Bisphosphonates are the best choice for long-term calcium control and for hypercalcemia from enhanced bone resorption. Calcitonin (4 U/kg subcutaneously every 12 hours) inhibits bone resorption and decreases renal tubular resorption of calcium, with a shorter onset of action than bisphosphonates; therefore, it is the better choice for short-term control of calcium.

Magnesium

Magnesium is essential for energy metabolism, protein synthesis, cell division, and calcium homeostasis. Normal serum magnesium level is 1.4 to 2.0 mEq/L. Magnesium is primarily intracellular, with less than 1% of body stores in the extracellular fluid.

Hypomagnesemia is defined as serum concentration below 1.6 mg/dL; it often is seen after surgery because of dilution. Alternatively, hypomagnesemia may occur as a result of poor intake or GI losses, including diarrhea and biliary and enteric fistulas. Signs and symptoms rarely occur unless serum levels are below 1.0 mEq/dL. Serum magnesium levels must be monitored after surgery because severe hypomagnesemia may cause ventricular arrhythmias such as torsades des points. Oral magnesium oxide is the agent of choice for correction of mild to moderate hypomagnesemia. IV therapy with $MgSO_4$ is reserved for severe hypomagnesemia associated with arrhythmias.

Magnesium is easily replenished with oral or IV magnesium sulfate. IV replacement is usually reserved for patients with serum magnesium levels below 1.2 mg/dL. Patients with development of ventricular arrhythmias are treated acutely with bolus doses of IV magnesium sulfate, 1 to 2 g over 3 to 5 minutes.

Hypermagnesemia is a rare disorder that usually is seen with burns, trauma, or long-term hemodialysis. Hypermagnesemia is defined as serum concentration above 2.8 mg/dL. Symptoms are uncommon until the serum magnesium reaches 4.0 mg/dL, at which point patients become lethargic. Treatment is similar to that for hypercalcemia. Calcium is given to stabilize cardiac myocytes, NS is given to expand the plasma volume, and loop diuretics are used to induce renal excretion. Severe hypermagnesemia is treated with IV calcium gluconate 10% (10 to 20 mL over 10 minutes).

Phosphorus

Similar to calcium, 80% of phosphorus is stored in bone, with less than 1% of total body phosphorus in the intravascular space. Normal serum phosphate ranges from 2.2 to 4.7 mg/dL.

Hypophosphatemia is defined as serum concentration below 2.5 mg/dL; symptoms include respiratory and cardiac failure. Hypophosphatemia is frequently encountered in the postoperative period. Common causes include decreased intake and intestinal malabsorption from vitamin D deficiency, increased renal excretion from diuretics, alkalosis, hyperparathyroidism and hungry bone syndrome, major hepatic resection, rhabdomyolysis, and refeeding syndrome. Refeeding syndrome occurs in nutritionally depleted patients who are given carbohydrates; the resultant insulin surge causes the already depleted phosphate pool to redistribute into cells. Phosphate is an essential component for the adenosine triphosphatase backbone and should be replenished when serum concentration falls below 2.0 mg/dL. Phosphorous replacement should begin with intravascular therapy in patients with mild or severe hypophosphatemia. Five to 7 days of IV fluids may be required to replenish serum phosphorous levels. Once the serum phosphorous levels exceed 2 mg/dL, patients can be switched to oral therapy.

Hyperphosphatemia is defined as serum phosphate concentration greater than 5.0 mg/dL. Patients with renal insufficiency can have hypophosphatemia develop primarily because of decreased 1,25 dihydroxy–vitamin D production. Hyperphosphatemia is also a common feature of postoperative hypoparathyroidism. Patients with hyperphosphatemia primarily have symptoms that result from hypocalcemia. Hypocalcemia occurs because of precipitation of calcium with excess phosphate ions in the serum. Treatment includes expanding the plasma volume with NS and then stimulating renal excretion with acetazolamide. Acute cases of severe refractory hyperphosphatemia can be treated with hemodialysis. Patients in renal failure with chronic hyperphosphatemia are maintained on phosphate binders such as aluminum hydroxide or sevelamer.

Preoperative Assessment of the Older Patient: Frailty

Mara McAdams-DeMarco, PhD, and Dorry Segev, MD, PhD

OVERVIEW

Approximately half of all operations in the United States are performed in older patients over the age of 65 years, and this number is rapidly growing. Surgical risk prediction and treatment decision-making in this population are challenging because of the heterogeneity of health status in older adults. For many years, it has been recognized, anecdotally and intuitively, that some older patients might not have the physiologic reserve to withstand surgery, but standardized measures of physiologic reserve have, until recently, been limited. Current research is focused on developing measures of frailty that improve prediction of adverse surgical outcomes in older adults; much of this work is already helping to guide clinical practice.

The purpose of this chapter is to: (1) describe the frailty phenotype; (2) review surgical risk prediction based on frailty; (3) relate frailty to disability and comorbidity; (4) describe the role of frailty in the preoperative assessment of older patients; and (5) explore sarcopenia as a potential measure of frailty.

OLDER SURGICAL PATIENTS

Approximately half of all surgical patients in the United States are over 65 years old. Recent population projections suggest that the average volume of a surgical practice will increase by 14% to 47% from the year 2000 to 2020 as a result of the increasing population of older adults. As the population of the United States ages, tools from the gerontology literature may prove critical in guiding clinical decision-making for older surgical patients.

Older surgical patients have a unique physiologic vulnerability that requires assessment beyond the standard preoperative evaluation to identify those at risk for postoperative complications. Older adults undergoing surgery are at increased risk for morbidity, mortality, and postoperative complications even after accounting for differences in comorbidity and disability. Older patients may experience a functional decline after major surgery, and 20% to 44% of older patients are discharged to a skilled nursing facility or other institutional care.

Surgical indications in younger patients are not necessarily generalizable to older patients because physiologic changes from aging can alter the risk-benefit balance by increasing the risk or reducing the benefit. Medical care for older patients must be based not only on the patient's long-term prognosis but also on the patient's personal goals. For older patients, survival may not be as relevant as other outcomes, including physical function, quality of life, and institutionalization. Traditional preoperative evaluation strategies identify risk based on a single domain; this approach does not capture the unique vulnerability of older patients. However, newly emerging research suggests that novel metrics from gerontology can provide insights into more accurate vulnerability assessment. Additional information that is not typically part of the surgical evaluation of younger patients may improve the accuracy of predictions during the preoperative assessment and thus help patients make more informed and personal treatment choices.

FRAILTY

Frailty is increasingly recognized as a unique domain of health status, separate from comorbidity and disability. Frailty is a global phenotype of physiologic reserve, resistance to stressors, and vulnerability in older patients. Although the concept of frailty may initially appear abstract, recent work helps to quantify this "foot of the bed" judgment of an experienced clinician in a generalizable, repeatable manner. Our goal is to move from the intuitive concept of frailty to the validated quantifiable measure of frailty.

Frailty is the composite of individual components of physiologic decline. These components can be measured in the preoperative clinic, usually in less than 5 to 10 minutes by trained personnel of various backgrounds, to generate a frailty score. This score can then be used to predict adverse surgical outcomes, which are directly related to the number of frailty components present. In general, each increase in the number of components of frailty is associated with an increase vulnerability to a surgical stressor and decreased physiologic reserve to withstand the operative stress.

Although many definitions of frailty are found in the gerontology literature, the definition of frailty by Fried and colleagues is one of the most cited; this definition is measured with a validated scoring system of five components and is widely used in both research and

clinical settings. The five components in Fried's scoring system include shrinking, weakness, exhaustion, low physical activity, and slowed walking speed (Table 1). These components have been found to have good validity and reliability.

Each component yields a score of 0 or 1 based on the criteria listed. The raw frailty score is the sum of the number of components (range, 0 to 5) and is usually categorized as frail or nonfrail—or frail, intermediately frail, or nonfrail—based on the distribution of the component score in the population of interest. For example, Makary and associates found that in surgical patients, those with a score of 4 or 5 were frail, of 2 or 3 were intermediately frail, and of 0 or 1 were nonfrail. Both intermediately frail and frail patients were predisposed to adverse outcomes; however, the risk was higher in those who were frail versus those who were intermediately frail.

The frailty phenotype was first described in the Cardiovascular Health Study, a cohort study of community-dwelling older adults. Frail participants had 2.24-fold higher risk (95% confidence interval [CI], 1.51 to 3.33) of mortality than their nonfrail counterparts, even after accounting for differences in comorbidity and disability. In nonsurgical populations, frailty has been associated with mortality, morbidity, falls, cardiovascular disease, insulin resistance, venous thromboembolism, and hospitalizations. The research identifying the consequences of frailty supports the hypothesis that frailty is the capacity to adapt to stressors.

It appears that the physiology underlying frailty is complex; evidence is accumulating that immune system dysregulation may play a leading role, resulting in heightened inflammation and alteration in innate and adaptive immune systems. The frailty phenotype has been associated with dysregulation of multiple physiologic systems, including not only a generalized inflammatory state but also dysregulated cortisol, altered heart rate variability, changes in hormonal status, and decreased immune function. It has been posited that each component of this phenotype is related in a vicious cycle of dysregulation, a cycle that spirals downward with decreasing adaptive capacity. The physiologic consequences of this dysregulation are easily recognizable in older surgical patients.

FRAILTY, COMORBIDITY, AND DISABILITY

Frailty is considered to be a phenotype that is independent of, but sometimes associated with, disability and comorbidity (Figure 1). Although older frail surgical patients are likely to have comorbidities and disability, some older patients are frail but do not have comorbidities or disability; likewise, some older patients have comorbidities or disability but not frailty.

In the formative studies of frailty, disability was defined as dependence in one or more activities of daily living (ADL) with the Katz activity of daily living score. ADLs describe six tasks necessary for independent living: bathing, dressing, transferring, walking, using a toilet, and feeding. In older patients undergoing surgery, disability has emerged as an important risk factor for mortality, postoperative institutionalization, and higher healthcare costs. In one study by Robinson in 2009, older surgical patients with ADL disability had 13.9-fold higher odds (95% CI, 2.99 to 65.49) of 6-month mortality compared with those with no ADL disability; ADL disability was the strongest predictor of mortality in this study. In another study by the same group, ADL disability was associated with 5.66-fold higher odds (95% CI, 2.37 to 13.52) of discharge to institutional care.

TABLE 1: Components of frailty

Component	Definition and measurement
Shrinking	Shrinking is defined as unintentional weight loss ≥10 lb in the past year.
Weakness	Weakness is assessed by grip strength and is measured directly with a hand-held Jamar dynamometer. Three serial tests of maximal grip strength with the dominant hand are performed, and a mean of the three values is adjusted by gender and BMI. Weakness is defined as an adjusted grip strength in the lowest 20th percentile of a community-dwelling population of adults 65 years of age and older. Men meet the criteria for weakness if BMI and grip strength are ≤24 and ≤29 kg; 24.1-26 and ≤30 kg; 26.1-28 and ≤31 kg; >28 and ≤32 kg, respectively. Women meet the criteria for weakness if BMI and grip strength are ≤23 and ≤17 kg; 23.1-26 and ≤17.3 kg; 26.1-29 and ≤18 kg; and <29 and ≤21 kg, respectively.
Exhaustion	Exhaustion is measured by responses to the following two statements from the modified 10-item Center for Epidemiological Studies depression scale: "I felt that everything I did was an effort" and "I could not get going." Patients are asked, "How often in the last week did you feel this way?" Potential responses were: 0, rarely or none of the time (<1 day); 1, some or a little of the time (1-2 days); 2, a moderate amount of the time (3-4 days); and 3, most of the time. Patients who answer either statement with response 2 or 3 meet the criteria for exhaustion.
Low physical activity	Physical activities are ascertained for the 2 weeks before this assessment with the short version of the Minnesota Leisure Time Activities Questionnaire and include frequency and duration. Weekly tasks are converted to equivalent kilocalories of expenditure, and individuals who report a weekly kilocalorie expenditure in the lowest 20th percentile for their gender (men, <383 kcal/wk; women, <270 kcal/wk) are classified as having low physical activity.
Slowed walking speed	Slowness is measured by averaging three trials of walking 15 ft at a normal pace. Individuals with a walking speed < 20th percentile, adjusted for gender and height, are scored as having slow walking speed. Men meet criteria if height and walk time are ≤173 cm and ≥7 seconds, or >173 cm and ≥6 seconds, respectively. Women meet criteria if height and walk time are ≤159 cm and ≥7 seconds, or >159 cm and ≥6 seconds, respectively.

BMI, Body mass index.

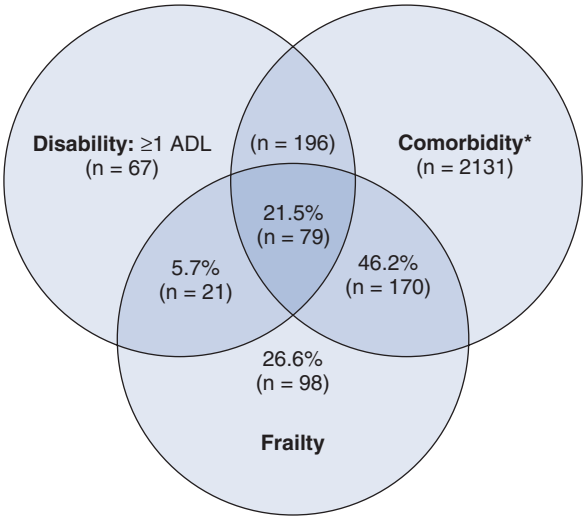

FIGURE 1 Overlap of frailty with disability and comorbidity in older adults participating in the Cardiovascular Health Study. *ADL*, Activities of daily living. *Two or more out of the following nine diseases: myocardial infarction, angina, congestive heart failure, claudication, arthritis, cancer, diabetes, hypertension, chronic obstructive pulmonary disease (COPD). *(From Fried LP, Tangen CM, Walston J, et al, Cardiovascular Health Study Collaborative Research Group: Frailty in older adults: evidence for a phenotype,* Gerontol A Biol Sci Med Sci *56(3):M146-M156, 2001.)*

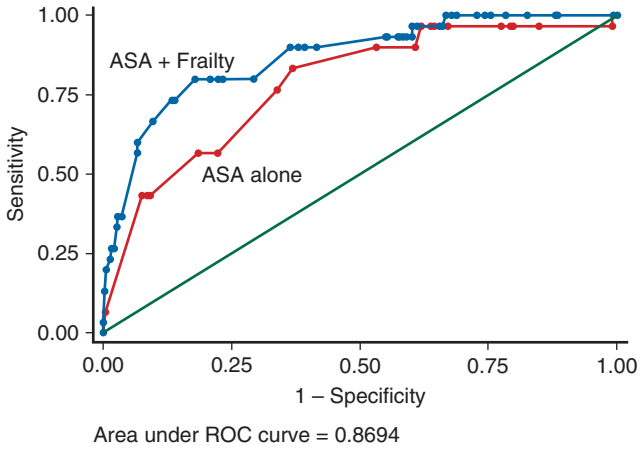

FIGURE 2 Example of nested receiver operator characteristic (ROC) curves that show the ability of frailty to predict surgical complications beyond established risk scores. *ASA*, American Society of Anesthesiologists. *(From Makary MA, Segev DL, Pronovost PJ, et al: Frailty as a predictor of surgical outcomes in older patients,* J Am Coll Surg *210(6):901-908, 2010.)*

In addition, in the formative studies of frailty, comorbidity was defined as the presence of two or more chronic diseases. Two thirds of individuals in the United States 65 years and older have two or more chronic diseases, and half of them have four or more chronic diseases. Multiple measures of comorbidity are available for preoperative assessment. Some measures of comorbidity are as simple as counting the number of chronic conditions. Others, such as the Charlson comorbidity index, are summary scores of chronic conditions. In the Charlson index, each chronic condition is given a score based on its particular risk of mortality, and the summary score represents the burden of comorbidities.

FRAILTY AND SURGICAL RISK PREDICTION

Numerous predictors of postoperative complications are commonly used, such as the Lee and Eagle criteria and the American Society of Anesthesiologists (ASA) score. However, these predictors have substantial limitations when used in older adults and do not account well for the physiologic reserve specific to this population. In older surgical patients, frailty improves risk prediction because a measure of physiologic reserve quantifies the resilience of an older adult to recover from an operation.

Frailty has been shown to predict operative risk in older surgical patients beyond that which is predicted with the Lee and Eagle or ASA scores. Makary and colleagues prospectively studied frailty as a predictor of surgical outcomes in older adults. At the time of surgery, 10.4% of the older patients were frail and 31.3% were intermediately frail. After a minor surgical procedure, 11.4% of the frail patients, 7.3% of the intermediately frail patients, and 3.9% of the nonfrail patients experienced a complication as defined by the American College of Surgeons National Surgical Quality Improvement Program (NSQIP). After adjusting for the Lee and Eagle and ASA scores, frailty was independently associated with increased risk of surgical complications; patients who were intermediately frail had 2.06-fold higher adjusted odds (95% CI, 1.18 to 3.60) of complications, and frail patients had 2.54-fold higher adjusted odds (95% CI, 1.12 to 5.77) of complications when compared with nonfrail patients. Furthermore, frailty predicted length of stay and discharge to an assisted or skilled nursing facility. When added to the best available surgical risk scores, frailty improved the ability to predict which older adults would experience a postoperative complication (improvement in area under the receiver operating characteristic curve [AUC] by frailty for each risk score: Lee, 0.05; Eagle, 0.04; ASA, 0.07) and which would be discharged to an assisted or skilled nursing facility (Lee, 0.13; Eagle, 0.10; ASA, 0.10; Figure 2).

Recent data suggest that frailty also improves risk prediction for patients undergoing kidney transplantation; interestingly, this risk prediction is relevant for patients of all ages undergoing this procedure, rather than just older adults, consistent with the conceptual framework that dialysis creates an "accelerated aging" of sorts and that patients on chronic dialysis react to stressors more like older adults than like their otherwise-healthy contemporaries. Among a cohort of kidney transplant recipients of all ages, 25% were found to be frail; this was about threefold higher than the rate of frailty in community-dwelling older adults. The adjusted risk of early allograft dysfunction, as measured by need for dialysis in the first week after transplant, was 1.94-fold higher for frail patients (95% CI, 1.13 to 3.36) compared with nonfrail patients. Frailty improved standard risk prediction in this study (the AUC improved from 0.67 to 0.73); in fact, frailty was the strongest predictor among recipient factors.

These studies show how preoperative characterization of frailty can predict surgical outcomes and augment other risk assessment tools. Frailty captures a quantifiable domain of surgical risk not previously measured in older adults. The measurement of frailty in the preoperative assessment could aid in predicting which older adults are at high risk of surgical complications and improve decision making for older surgical patients.

ALTERNATIVE MEASURES OF FRAILTY AND SURGICAL OUTCOMES

In addition to the validated Fried criteria for frailty, other definitions of frailty have been evaluated. Alternative definitions of frailty include components such as functional decline, low cognition, poor nutrition, high chronic disease burden, perceived poor health,

depression, medication issues, incontinence, low social support, mobility difficulties, and the presence of the "geriatric syndrome."

Robinson and colleagues in 2009 measured frailty with an alternative definition in older patients undergoing elective surgery and found that this alternative definition was associated with increased risk of 6-month mortality. In addition, patients who were classified as frail were more likely to be discharged to institutional care (59% vs 0%; *P* value, <0.001) and readmitted to the hospital (32% vs 4%; *P* value, 0.04). This research group also showed that, with increasing number of alternative frailty components, there was an increase in hospital ($76,363 vs $27,731; *P* value, <0.001) and postoperative ($110,702 vs $33,453; *P* value, <0.001) costs.

Although there are multiple definitions of frailty, physiologic reserve is an important predictor of surgical outcomes; until comparative data are available, the choice of frailty measure to be used in clinical practice might be best made based on experience of the provider or hospital.

SARCOPENIA AND SURGERY

Two of the components of frailty, walking speed and grip strength, represent muscle wasting and sarcopenia. As such, an alternate way to measure physiologic reserve is to measure sarcopenia directly with radiographic imaging. Englesbe and colleagues have studied sarcopenia as an objective and reproducible measure of frailty. Sarcopenia is not only considered to be part of the aging process but is also accelerated by chronic illness. However, sarcopenia is not altered by acute illness and thus is a good measure of overall health. Sarcopenia is easily quantified with a preoperative computed tomographic (CT) scan to measure the size of the psoas muscle, a core muscle of the trunk that is susceptible to changes in chronically ill patients.

Englesbe and colleagues in 2010 found a correlation between cross-sectional psoas area and model for end-stage liver disease (MELD) score (i.e., the probability that the patient would die in the next 90 days) in patients undergoing liver transplantation. Not surprisingly, increased total psoas area was associated with a decrease in 1-year mortality (hazard ratio, 0.27; 95% CI, 0.14 to 0.53), even after accounting for pertinent patient and donor factors. The same research group has shown that in elective general surgery, vascular abdominal surgery, and abdominal aortic aneurysm repair, psoas area is associated with mortality; in major, elective general, and vascular surgery, the 1-year survival rate was 87% versus 95% for those with smaller psoas area. In addition, the cost increased by $10,110 for every 1000-$mm^2$ decrease in core muscle size. This work suggests that sarcopenia is a clinical measure of risk in older surgical patients and may be a useful objective measure for clinical decision making.

LOGISITICS OF PREOPERATIVE MEASUREMENT OF FRAILTY

The growing literature on frailty and adverse surgical outcomes in older patients supports the clinical utility of measuring frailty as part of the preoperative assessment. Implementing a frailty scoring system during a preoperative assessment to identify vulnerable older patients who are considering surgery is feasible and may aid in clinical decision-making.

A preoperative screening for frailty can easily be implemented into clinical practice. For example, the frailty assessment outlined in Table 1 can be performed in every older preoperative patient by, for example, the person who obtains vital signs. Frailty assessment takes no more than 5 to 10 minutes and can be completed before the physician encounter. A template to record frailty components could be incorporated into the electronic health system to allow for quick calculations of the frailty score and longitudinal measurement. The frailty score can provide prognostic information about older patients during the preoperative consultation, during which a decision regarding surgical intervention might take place. If a patient is identified as frail, the implications of this can be integrated into the discussions of the risks and benefits of surgical intervention. The clinical assessment of frailty used for preoperative decision making should be viewed as a supplement to, but not replacement of, the traditional risk assessment.

As more studies establish frailty as an important phenotype in surgery, growing evidence shows that patients might benefit from interventions to reduce frailty, such as preoperative conditioning (sometimes referred to as "prehabilitation"). In the postoperative period, it might be possible to decrease the risk of complications in frail patients through closer monitoring, attention to nutrition and mobility, and aggressive physical and occupational therapy. Anticipation of which older adults are at risk for surgical complications and which will need discharge to an institutional care facility after a major operation is important for preoperative counseling of expected outcomes and preoperative care planning for older patients and their caregivers.

CONCLUSION

Frailty is a well-established phenotype that was developed in gerontology and is directly applicable to older surgical patients. Older patients who are frail are at increased risk for adverse surgical outcomes, including complications, longer length of stay, discharge to institutional care, and mortality. Although patients who are frail are likely to also have disability and comorbidities, frailty is a distinct phenotype and provides information and risk prediction above and beyond the other two domains. Sarcopenia is an objective measure of frailty, and novel research is exploring risk prediction based on radiographic measures of muscle mass. In conclusion, frailty is a clinically useful predictor of adverse surgical outcomes that can be incorporated into the preoperative assessment of older adults.

Preoperative Preparation of the Surgical Patient

Kristine E. W. Breyer, MD, and Michael A. Gropper, MD, PhD

INTRODUCTION

The patient population undergoing surgery is becoming increasingly complex from a medical standpoint. At the same time, there is increasing pressure to provide cost-effective care. In order to improve outcomes, understanding the patient's medical history and optimizing comorbidities prior to surgery are essential. The preoperative preparation of the surgical patient serves to evaluate and optimize comorbidities in order to minimize morbidity and mortality during and immediately following the surgical procedure.

Many patients ask, "What are my risks from anesthesia?" This is a complicated question, which depends not only on the type of anesthesia administered but also on the type of surgical procedure planned and the patients' comorbidities. Generally, anesthesia has become incredibly safe over the past several decades. Major perioperative events are rare, but they can be devastating and can include myocardial infarction, stroke, renal failure, airway compromise, and death. The American Society of Anesthesia (ASA) classifies patients according to the number of comorbidities and the severity of illness called the ASA class (Table 1). This classification system is well validated, and the risk of a major adverse event during anesthesia increases with increasing ASA class.

Preoperative preparation varies by institution and practices, depending on what preoperative services are available. Large institutions often have preoperative clinics staffed by members from the anesthesia department to which surgeons can refer patients for history and physical examination. Some surgical practices will not have this luxury, and the surgeon may have the burden of collecting and ordering preoperative tests to ensure his or her patient is prepared for surgery. Although the availability of specific surgical preoperative services varies greatly, the goal is always the same: to minimize as many risks as possible to ensure that the patient goes through surgery as safely as possible. This chapter outlines the major and most common risks, testing, and medication recommendations.

Generally, a healthy ASA I or II patient undergoing low- to intermediate-risk surgery should not require evaluation by a preoperative clinic or primary care physician. However, for patients who are ASA III or greater or undergoing high-risk surgery, evaluation by a preoperative clinic or primary care physician prior to surgery is important (Figure 1).

ORAL INTAKE GUIDELINES

The ASA recently revised guidelines for fasting prior to anesthesia. These recommendations include fasting before administration of anesthesia regardless of type of anesthetic—general, regional, or monitored anesthesia care. Adult and pediatric patients should fast from intake of clear liquids at least two hours prior to the start of anesthesia. The guidelines state that the type of liquid is more important than the specific volume and therefore do not give specific recommendations on volume. A clear liquid includes water, coffee, or tea without dairy; clear fruit juice without pulp; and clear carbonated beverages. Pediatric patients should fast from human breast milk for 4 hours and from infant formula for 6 hours prior to the start of anesthesia.

All patients should fast from solid food and nonhuman milk for a minimum of 6 hours prior to the start of anesthesia. The guidelines do make note that a large meal or a fatty meal may benefit from a longer duration of fasting and recommend 8 hours of fasting in these cases.

PREOPERATIVE TESTING

In recent years there has been momentum to move away from routinely testing every patient. Selective testing is recommended when tests may change perioperative management. Changes in perioperative management include medical optimization, changes to intra- and postoperative monitoring, and preoperative coronary revascularization, to name a few. Unnecessary testing can burden patients, increase expenses, and even cause delays over unanticipated nonspecific test results. However, the decision not to order certain tests must be weighed against possible surgical delays if a test was not ordered that is needed. Of course, ultimately the preoperative testing required for a particular patient will need to be determined by both the surgeon and the anesthesiologist.

Electrocardiograms and Other Cardiac Testing

The ASA, American College of Cardiology (ACC), and the American Heart Association (AHA) all agree that resting electrocardiograms (ECGs) for asymptomatic patients undergoing low-risk surgery are unnecessary. The ACC and AHA recommend cardiac evaluation based on the Lee Revised Cardiac Risk Index (RCRI) and surgical risk (Box 1 and Table 2). According to the 2007 ACC/AHA Guidelines and 2009 update, ECGs are recommended for patients with at least one RCRI risk factor who are undergoing vascular surgery. Resting ECGs are also recommended for all patients with known coronary artery disease, peripheral vascular disease, or cerebral vascular disease who are undergoing intermediate- or higher-risk surgery. The guidelines also state that it is "reasonable" to obtain resting ECGs in patients undergoing vascular surgery or in any patient undergoing at least intermediate-risk surgery who also have one or more RCRI risk factors.

Further cardiac evaluation may be indicated for patients with cardiac risk factors or active cardiac disease, depending on the surgical risk (Figure 2). In patients with known cardiac disease or severe pulmonary disease, an echocardiogram can be helpful in delineating systolic and diastolic dysfunction and pulmonary artery hypertension. This in turn may inform intraoperative monitoring plans.

Chest Radiographs

The ASA does not offer specific recommendations on preoperative chest radiographs (CXRs). The ASA does not recommend routine CXRs but does recommend consideration for obtaining CXRs in patients who are smokers, have had recent upper respiratory tract infections, have chronic obstructive pulmonary disease (COPD), and have heart disease. The CXR is more likely to provide useful information in patients with less stable pulmonary disease and also in patients with heart failure.

Blood Tests

Routine blood testing is not recommended, but blood testing is reasonable in ASA III or greater patients and should be considered in all patients undergoing high-risk surgery. Hematocrit, or hemoglobin, is specifically recommended in higher-risk patients for more invasive procedures, patients with liver disease, patients with a history of bleeding or anemia, and patients at extremes of age. Coagulation studies are specifically recommended by the ASA for patients with dysfunctional bleeding, renal disease, and liver disease.

TABLE 1: American Society of Anesthesia classification system

ASA class	
I	Healthy patient
II	Mild/well-controlled disease
III	Severe/multiple systemic disease(s)
IV	Life-threatening disease
V	Severely ill patient who may not survive without operation
VI	Brain-dead patient for organ procurement

From American Society of Anesthesia (ASA) Classification System.

BOX 1: Revised cardiac risk index

1. Heart failure
2. Cerebrovascular disease
3. Ischemic heart disease
4. Diabetes
5. Creatinine >2.0 mg/dL

Adapted from Fleisher LA: Cardiac risk stratification for noncardiac surgery: update from the American College of Cardiology/American Heart Association 2007 guidelines, Cleve Clin J Med *76 Suppl(4):S9-S15, 2009; and Lee TH, et al.: Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery,* Circulation *100(10):1043-1049, 1999.*

TABLE 2: Risk of perioperative cardiac morbidity for noncardiac surgery

Risk category	Surgical procedure	Cardiac morbidity risk
High	Vascular	>5%
Intermediate	Carotid, neurosurgery, ears/nose/throat, abdominal, thoracic, urologic (excluding endoscopic), and orthopedic	1% to 5%
Low	Superficial, cataract, endoscopic, and breast	<1%

Adapted from ACC/AHA 2007 guidelines for noncardiac surgery.

History and physical performed with the anesthesiologist. *COPD,* Chronic obstructive pulmonary disease; *ESRD,* end stage renal disease, *H&P,* history and physical; h/o, history of; *HTN,* hypertension; *ILD,* interstitial lung disease; *PFO,* patent foramen ovale; *RA,* rheumatoid arthritis; *VSD,* ventricular septal defect. *(Adapted from UCSF preoperative stepwise approach to determining the timing and nature of the preoperative assessment for elective noncardiac surgery [2013]).*

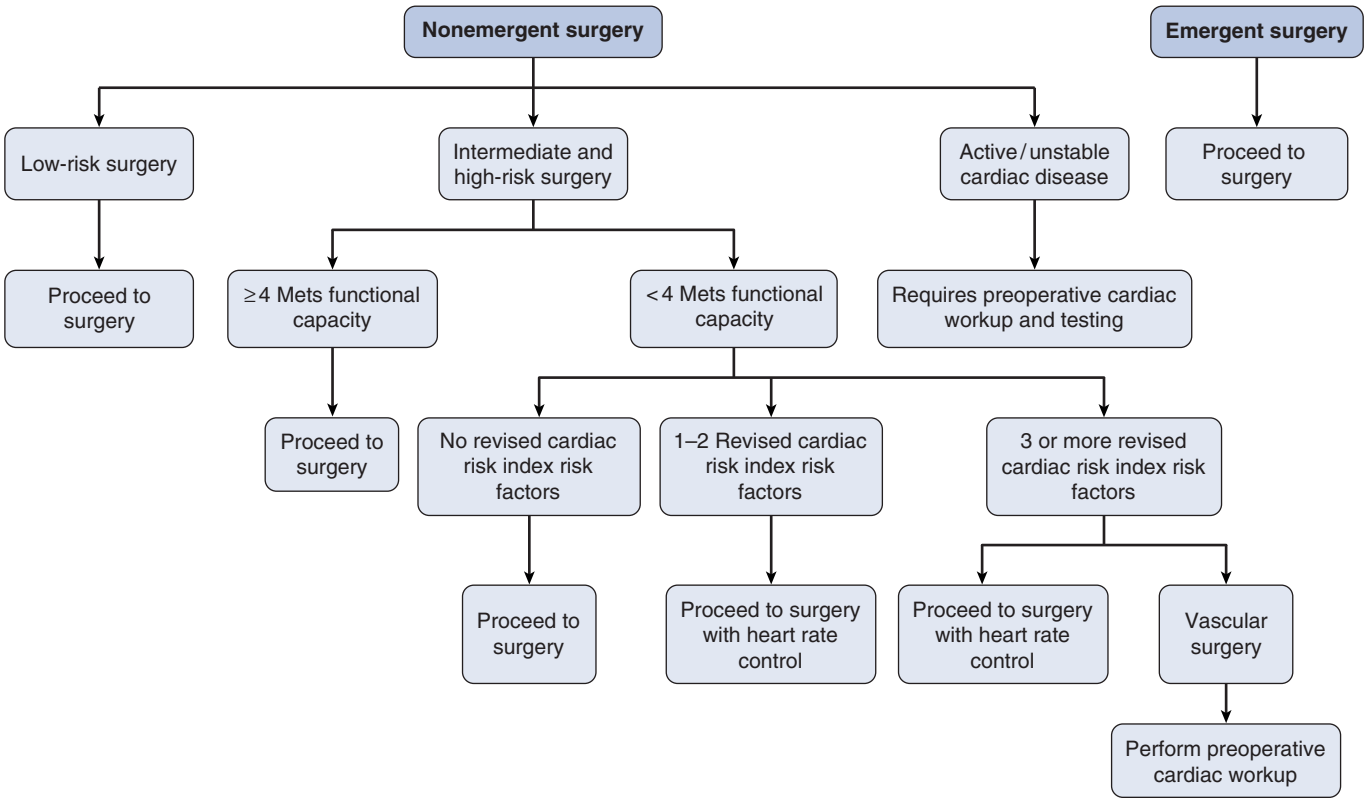

FIGURE 2 Algorithm for preoperative cardiac testing. Note this algorithm refers to the need for additional specific cardiac testing only. Depending on the patient's comorbidities and planned surgery, preoperative testing and evaluation may still be required. *(Adapted from Fleisher LA, et al: ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. Executive summary: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines [writing committee to revise the 2002 guidelines on perioperative cardiovascular evaluation for noncardiac surgery] developed in collaboration with the American Society of Echocardiography, American Society of Nuclear Cardiology, Heart Rhythm Society, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, and Society for Vascular Surgery,* J Am Coll Cardiol *50(17):1707-1732, 2007.)*

Urine Testing

Urinalysis is specifically recommended by the ASA for patients scheduled for prosthetic implantation, patients with urinary tract infection symptoms, and some urologic procedures. Pregnancy testing should be obtained in any female of childbearing age.

COMORBIDITIES

Chronic comorbidities are common in the surgical patient, and many patients often have multiple comorbidities. The most important principles in managing chronic disease in the preoperative setting are to optimize and stabilize patients' diseases as much as possible. It's always preferable to delay operation, whenever possible, in the setting of an acute or recent exacerbation of any chronic state. Communication among the surgeon, anesthesiologist, primary care physicians, and specialists is essential. Usually, patients with stable chronic disease who receive normal follow-up for their disease will not require additional testing prior to surgery.

Cardiac Disease

Ischemic heart disease, heart failure, and valvular abnormalities represent the most common cardiac conditions encountered in the perioperative period. Surgery should be delayed in any patient with unstable angina, with unstable heart failure, or who otherwise meets criteria for further cardiac workup until that workup is completed (see Box 1 and Figure 2). A recent echocardiogram should be available in patients with moderate to severe valvular disease and heart failure.

If surgery is emergent and a necessary workup cannot be completed, then obtaining an ECG, CXR, and a full set of labs may be helpful. Many institutions can provide transthoracic echocardiography on an emergent basis, and this is likely the single most useful evaluation.

Ischemia and Stents

Following placement of coronary artery stents, dual antiplatelet therapy with aspirin and glycoprotein IIb/IIIa inhibitors is critical to prevent major adverse cardiac events from stent thrombosis. Discontinuation of this therapy places the patient at risk for in-stent thrombosis. Bare-metal stents require a minimum of 1 month of dual antiplatelet therapy, whereas drug-eluting stents require a minimum of 3 months of dual antiplatelet therapy for Sirolimus stents and 6 months of minimum therapy for Paclitaxel stents. One year of therapy is strongly recommended for all stent placements. In-stent thrombosis rates of up to 25% to 30% have been reported in patients when dual antiplatelet therapy was prematurely discontinued.

Whenever possible, all elective surgical procedures should be deferred until the patient is out of this initial 1-year window following stent placement. If semielective or urgent surgery is necessary, it is preferred to delay the procedure until a patient with a bare-metal

stent is 1 month out from stent placement and a patient with a drug-eluting stent is 3 months out from stent placement. The American College of Chest Physicians advocates waiting 6 weeks after bare-metal stent placement and 6 months after drug-eluting stent placement. Aspirin should be continued if possible. Close communication with the patient's cardiologist is critical for perioperative management recommendations and to determine whether ASA can be continued perioperatively.

Pacemakers and Defibrillators

Pacemakers and defibrillators are becoming more common in the surgical patient. The increasing variety and complexity of these devices can make perioperative care challenging. Device firing and malfunction are a risk with most surgical procedures. For example, some pacemakers may sense electrocautery discharges as abnormal heartbeats and therefore suppress discharges. This is particularly problematic in pacemaker-dependent patients. An internal defibrillator may sense the same electrocautery discharges as an arrhythmia, causing the defibrillator to attempt cardioversion.

Historically, a magnet was placed over the electric cardiovascular device during surgery. However, with the current generation of devices, the response to magnet placement is not always predictable. Some defibrillators turn off when a magnet is placed over them and do not turn back on until the magnet is removed and replaced over the device again. Some pacemakers enter a no-sense pacing mode when a magnet is placed over them, whereas other pacemakers may reprogram with magnet placement. Pacemaker-defibrillator combination devices are also common with unpredictable magnet responses. The guidelines for preoperative management were organized in a 2011 consensus statement by the Heart Rhythm Society and the American Society of Anesthesiologists.

Find out the type of cardiovascular implantable device and the indication for the device. If the patient does not know, try to obtain this information from the patient's primary caregiver or cardiologist. Pacemakers should be interrogated every 12 months and defibrillators interrogated every 6 months at a minimum in stable patients. Obtain information about the last interrogation, pacemaker dependency, underlying rhythm, battery longevity, and magnet response. Patients are also given wallet-size cards with their device name and serial number. These cards will have the phone number of the company that manufactured the device, which can be contacted for information and advice. Companies keep records of the patients, their devices, indications, and programming. Representatives will be able to tell you what the implanted device does and its response to magnets. This is particularly useful in the case of emergent surgical procedures where outside records are not easily accessible. It is also recommended that the devices be interrogated at the conclusion of the procedure to be sure they are functioning as intended.

Pulmonary Disease

Pulmonary diseases can increase the risk of both pulmonary and nonpulmonary perioperative complications. Asthma does not increase the risk of postoperative pulmonary complications but does increase the risk of intraoperative pulmonary complications, such as bronchospasm with intubation. COPD and obstructive sleep apnea (OSA) both increase the risk of intraoperative and postoperative pulmonary complications. A diagnosis of COPD confers the highest risk of postoperative pulmonary complications. OSA increases the risk for airway management problems in the perioperative period. Extremes of age and higher ASA status have been shown to be independent predictors of increased postoperative pulmonary complications. Thoracic, major abdominal, open abdominal aortic aneurysm repair, and surgical procedures lasting more than 3 hours all increase the risk of postoperative pulmonary complications. However, additional testing is usually not necessary prior to surgery for these patients.

Specific questions to ask your patient include ascertaining the severity of their illness, exercise tolerance, baseline symptoms, recent exacerbations, and medications. Generally, regular medications, such as inhaled bronchodilators and corticosteroids, should be continued through the perioperative period. Patients taking oral corticosteroids should continue their corticosteroid medications and may require a perioperative burst dose. Smoking cessation should be encouraged. Smoking does increase the risk of postoperative pulmonary complications. Carbon monoxide levels from smoking within 12 hours of cessation and sputum production will begin to decrease within 1 to 2 months.

Routine spirometry testing is usually not indicated. Spirometry may be indicated in patients undergoing specific thoracic procedures, especially lobectomy and pneumonectomy. Low serum albumin is an independent predictor of postoperative pulmonary complications, as well as a predictor of increased postoperative morbidity and mortality.

For patients with high risk of intraoperative and postoperative pulmonary complications, the anesthesiologist may recommend peripheral or neuraxial nerve blockade versus general anesthesia where appropriate. For patients undergoing thoracotomy, epidural analgesia is particularly useful for postoperative pain management because it can spare large doses of opiates that cause respiratory depression.

Liver Disease

Liver disease is common in the surgical patient. Alcohol, viral hepatitis, and now nonalcoholic fatty liver disease are the most common causes of cirrhosis in the United States. Patients with liver disease are at significantly increased risk for perioperative morbidity and mortality. Classically, the Childs-Pugh score has been used to predict postoperative mortality. The Model for End Stage Liver Disease Score is now used more frequently to confer the severity of liver disease and perioperative risk.

All patients with liver disease should have complete blood counts, coagulation studies, complete metabolic panels, and albumin levels tested preoperatively. In fact, patients with unexplained thrombocytopenia should be investigated for possible liver disease. Hepatosplenomegaly, ascites, and signs of portal hypertension should all be sought on physical exam. Up to 30% of patients with cirrhosis have evidence of hepatopulmonary syndrome leading to hypoxemia. Low oxygen saturation, peripheral cyanosis, or clubbing should prompt investigation with arterial blood gases and possible echocardiography with bubble study to identify intrapulmonary or extrapulmonary shunting.

Diabetes

Diabetes is prevalent in the United States, and complications from diabetes affect multiple organ systems. Managing glucose perioperatively is essential but difficult. Hyperglycemia is associated with increased surgical site infections, whereas hypoglycemia can be devastating to the patient.

Patients with insulin pumps should continue their basal insulin rate unchanged. The only exception to this is if the patient has been hypoglycemic on his or her basal infusion, indicating that the basal infusion is too high. In this case, the basal rate should be decreased. Patients taking long-acting insulins such as glargine should continue to take it, but the preoperative dose should be 75% of normal. Patients taking NPH insulin can take their full dose of NPH the evening prior to surgery but decrease any morning dose by 50% on the day of surgery. Oral hypoglycemic agents can be taken the day prior to surgery but discontinued on the day of surgery. Metformin

is an exception and should be discontinued the night prior to surgery. Of course, all diabetic preoperative patients should carefully monitor their glucose levels to avoid hypoglycemia or extreme hyperglycemia.

Diabetic patients are at risk for electrolyte abnormalities, as well as heart, vascular, kidney, and neuropathic disease and should be screened accordingly preoperatively. Obtain an ECG, complete blood count, and chemistry panel.

Renal Disease

Chronic kidney disease, defined as 3 months or greater with a glomerular filtration rate of less than 60 mL/min/1.73 m^2 or pathologic evidence of kidney damage, is estimated to affect over 26 million Americans. Diabetes and hypertension are common comorbidities that can make these patients challenging to manage perioperatively. In fact, kidney disease is an independent risk factor for cardiac disease (see Box 1). Additionally, the perioperative period marks a vulnerable time for chronic kidney patients who are not on dialysis. These patients are extremely susceptible to further kidney impairment, which often does not return to baseline.

Patients with chronic kidney disease requiring hemodialysis should receive dialysis as scheduled preoperatively, with laboratory studies checked following dialysis. Patients not on dialysis should be at their baseline creatinine preoperatively whenever possible. Chronic kidney disease patients are prone to volume shifts, electrolyte abnormalities, and anemia. Obtain a preoperative ECG, a chemistry panel, and complete blood counts preoperatively.

Obesity

Obesity is a growing epidemic in the United States and most developed countries. The obesity syndrome is often complicated by many of the comorbidities already mentioned. However, it is important to note that obesity itself represents an additional risk during surgery and anesthesia. Obese patients have a higher risk of surgical site infection and thromboembolic complications. Obese patients are also more likely to present airway management challenges for the anesthesiologist. Obstructive sleep apnea is a common comorbidity that may benefit from additional postoperative monitoring, such as continuous pulse oximetry or a more highly monitored bed. Obese patients are also more prone to positioning injuries and can have difficult intravenous access leading to infiltrated lines and may require central line placement. Optimizing as many of the associated comorbidities as possible in your obese patients prior to surgery is critical. Educating patients about these specific risks is important as well.

Obstructive sleep apnea is exacerbated postoperatively due to residual anesthetic and analgesic medications. If your patient does have obstructive sleep apnea, instruct him or her to bring their continuous positive airway pressure (CPAP) machine with them to the hospital for use in the recovery room and postoperative ward. If your patient does have OSA but does not have a CPAP machine, consider requesting one for use in-house. Use of a CPAP machine may require a ward with a higher level of care, depending on your institution. Requesting critical care or step-down care ahead of time will help to set patient expectations and reduce delays after surgery.

MEDICATION MANAGEMENT

Angiotensin Converting Enzyme Inhibitors

Angiotensin converting enzyme inhibitors (ACE-inhibitors) and angiotensin receptor blockers (ARBs) are common antihypertensive agents. These agents have shown specific mortality benefit post myocardial infarction and in systolic heart failure. Intraoperative hypotension is a major side effect of ACE-inhibitors and ARBs. Intraoperative hypotension can be refractory, sometimes requiring vasopressin infusions. Common practice is to hold the ACE-inhibitor/ARB the morning of surgery. New studies are emerging showing a possible trend toward an increased number of postoperative cardiovascular events in patients where an ACE-inhibitor/ARB was held. Randomized controlled trials are needed to fully investigate this question. Given the known risk of refractory intraoperative hypotension, we recommend holding ACE-inhibitors/ARBs the morning of surgery and restarting this therapy as soon as the surgical patient is stable postoperatively.

Anticoagulants

Over 250,000 patients in North America are currently taking either a vitamin K antagonist (VKA) or antiplatelet drugs. The American College of Chest Physicians developed guidelines to inform decision making with regards to antithrombotic management in the perioperative period. Management should take into account the patient's risk for a thromboembolic event and the patient's risk of bleeding during the procedure.

Patients who require temporary interruption of VKAs for surgery should stop taking the VKA 5 days prior to surgery and resume taking the VKA 12 to 24 hours after surgery, providing adequate hemostasis. Patients with mechanical heart valves, history of venous thromboembolism, or atrial fibrillation at low risk for thromboembolism do not need bridging anticoagulation therapy. Those at high risk for thromboembolism do require bridging therapy (Table 3).

Patients undergoing minor dental procedures, dermatologic procedures, or cataract surgery should continue VKA therapy uninterrupted. Consider stopping VKA 2 to 3 days prior to dental procedure if the procedure is higher risk for bleeding or difficult hemostasis.

Direct thrombin inhibitors (DTIs) are an emerging drug class that can be used as an alternative to VKAs. The four most common DTIs are apixaban, dagibatran, edoxaban, and rivaroxaban. Clinically these drugs differ from VKAs in several ways. Therapeutic anticoagulation is achieved within hours of starting a DTI versus days for VKAs. DTIs affect INR, but the INR does not accurately reflect the level of anticoagulation. Currently, we do not have a readily available standardized laboratory test to monitor DTI anticoagulation levels. Importantly, there are no specific reversal agents for DTIs. This is particularly important to be aware of perioperatively. Activated factor VIIa is a nonspecific agent that can be used to promote hemostasis.

DTIs should be managed similarly to VKAs preoperatively with regards to risk stratification of venous thromboembolism and risk of surgical bleeding. One reasonable management scheme includes stopping the DTI 5 days prior to surgery and, when necessary, briding the patient with heparin (low molecular weight or unfractionated).

Aspirin should be continued for patients on aspirin therapy at high risk for cardiovascular events undergoing noncardiac surgery. If the patient is at low risk for cardiovascular events, aspirin can be discontinued 7 to 10 days prior to noncardiac surgery. Aspirin should be continued prior to cardiac surgery. Cardiac surgery patients on dual antiplatelet therapy should stop the antiplatelet drug prior to cardiac surgery but continue their aspirin. New antiplatelet drugs require different discontinuation times prior to surgery. Clopidogrel should be discontinued 5 days prior to surgery when appropriate. Other antiplatelet agents may require different stop times depending on their pharmacology.

Bridging therapy with unfractionated heparin drips should be discontinued 4 to 6 hours prior to surgery. Therapeutic enoxaprin should be discontinued 24 hours prior to the start of surgery and resumed 48 to 72 hours after surgery.

TABLE 3: Risk stratification for perioperative thromboembolism

Risk	Mechanical heart valve	Atrial fibrillation	Venous thromboembolism (VTE)
High (>10% annual risk)	Any mitral valve prosthesis Mechanical aortic valve prosthesis Stroke or TIA <6 months	$CHADS_2$ 5-6 Stroke or TIA <3 months Rheumatic heart disease	VTE <3 months Thrombophilia
Moderate (5% to 10% annual risk)	Bileaflet aortic valve prosthesis + (*1 of the following*): Atrial fibrillation Prior stroke/TIA HTN DM CHF >75 years old	$CHADS_2$ 3-4	VTE 3 to 12 months Factor V Leiden Recurrent VTE Active cancer
Low (<5% annual risk)	Bileaflet aortic valve prosthesis *without* additional risk factor	$CHADS_2$ 0-2	VTE > 12 months prior

Perioperative thromboembolism risk stratification. $CHADS_2$, Congestive heart failure (1 point); Hypertension (1 point); Age ≥ 75 years old (1 point); Diabetes (1 point); and VTE/stroke/TIA (2 points).

Beta-Blockers

Recently, several large randomized control trials have investigated the benefit of beta-blockers in the perioperative setting. Early studies pointed to a decrease in perioperative myocardial ischemia and even decreased long-term postoperative mortality. More recent studies have elucidated some of the risks of beta-blocker therapy, most noticeably an increased risk for stroke in some beta-blocked surgical patients or increased postoperative mortality, particularly with high-dose untitrated beta-blockade.

The AHA has released new guidelines for beta-blocker therapy in the surgical patient. Patients who are currently taking beta-blockers should continue to take their beta-blocker perioperatively. Patients whose beta-blocker is taken twice daily should take their morning dose of the medication on the day of surgery. Beta-blockers are recommended for patients with signs of ischemia on preoperative testing or with known coronary artery disease who are undergoing vascular surgery. Initiation of beta-blockers is reasonable in patients undergoing vascular surgery, patients at risk for coronary artery disease, or patients at high cardiac risk who are undergoing intermediate risk surgery. Any patient initiated on beta-blocker therapy needs to be closely monitored and the beta-blocker started and titrated prior to surgery.

Herbal Medications

Herbal medications are becoming increasingly popular. Herbal medications are considered dietary supplements and therefore are not regulated for safety or efficacy. Many patients do not consider herbs and vitamins as medications and may not disclose them with their medication lists. Herbal medications have a wide range of possible clinical implications from garlic's antiplatelet properties to St. John's wart's inhibition of serotonin, norepinephrine, and dopamine reuptake.

Given the expanse of herbal medications available, some with known and some with unknown medical implications, we conservatively recommend discontinuing herbal medications for 7 to 10 days prior to surgery.

Opiates

Many surgical patients take opiates chronically. These patients can be challenging to manage perioperatively. An important aspect to keep in mind is that the pain medications the patient takes on a daily basis represent that patient's baseline opiate requirements. Obtaining an accurate history as to the actual opiate consumption preoperatively is crucial. The chronic pain patient will require pain medications in addition to this baseline requirement postoperatively. Therefore, we recommend that these patients take their scheduled opiates even on the day of surgery. Patients also taking as-needed opiates should continue to take those opiates if needed on the day of surgery.

Proton Pump Inhibitors and Histamine-2 Blockers

Patients routinely taking proton pump inhibitors or histamine-2 blockers should continue taking these medications throughout the perioperative period. Patients should take their daily dose of this medication on the morning of their surgical procedure.

SUMMARY

As our medical capabilities and knowledge expand, our surgical population grows more complex. Today our perioperative patients have more comorbidities than ever before. Similarly, the preoperative preparation of our patients is more important than ever. Our common goal is to safely get these patients into and out of the operating room. This chapter summarizes some of the common surgical comorbidities, testing, and medication strategies. No preoperative test will ever take the place of the thoughtful history and physical examination, and robust communication between the anesthesia and surgical teams provides the framework for optimal outcomes.

Is a Nasogastric Tube Necessary After Alimentary Tract Surgery?

Jordan E. Fishman, MD, MPH, and Adrian Barbul, MD, FACS

Nasogastric (NG) tubes have long been a mainstay in the surgical armamentarium and remain a well-established method for both gastrointestinal decompression and the provision of enteral nutrition. Routine postoperative placement of NG tubes entered clinical practice in the 1930s. Guided by both early clinical evidence and an understanding of the relevant gastrointestinal physiology, widespread adaption soon followed. So revered was NG tube placement that W.J. Mayo once remarked that he "would rather have a resident with a nasogastric tube in his pocket than a stethoscope." With the introduction of evidence-based medicine, many tenets long associated with surgical dogma have been evaluated in a prospective randomized controlled trial format; routine placement of NG tubes after alimentary tract surgery is no exception.

Some historical controversy surrounds the origin of NG tube usage. Many attribute the first NG tube to renowned anatomist and Italian surgeon Hieronymus Fabricius (Fabricus ab Aquapendente, 1537-1619) who described the insertion of a silver tube into a patient to provide enteral feeds. Others credit John Hunter with the first reported use of a NG tube based on a 1790 publication of the Transactions of a Society for the Improvement of Medical and Chirugical Knowledge. In it, Hunter describes the insertion of a tube composed of eel skin stretched over a whale bone into a patient who was unable to feed himself after a cerebrovascular accident. Although NG tube gastric lavage was reported in the early 19th century, it remained a largely ignored footnote. Adolph Kussmaul is credited with the first use of a NG tube for gastric decompression in 1884. The introduction of a flexible rubber tube (the Levin tube) in 1921 and McIver's theory published 5 years later that postoperative abdominal distention is caused by swallowed air and could be prevented with use of the Levin tube set the groundwork for mainstream application of NG tubes. McIver's theory was tested in 1933 by Wangensteen and Paine who proposed NG tube decompression for small bowel obstruction as an alternative to surgical intervention. This therapy was so successful that widespread adaptation of this practice soon followed, and prophylactic placement of a NG tube after abdominal surgery became de rigueur. This belief was further codified in 1971 by the American College of Surgeons manual of preoperative and postoperative care, which explicitly stated that "intestinal decompression is required after resection and reanastomosis of gastrointestinal tract."

Currently, two distinct purposes exist for the continuation of NG tubes after alimentary tract surgery: provision of enteral nutrition and decompression of the gastrointestinal tract. Although the specific route of enteral feeds (i.e., NG vs oral gastric vs percutaneous gastric, etc.) has not been explicitly addressed in a prospective randomized controlled trial, the superiority of enteral nutrition to both parenteral nutrition and nil per os (NPO) status after surgery has been addressed. Multiple prospective randomized controlled trials and subsequent meta-analyses have shown a reduction in overall mortality, postoperative infectious complications, length of hospital stay, and even decreased gastrointestinal anastomosis breakdown in patients who were fed enterally soon after surgery. Although a more thorough review of enteral feeding after gastrointestinal surgery is beyond the scope of this chapter, it can be reasonably surmised that in patients who are not expected to able to feed themselves after surgery, the placement and maintenance of a NG tube for the specific purpose of enteral nutrition is in keeping with best current surgical practice.

Unlike the placement of a NG tube specifically for enteral nutrition, the role of postoperative NG tube placement for gastrointestinal decompression has been well studied. Early proponents for NG tube placement after surgery believed that gastrointestinal decompression would decrease patient discomfort, reduce postoperative nausea and vomiting, and speed the recovery from postoperative ileus. It was also believed that decompression would decrease the intraluminal

pressure of the gastrointestinal tract and thereby protect the newly created anastomosis from excessive tension and subsequent breakdown. Furthermore, NG tube decompression was postulated to reduce tension on the abdominal wound and thereby reduce the rates of wound infection, wound failure, and hernia formation. NG tube usage was also thought to provide the surgeon insight into potential intraluminal complications such as postoperative leaks and hemorrhage.

The first to challenge the necessity of NG tube decompression after surgery was Gerber in 1958. In a nonrandomized study of 600 patients with paralytic ileus, half of the patients received a NG tube, and the other half did not. Patients who did not receive nasogastric decompression had less mortality and morbidity than those who did. NG tube decompression was also associated with a higher incidence of respiratory tract complications. After this publication, many case series and nonrandomized trials showing the safety of gastrointestinal surgery without the use of NG tube decompression were published throughout the 1960s and 1970s. Although these publications began to erode the belief in the necessity of gastrointestinal decompression, a greater understanding of the anatomy and physiology of the gastrointestinal tract was necessary before further changes in practice could be accepted.

The belief that postoperative ileus was a gastrointestinal problem was specifically challenged by Woods and colleagues in 1978. Previous work by Smith and associates showed that small bowel motility returns soon after surgery. Woods and colleagues, however, evaluated the entire gastrointestinal tract. With use of an animal model of laparotomy, the postoperative electromechanical activity of the gastric antrum, small bowel, right colon, and sigmoid colon were recorded. They noted that the electromechanical activity of the gastric antrum and the small bowel were affected by surgery but that they returned to normal levels almost immediately. This was in stark contrast to the electromechanical activity of the right colon, which was significantly decreased for a 24-hour period, and that of the sigmoid colon. The decrease in the electromechanical activity of the sigmoid colon was both more profound than that of any other segment and found to last for much longer, namely, 72 hours. Thus, postoperative ileus was cast as a dysfunction of the colon, not a dysfunction of the stomach or the small bowel, and therefore was unlikely amenable to decompression of the stomach or small intestine.

The first study to specifically address this issue in a prospective randomized controlled trial format was published by Reasbeck and associates in 1984. Patients with an operation that resulted in an enteric suture line were divided into two groups: one group received a prophylactic NG tube, and the other group did not. The outcomes studied were differences in postoperative complication rates. This study is notable for its broad inclusion of surgical anastomoses, ranging from the biliary-enteric to the colocolonic. No statistical difference in postoperative complication was noted between the two arms of the study. Unfortunately, because of the large range of surgical procedures and the relatively small sample size, a large number of the same type of cases was not included in the study.

In 1985, Bauer and colleagues examined the role of prophylactic postoperative NG tube placement in a prospective randomized control trial format in a study involving 200 patients. One hundred patients received a NG tube that was placed during surgery and remained in place until the passage of flatus; 100 other patients underwent NG tube placement during surgery and removal at the conclusion of the procedure. Although most cases in this study involved an anastomosis, the authors included a number of additional intraabdominal procedures that did not (splenectomy, cholecystecomy, etc.). Five patients who were randomized to the nasogastric decompression group had a NG tube reinserted after removal; six patients who were not subjected to postoperative NG tube decompression subsequently needed NG tube insertion. Indications for NG insertion or reinsertion included vomiting, gross distention, or overt obstruction in the postoperative period. No statistical difference was found in frequency or type of postoperative pulmonary complication (pneumonia or atelectasis). In addition, no statistical difference was seen between wound dehiscence, anastomotic leak, or wound infection.

Although these studies were effective in establishing the general concept that routine NG tube decompression after alimentary tract surgery is unnecessary, many surgeons believed that they were inadequately powered to change management for specific operations. Given the large clinical interest in this subject, further prospective randomized control trials followed. Some of these trials showed that prophylactic postoperative nasogastric decompression via NG tube increased subsequent complications, and others reported no statistical difference in the overall complication rate. By the mid 1990s, a sufficient number of publications showed some diversity of opinion to support a meta-analysis.

Cheatham and associates published the first large scale meta-analysis of the use of prophylactic postoperative NG tubes in 1995 and included publications from 1955 through 1993. Both randomized and nonrandomized trials were included in the meta-analysis, encompassing a total of 26 trials, which brought the study population to 3964. Specific postoperative complications investigated included: death, pneumonia, atelectasis, aspiration, fever, nausea, vomiting, abdominal distention, wound dehiscence, wound infection, anastomotic leak, oral feeding, and hospital length of stay. In all measured outcomes, no advantage was found to routine use of postoperative NG tube placement. A statistically significant reduction was seen in the overall complication rate for patients who were not treated with routine placement of a NG tube. This was manifest as a statistically significant decreased rate of postoperative pneumonia, atelectasis, and fever. Although a trend towards significance in increased postoperative vomiting and abdominal distention was found, especially when six less rigorous clinical trials were excluded from the meta-analysis, this did not increase the incidence of serious or nonserious postoperative complications. This meta-analysis included a wide variety of intraabdominal surgical procedures, but it is notable for its inclusion of 20 nonrandomized trials and relative paucity of emergency cases. Additional research was needed to further resolve this issue.

Nelson and associates conducted an additional large-scale meta-analysis that was subsequently published in 2005 and supported the nonsuperiority of prophylactic NG tube placement. Several more followed, many including earlier studies (Table 1). In none of these analyses was any detrimental effect associated with the avoidance of routine NG tube placement.

Although there is a preponderance of high-quality research evaluating the issue of routine prophylactic nasogastric decompression, many surgeons still practice this treatment modality on the belief that it will hasten the return of bowel function, ease respiration or aspiration of gastric contents by emptying the stomach, increase patient comfort, protect intestinal anastomoses, and shorten hospital stay. In addition, many surgeons believe the complications of NG tube intubation are so rare and infrequent that it is essentially a risk-free procedure. In their 1985 article, Bauer and colleagues reported that 70% of patients found the NG tube to be a source of significant discomfort. Essenhigh and associates describe how 70% of patients found NG tube intubation either "distressing" or "unpleasant." One study that examined NG tube complications found these to occur in 63% of patients studied. Although many of these complications were minor, such as vomiting, nasopharyngeal soreness, cough, wheezing, or sinusitis, the result is nonetheless compelling. Reported complication rates for NG tube intubation vary from 0.2% to 7.6%. The most common complication, malposition, occurs between 1.3% and 2.4% and can result in both pneumonia and pneumothorax. Other reported serious complications include esophageal perforations, tracheoesophageal fistulas, gastric perforations, sinusitis, epistaxis, and intracranial placement. These complications are infrequent, but they serve to dispel the myth that NG tube intubation is entirely benign.

NG tube insertion should be undertaken with great care and with an understanding of the relevant anatomy involved. Numerous

TABLE 1: Summary of meta-analyses that address nasogastric tube placement

Author	No. of patients/no. of included studies	Outcomes evaluated	Benefits noted
Cheatham	3964/26	Death, pneumonia, atelectasis, aspiration, fever, nausea, vomiting, distension, wound dehiscence, SSI, leaks, time to oral feeds, hospital LOS	Decreased pneumonia, atelectasis, and fever
Nelson (2005)	4194/28	Time to flatus, pulmonary complications, SSI, ventral hernia, leaks, LOS, nausea/vomiting	Earlier return of bowel function
Nelson (2007)	5240/33	Time to flatus, pulmonary complications, fever, SSI, wound dehiscence, leaks, LOS, incisional hernia, nausea/vomiting, tube complications	Earlier return of bowel function, decrease in pulmonary complications
Yang	717/5	All gastrectomy: time to flatus, time to oral intake, leaks, pulmonary complications, LOS, morbidity, mortality	Decrease in time to starting oral diet
Verma	5711/37	Time to flatus, pulmonary complications, SSI, leak, incisional hernia, LOS, gastric upsets	Decrease pulmonary complications, earlier return bowel function

LOS, Length of stay; *SSI,* surgical site infection.

reports are found of NG tube passage into both the cranial vault, via the cribriform plate, and the mediastinum, through a perforated esophagus. Therefore, NG intubation should be undertaken with extreme caution, if at all, in patients with maxillofacial trauma. In addition, care must be taken in patients who have ingested caustic material, have a history of esophageal strictures, or have had recent esophageal surgery to avoid esophageal perforation.

Placement of the NG tube can be facilitated with application of topical anesthetics to the nasal and oral mucosa with viscous lidocaine jelly, or preferably, aerosolized benzocaine. Once the patient has been adequately anesthetized and the procedure has been adequately explained, the passage depth needed is approximated with measurement of the distance between the nostrils through the angle of the mandible to the xiphoid process. This position should be marked on the tube. Ask patients to sit up and place their chin to their chest to help facilitate esophageal placement. The tip of the NG tube is then lubricated with surgical jelly and advanced into the nares, with aiming posteriorly and inferiorly. Many patients gag as the tube approaches the laryngeal apparatus. Instruct the patient to swallow and time further tube advancement to occur during active swallowing. The NG tube is advanced in this fashion until the previously measured mark is reached. Rapid but imprecise confirmation of tube placement can be done with aspiration of gastric contents or audible gastric sounds with tube insufflation. Proper placement, however, should always be confirmed radiologically with visualization of the NG tube tip below the diaphragm. An excellent video tutorial describing NG tube placement is available online.

Since the advent of the Levin tube, nasogastric decompression has revolutionized the treatment of bowel obstruction. In fact, it remains the treatment of choice for temporizing bowel obstructions, often allowing for successful nonoperative management. There are also clear indications for the use of NG tubes for gastrointestinal decompression after gastrointestinal surgery (e.g., persistent vomiting and bowel obstruction). In addition, NG tube intubation is an easy solution for patients who need enteral nutrition or medication that cannot be delivered orally. However, despite these specific indications for use, current evidence clearly shows that the routine placement of NG tubes after alimentary tract surgery does not benefit the patient and possibly causes an increase in detrimental outcomes and discomfort. In summary, the authors do not recommend routine or prophylactic NG tube usage after gastrointestinal surgery.

Surgical Site Infections

Laura H. Rosenberger, MD, MS, and Robert G. Sawyer, MD

OVERVIEW

Surgical site infections (SSIs) are a common surgical complication that affects between 2% and 5% of the 30 to 40 million operations that occur in the United States per year. SSIs are the most common nosocomial infection among surgical patients and are consistently the second most common healthcare-associated infection overall. Mortality rates after SSI are markedly higher when compared with patients without an SSI, as are the patient's length of stay (mean, 7 days), hospital readmission rates, and direct patient costs ($500 to $3000 per infection).

DEFINITION

Controversy and ambiguity continue to exist in the definition of an SSI. Experts may disagree about the appearance of an incision in regards to SSI, particularly in the presence of surrounding cellulitis or wound drainage. In 1970, the Centers for Disease Control and Prevention (CDC) established the National Nosocomial Infections Surveillance (NNIS) system (now part of the National Healthcare Safety Network [NHSN]) in part to create criteria defining SSI and to standardize the definition for accurate surveillance and reporting. Currently, it is the national standard by which medical personnel and researchers consistently define SSI.

By definition, SSIs occur within the first 30 days after the operation if no implant is placed or within 1 year if an implant remains. The classification scheme defines the following two categories of SSI based on location: incisional SSI (subdivided into superficial and deep) and organ/space SSI (Figure 1). Specific criteria for defining each of the categories of SSI infection can be found in the CDC's Guidelines for Prevention of Surgical Site Infection.

RISK FACTORS

Development of an SSI requires microorganism contamination at the surgical site. During an operative procedure in which skin is incised, endogenous skin flora, the most common source of pathogens, are introduced into the exposed tissue. Additional sources of bacteria include patient colonization, mucous membrane or hollow viscous pathogens encountered during the operation, surgical personnel, operative instruments, and the operating room environment.

An accepted surrogate for bacterial contamination at the surgical site is the wound classification. The risk of SSI increases with the degree of contamination and higher wound classifications. Wounds are classically defined as clean, clean-contaminated, contaminated, or dirty/infected, as seen in Table 1. Numerous additional characteristics contribute to the risk of SSI development, including patient factors, environmental factors, and treatment factors, as seen in Table 2.

The NHSN developed a risk index by which the risk of an SSI can be predicted based on three major criteria: wound classification, American Society of Anesthesiologists (ASA) score, and duration of the operation. The SSI risk category is based on the number of factors present at the time of operation, including a wound class of 3 (contaminated) or 4 (dirty), an ASA class of 3 or greater, and an operation lasting longer than the 75th percentile of the duration of the specific operation. Each independent factor is given a single point if present, which determines the NHSN risk index category (0 to 3). As seen in Table 3, the risk of SSI increases with progressive wound classifications and with progressive NHSN score.

The laparoscopic approach to an operation has been associated with a decreased risk of SSI as a result of small wound size, limited use of cautery, and decreased inflammatory response to tissue injury. This decrease in SSI risk has led to a modification of the risk classification. For laparoscopic biliary, gastric, or colon operations, a –1 is applied, essentially subtracting one risk factor when the operation is completed via a laparoscope.

PREVENTION

Patient Preparation

Prevention of SSIs should start as early as the preoperative clinic visit. Patient factors that may be modified before surgery should be corrected when possible. This includes clearing of remote site infections; initiation of an active smoking cessation program; optimization of nutritional status, including potential supplemental enteric feeding; weight loss for obese patients; whole body showering with a chlorhexidine antimicrobial solution; and prohibition of shaving just before the operation. Although not all of these interventions have proven benefits, they are simple inexpensive interventions that involve patients in their own medical care, an invaluable contribution to SSI prevention.

Immediate Preoperative Prevention

In response to inconsistent compliance with *proven* infection prevention measures, the Centers for Medicare and Medicaid Services (CMS) collaborated with the CDC on the Surgical Infection Prevention (SIP) project in 2002. This project developed quality improvement measures including the timeliness, selection, and duration of prophylactic antibiotics. In 2006, the Surgical Care Improvement Project (SCIP) developed out of the SIP and its process measures. The SCIP initiatives were published in the Specifications Manual for National Inpatient Quality Measures (Specifications Manual) and provided a standard form of quality measures to document and track standards of care (available online at www.qualitynet.org). The manual outlined seven infection-related process measures applicable to the perioperative period (Table 4). The initiatives that are outlined in SCIP infection measures (INF) 1 to 4, 6, and 10 highlight important process measures to prevent SSIs.

Prophylactic Antibiotics (SCIP INF 1 to 3)

Numerous studies have shown that provision of antimicrobial prophylaxis within 1 hour before the surgical incision allows blood and tissue concentrations adequate to prevent SSIs. A number of studies revealed enhanced compliance with antibiotic timing significantly reduced postoperative infectious complications, including SSIs. One notable prospective multicenter study attempted to define the optimal timing for antimicrobial prophylaxis and found 0 to 30 minutes to be associated with the fewest SSIs (1.6%). They found the infection risk increased with an extended interval between administration of antimicrobials and incision and with antimicrobial prophylaxis given after incision (Table 5).

Prophylactic antimicrobials should provide coverage for the pathogens most likely to be encountered during the operation, have pharmacokinetics that ensure adequate serum and tissue concentrations, have demonstrated safety, and be cost effective. The class of antibiotics most commonly used for perioperative prophylaxis is the cephalosporins. They are effective against gram-positive and gram-negative pathogens commonly encountered in general surgery and meet other criteria for appropriate prophylactic antimicrobials. Cefazolin is generally the agent of choice for clean and many clean-contaminated cases; a second-generation cephalosporin such as cefoxitin is commonly selected for colon operations for additional anaerobic coverage. For specific classes of operations such as cardiac or orthopedic operations, the antibiotic selection becomes more complex. The SCIP released a pocket card (October 2010) to guide the selection of appropriate antimicrobials based on operative location, class, and potential allergies (Table 6). The authors recommend the surgeon consult a pathogen reference table to determine prophylaxis based on operative type and most likely pathogens encountered (Mangram and colleagues).

The discontinuation of prophylactic antimicrobials is also important in terms of infection control and outcomes regarding SSIs. Significant evidence shows no additional benefit to lengthening the course of prophylactic antimicrobials beyond 24 hours. This is consistent with the rationale that perioperative antibiotics are not meant to sterilize the tissue but rather to reduce the bacterial burden to an inoculum that may be controlled by the patient's defenses. Extending the length of prophylaxis increases the risk of drug resistance and secondary infections, such as *Clostridium difficile*–related disease; therefore, the authors recommend the discontinuation of prophylactic antibiotics after 24 hours.

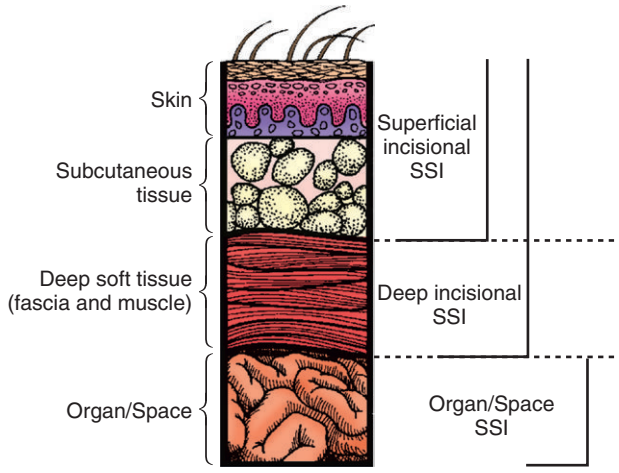

FIGURE 1 Cross section of abdominal wall depicting Centers for Disease Control classifications of surgical site infection *(SSI). (From Mangram AJ, Horan TC, Pearson ML, et al: Guideline for prevention of surgical site infection,* Infect Control Hosp Epidemiol *20(4):247-278, 1999.)*

Appropriate Hair Removal (SCIP INF 6)

The method of hair removal in the preoperative period has been related to the incidence of SSIs. A large prospective trial randomized 2000 patients to either electrical clipping or manual shaving with a razor for hair removal before open heart surgery. The patients who were electrically clipped had a significantly lower rate of mediastinitis compared with the manually shaved group ($P = 0.024$). A Cochrane systematic review confirmed these findings, revealing three randomized trials that compared shaving with clipping. Statistically more SSIs occurred with shaving than with clipping. Shaving with a blade is now considered an inappropriate method of hair removal in the preoperative period and should not be done.

Postoperative Normoglycemia (SCIP INF 4)

Appropriate glucose control in the perioperative period has been shown to reduce the incidence of SSIs. Hyperglycemia impairs the immune system, increases the risk of infection, and worsens the outcomes in sepsis. Studies have shown that tight intraoperative glucose control by anesthesia personnel significantly decreases the risk of SSIs, as does implementation of a postoperative intravenous insulin therapy protocol, continuous insulin infusions (as compared with subcutaneous injections), and maintenance of a mean capillary glucose concentration below 200 mg/dL for a minimum of 48 hours after surgery.

TABLE 1: Surgical wound classifications

Surgical wound classification	Description
Class I/clean	An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or uninfected urinary tract is not entered. In addition, clean wounds are closed primarily and, if necessary, drained with closed drainage.
Class II/clean-contaminated	An operative wound in which the respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions and without unusual contamination. Specifically, operations that involve the biliary tract, appendix, vagina, and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered.
Class III/contaminated	Open, fresh, accidental wounds. In addition, operations with major breaks in sterile technique (e.g., open cardiac massage) or gross spillage from the gastrointestinal tract and incisions in which acute, nonpurulent inflammation is encountered are included in this category.
Class IV/dirty, infected	Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera. This definition suggests that the organisms that cause the postoperative infection were present in the operative field before the operation.

Modified from Mangram AJ, Horan TC, Pearson ML, et al: Guideline for prevention of surgical site infection, Infect Control Hosp Epidemiol *20(4):247-278, 1999.*

TABLE 2: Patient and operative characteristics that may influence the risk of surgical site infection development

Patient factors	Environmental factors	Treatment factors
Ascites	Contaminated medications	Emergency procedure
Chronic inflammation	Inadequate disinfection/sterilization	Failure to obliterate dead space
Coexistent remote infection	Inadequate skin antisepsis	Hypothermia
Colonization with microorganisms	Inadequate ventilation	Inadequate antibiotic prophylaxis
Corticosteroid therapy		Intraoperative blood transfusion
Diabetes		Oxygenation
Extended preoperative admission		Poor hemostasis
Hypocholesterolemia		Prolonged operative time
Hypoxemia		Surgical drains
Malnutrition		Tissue trauma
Obesity		
Peripheral vascular disease		
Perioperative anemia		
Preoperative shaving		
Prior site irradiation		
Recent operation		
Skin disease in the area of infection (e.g., psoriasis)		

Modified from the National Nosocomial Infections Surveillance (NNIS) system report: data summary from January 1992-June 2001, issued August 2001, Am J Infect Control *29:404-421, 2001; and from Mangram AJ, Horan TC, Pearson ML, et al: Guideline for prevention of surgical site infection,* Infect Control Hosp Epidemiol *20(4):247-278, 1999.*

TABLE 3: National Healthcare Safety Network (NHSN) risk index scoring

	NHSN risk index category*				
Wound class	*NNIS 0*	*NNIS 1*	*NNIS 2*	*NNIS 3*	*All*
I: Clean	1.0%	2.3%	5.4%	NA	2.1%
II: Clean-contaminated	2.1%	4.0%	9.5%	NA	3.3%
III: Contaminated	NA	3.4%	6.8%	13.2%	6.4%
IV: Dirty/infected	NA	3.1%	8.1%	12.8%	7.1%
All	1.5%	2.9%	6.8%	13.0%	2.8%

NA, Not applicable; *NNIS,* National Nosocomial Infections Surveillance system.
*NHSN risk index is based on three independent variables: American Society of Anesthesiologists (ASA) score > 2, contaminated or dirty/infected wound class, and length of operation above the 75th percentile for the operation being performed.
Modified from data presented in National Nosocomial Infections Surveillance (NNIS) system report: data summary from January 1992-June 2001, Am J Infect Control *29(6):404-421, 2001.*

Although early data supported strict blood glucose control (<110 mg/dL) as a means to decrease morbidity and mortality in critically ill patients, recent data show higher rates of severe hypoglycemia and adverse events with intensive insulin protocols. The NICE-SUGAR study supported conventional (<180 mg/dL), as opposed to strict, insulin control with equivalent outcomes. This was not specific to SSI outcomes, but this target (180 mg/dL) is recommended as an appropriate glucose concentration level for surgical patients in the perioperative period.

Postoperative Normothermia (SCIP INF 10)

Postoperative hypothermia is a common problem and has been hypothesized to increase SSIs by peripheral vasoconstriction, reduced blood flow and oxygen tension at the tissue level, and impaired immune function in terms of decreased antibody production and reduced neutrophil function. A prospective randomized clinical trial found an active intraoperative warming protocol had significantly fewer SSIs when compared with a standard of care group ($P = 0.009$). Active warming protocols should be implemented in all surgical patients because this is a simple prevention strategy to reduce SSIs.

TABLE 4: Surgical Care Improvement Project (SCIP) performance measures applicable to the perioperative period

SCIP Infection (INF) measure designation	Performance measure title
INF 1	Prophylactic antibiotic received within 1 hour before surgical incision
INF 2	Prophylactic antibiotic selection for surgical patients
INF 3	Prophylactic antibiotics discontinued within 24 hours after surgery end time
INF 4	Cardiac surgery patients with controlled 6:00 AM postoperative blood glucose
INF 6	Surgery patients with appropriate hair removal
INF 9	Urinary catheter removed on postoperative day 1 or postoperative day 2 (with day of surgery being day 0)
INF 10	Surgery patients with perioperative temperature management

Modified from Rosenberger LH, Politano AD, Sawyer RG: The surgical care improvement project and prevention of post-operative infection, including surgical site infection, Surg Infect *12(3):163-168, 2011.*

TABLE 5: Association between timing and surgical site infections for antimicrobial prophylaxis, cephalosporins, or antimicrobials designated to be given within 60 minutes of incision

Timing of antimicrobial prophylaxis	Infections/no. of operations	Infection risk
>120 min before incision	4/96	4.7%
61-120 min before incision	12/489	2.4%
31-60 min before incision	38/1558	2.4%
0-30 min before incision	22/1339	1.6%
1-30 min after incision	4/100	4.0%
>30 min after incision	5/74	6.8%

TABLE 6: Surgical Care Improvement Project (SCIP) pocket card: prophylactic antimicrobial regimen selection for surgery

Surgical procedure	Approved antibiotics
Coronary artery bypass grafting, other cardiac or vascular procedures	Cefazolin, cefuroxime, or vancomycin* If β-lactam allergy: Vancomycin† or clindamycin†
Hysterectomy	Cefotetan, cefaxolin, cefoxitin, cefuroxime, or ampicillin/sulbactam If β-lactam allergy: Clindamycin + aminoglycoside, or Clindamycin + quinolone, or Clindamycin + aztreonam or Metronidazole + aminoglycoside, or Metronidazole + quinolone
Hip/knee arthroplasty	Cefazolin or cefuroxime or vancomycin* If β-lactam allergy: Vancomycin† or clindamycin†
Colon operations	Cefotetan, cefoxitin, ampicillin/sulbactam, or ertapenem‡ or Cefazolin or cefuroxime + metronidazole If β-lactam allergy: Clindamycin + aminoglycoside, or Clindamycin + quinolone, or Clindamycin + aztreonam or Metronidazole + aminoglycoside, or Metronidazole + quinolone

This table does not necessarily reflect Centers of Medicare and Medicaid Services policy.
*Vancomycin is acceptable with a physician, nurse practitioner, physician assistant, or pharmacist documented justification for its use.
†For cardiac, orthopedic, and vascular surgery, if the patient is allergic to β-lactam antibiotics, vancomycin and clindamycin are acceptable.
‡A single dose of ertapenem is recommended for colon procedures.
Modified from the Oklahoma Foundation of Medical Quality, the Quality Improvement Organization Support Center for Patient Safety, under contract with the Centers of Medicare & Medicaid Services (CMS), an agency of the U.S. Department of Health and Human Services: Surgical care improvement project pocket card, *October 2010.*

Performance Measures

The SCIP quality measures have been implemented by CMS, and mandatory reporting of certain performance measures now helps determine hospital reimbursement. Numerous organizations endorse the notion that adherence to process measures serves as a valid assessment of surgical quality, and public reporting is intended to guide patients to quality centers for surgical care. The authors caution this methodology because process measures often serve as poor proxies for overall quality of surgical care and a number of studies have revealed adherence to quality measures does not always result in improved outcomes. Overall, the authors encourage the implementation of performance measures to improve surgical outcomes; however, they do not support their use as quality metrics or reimbursement standards because limited data exist to prove adherence advances outcomes.

The inconsistent correlation between increased rates of adherence to these process measures (all based on previous positive trials) and decreased SSI rates has two other implications. First, even with total adherence to these measures, SSIs still occur, highlighting the fact that the pathophysiology of SSI is not completely understood. More research is needed to delineate the causes of SSI and to develop new

technologies that can prevent them. Second, SSIs cannot, at this point in medical history, be considered "never events" and must not be considered so by regulating agencies.

Intraoperative and Postoperative Incision Management

Sound surgical technique must be used, including adequate hemostasis, conservation of blood supply when possible, atraumatic tissue handling, and a limited use of electrocautery. Clean and clean-contaminated incisions should be closed primarily and covered with a sterile dressing for 24 to 48 hours to allow sealing of the wound by epithelialization before dressing removal. Tissue adhesives or glue, such as Dermabond (Ethicon, Somerville, NJ), an octyl-cyanoacrylate, are alternatives to sterile dressings and provide an effective barrier to bacterial contamination of a sterile incision. Closing of the contaminated or dirty wound continues to be a dilemma for surgeons because the data are conflicting. One large prospective randomized study found greater wound failures and greater cost with closure of a contaminated abdominal incision as compared with delayed primary closure. In these conditions, delayed primary closure is frequently favored to minimize patient morbidity.

The use of drains for clean or clean-contaminated incisions is not supported because they provide a portal for pathogen entry and have been shown to increase the rate of SSI in these wound classes. When drains are used, they should be removed as soon as possible and should not justify concomitant antimicrobial therapy.

Special Considerations

Hand hygiene is an important topic within infection control practices. Preoperative surgeon hand antisepsis has transformed from the historic full 10-minute hand scrubbing to quicker protocols with various alcohol rubs. A large randomized clinical trial found a 1-minute nonantiseptic hand wash followed by an aqueous alcohol-based hand rub was equivalent to the traditional hand-scrubbing protocol. Numerous additional studies have found alcohol-based rubs are as effective as aqueous scrubbing procedures in SSI prevention.

Controversy certainly exists regarding the ideal preoperative skin antisepsis for the surgical site. The intent of skin preparation is to cleanse the skin of any microorganisms, the far leading source of pathogens for postoperative SSIs. Numerous skin preparations are available that use various combinations of chlorhexidine, povidone-iodine, iodine povacrylex, and isopropyl alcohol. The data are inconsistent, with the most recent large randomized trial concluding chlorhexidine-alcohol is superior to povidone-iodine, leaving the believers of isopropyl alcohol wondering whether the chlorhexidine matters. The authors conclude the routine use of a skin antiseptic should be undertaken with attention to the correct application protocol for the particular agent being used. Povidone-iodine alone, without alcohol, however, is probably inferior and should not be used. Differences between combinations of chlorhexidine or an iodophor with alcohol are perhaps minimal, and either approach is currently acceptable.

The pendulum continues to swing in terms of bowel preparation and enteric antibiotics for elective colorectal surgery. Traditional belief was that mechanical bowel preparation would reduce SSI and anastomotic leak. Recent data have revealed no statistically significant evidence that patients benefit from bowel preps or enemas in terms of wound infection or anastomotic leak. Antimicrobials, however, have been shown to reduce postoperative infectious complications substantially. Data reveal antibiotics covering aerobic and anaerobic organisms should be given both orally and intravenously before colorectal surgery. Some expert opinion continues to recommend mechanical bowel preparation before enteric antibiotics for improved efficacy; however, data are conflicting. Currently, mechanical bowel preparation is only clearly indicated when intraoperative colonoscopy is either planned or likely, and its use at other times is based on surgeon preference, not evidence.

TREATMENT

All clearly infected wounds should be opened, irrigated, débrided, and treated with basic wound care. Most superficial and deep incisional SSIs can be managed with these techniques. The wound should be opened sufficiently for adequate visualization of the underlying tissue to ensure no additional processes are occurring, such as fascial dehiscence, drainage from an organ/space SSI, or enteric fistula.

Infected incisional wounds should be irrigated with an isotonic solution such as a saline solution to remove loose dead tissue and exudate, and mechanical débridement may be indicated to remove devitalized tissue. Wounds should be packed in a "wet to dry" fashion, with moistened gauze against the wound bed covered by layers of dry gauze. Daily dressing changes assist in débridement as the wet gauze removes residual necrotic tissue and exudate. Once the wound has stabilized and most of the devitalized tissue has been removed, consideration can be given to placement of a negative-pressure wound therapy device ("wound vac"). Although the overall outcome may not change, placement of such a device generally speeds closure and may be particularly helpful in larger wounds and those in which dressing changes are difficult, such as with the distal extremities.

The need for antimicrobial therapy is determined by magnitude of the infection, evidence of systemic involvement, presence of prosthetics, and status of the patient, including comorbidities. Uncomplicated SSIs that have been managed with incision and drainage can usually be managed without antibiotics. Topical antibiotics and additional agents such as antiseptics (hydrogen peroxide, povidone-iodine) have an unclear role in the management of infected wounds. Traditionally, many antiseptics have been applied to wounds, including iodine-containing solutions and sodium hypochlorite (Dakin's solution). These compounds can inhibit fibroblast growth in vitro and are only used for a relatively short period of time. Topical antibiotics, as opposed to antiseptics, probably have no role in the management of infected wounds. In resource-poor areas, both honey and granulated sugar have been used to treat open wounds, and their effectiveness may be based on their hypertonicity. Enzymatic débridement of wounds may be beneficial where aggressive wide surgical débridement is impossible.

For moderate to severe SSIs, including those associated with systemic toxicity, significant cellulitis (>2 cm beyond the incision), purulent drainage, fascial dehiscence, and deep drainage, antibiotics should be administered empirically. Initial selection should cover gram-positive organisms and likely infecting organisms based on colonization status, operative location, and recent infections. For wounds associated with operations on the gastrointestinal or genitourinary tracts, gram-negative coverage should also be provided. Source control is imperative for organ/space SSIs, including intraabdominal abscess, and requires either percutaneous or operative drainage.

Culture of wounds is at the discretion of the surgeon. Straightforward uncomplicated incisional SSIs without significant cellulitis that do not require antimicrobial therapy do not need to be cultured. On the other hand, all organ/space SSIs should be cultured because the role of antibiotics is greater in this instance. For other cases, cultures should only be sent when antibiotics are planned, the culture results will be used to guide antibiotic choice, and the patient is at high risk of having resistant pathogens. Patient characteristics that suggest culture might be indicated include recent receipt of therapeutic antibiotics, immunosuppression, care in an intensive care unit, and an unusually aggressive infection. Ideally cultures should be sterile aspirations or tissue, but swabs are useful if cautious interpretation of the results is used.

SUMMARY

SSIs are a common surgical complication and represent the most common nosocomial infection among surgical patients. These infections cause significant morbidity and increase costs, making them the focus of discussion and regulation at various levels. A number of process measures have been identified to reduce the risk of SSIs, and evidence-based standards should be incorporated into all surgeons' practices.

The Management of Intra-abdominal Infections

Adam D. Fox, DPM, DO, FACS, and David H. Livingston, MD, FACS

INTRODUCTION

With intra-abdominal infection being one of the most common reasons for surgical consultation, understanding the evaluation and management of these processes becomes paramount in the day-to-day practice of the surgeon. The very broad nature of who is affected coupled with the interplay of patient comorbidities and their medications make dealing with intra-abdominal infections a challenge.

As with most complex problems in medicine, it is often useful to break them down into simpler and smaller parts. One useful way to categorize intra-abdominal infections is to divide them into those originating from previous abdominal trauma or operations and those presenting in a "virgin" abdomen. The latter group most commonly includes those patients presenting with specific organ-based infectious processes such as appendicitis, cholecystitis, or diverticulitis. These individual diseases are covered extensively in other chapters and are discussed only superficially in this chapter. The former are those patients who have sustained intra-abdominal trauma or have undergone previous abdominal interventions and are not recovering in the usual expected course. It is this group that taxes diagnostic and clinical skills and may require the most complex medical decision making.

DEFINITIONS

Intra-abdominal infections are a broad range of processes that result from bacterial invasiveness and growth in the abdominal cavity. There are several ways these types of infections have been defined or classified. One schema categorizes the infectious process into uncomplicated and complicated. The uncomplicated process is, in general, confined to the involved organ system. Examples of this include acute nonperforated appendicitis or localized acute diverticulitis. Many of these just require administration of appropriate antibiotics. Complicated intra-abdominal infections are those that extend beyond the normal confines of the organ system and diffusely invade the peritoneum. In addition to antibiotics, these infections usually require an invasive procedure in order to obtain source control.

When speaking of a complicated infection, the diffuse nature usually implies a degree of peritonitis. Peritonitis itself can be divided into primary, secondary, and tertiary. Primary peritonitis is an infection that develops in the absence of a distinct break in the structural

integrity of the gastrointestinal (GI) tract. It is usually the result of bacterial translocation, hematogenous spread, or lymphatic seeding. The resulting infection is often monomicrobial, commonly gram-negative Enterbacteriaceae species or streptococci. Secondary peritonitis results from a break in the continuity of the GI tract. It is a polymicrobial infection often with both aerobic and anaerobic enteric bacteria. Tertiary peritonitis is often seen in immunosuppressed patients and results from failure of treatment of a secondary peritonitis. The flora seen with these types of infections are often nosocomial and include resistant gram-negative bacilli, enterococcus, staphylococcus, and yeast. This classification is somewhat more useful because primary peritonitis is treated by antimicrobial therapy alone compared to secondary and tertiary peritonitis, which almost always require some type of interventional procedures.

DIAGNOSTICS

The approach to each patient should begin with the standard history and physical, with a focus on signs of systemic illness and abdominal processes. Early recognition of systemic inflammatory response syndrome (SIRS) criteria (Box 1), especially in patients who are not in the early postoperative or posttrauma period, combined with abdominal findings such as pain, nausea, vomiting, and anorexia, are highly suggestive of a complicated intra-abdominal infection. An adequate history and physical examination in the awake patient will provide the information necessary to make a diagnosis in many cases. The severity of the illness should dictate what, if any, laboratory studies are needed. In the patient with a simple intra-abdominal process without hemodynamic or physiologic derangement, a white blood cell count with differential is sufficient. In those patients presenting with a more in-depth process, thought should be given to obtaining a complete blood count, electrolyte panel, arterial or venous blood gas, lactate, and blood cultures.

While hard to believe in today's modern imaging world, a percentage of these patients require little if any further diagnostic studies. However, many patients with intra-abdominal infections may present with physiologic derangements, including an altered mental status that precludes a complete history or physical exam. In this patient population or those in which more information is needed, further diagnostic studies are required. Standard radiography has a limited role, but the upright chest radiograph or lateral decubitus film remains very useful to help identify free air. Although ultrasound has been shown to have some utility in diagnosing acute appendicitis, with some studies reporting over 80% sensitivity and 90% specificity, it remains operator dependent, and its use has not been fully evaluated for other forms of intra-abdominal infection.

Computed tomographic (CT) scanning with oral and intravenous contrast has become the "gold standard" of diagnosing intra-abdominal infection. In fact, it is the rare patient who makes it from the emergency department to the operating room without a CT scan. While abdominal CT scanning is extraordinarily useful in identifying the breadth of intra-abdominal pathology, there remain situations where it is unnecessary or unhelpful. An example of the former is the patient with free air on a chest x-ray. Examples of the latter are those patients imaged soon after an abdominal operation. Even with newer high-resolution CT technology, it remains almost impossible to differentiate infected versus noninfected fluid collections before postoperative day 5. The accuracy of CT is also dependent on technique. While the utility and added benefit of oral contrast has been questioned, the use of intravenous contrast markedly improves diagnostic accuracy. Thus, noncontrast CT scans are of limited usefulness and should be used to investigate possible intra-abdominal infections sparingly, if at all. Because new contrast agents are less nephrotoxic and allergenic, given the risk to benefit ratio, it is a rare patient who cannot tolerate one dose of intravenous contrast. Lastly, in this digital age of remote imaging and interpretation, routine direct communication between surgeons and radiologists has been often lost. In patients who have undergone complicated operations, it is incumbent on the operating surgeon to personally discuss the case with the radiologist, including what has been done and what is being searched for, so the proper study and interpretation are possible.

BOX 1: Systemic inflammatory response syndrome criteria

Temperature: <36° C (96.8° F) or >38° C (100.4° F)
Heart rate: >90 beats per minute
Respiratory rate: >20 breaths per minute, or a $PaCO_2$ <4.3 kPa (32 mm Hg)
White blood cell count: <4000 cells/mm^3 (4×10^9 cells/L), or >12,000 cells/mm^3 (12×10^9 cells/L), or the presence of >10% immature neutrophils (band forms)

INTRA-ABDOMINAL INFECTIONS FOLLOWING ABDOMINAL TRAUMA OR SURGERY

The recovery from abdominal trauma or abdominal operation is similar with most patients, progressing in a standardized manner. Quite often, even patients who were desperately ill preoperatively "look great" on postoperative day 1 or 2. Physiologic derangements such as tachycardia, fever, and even pressor requirements are often improved, and the abdominal pain of peritonitis is often replaced by surgically induced incisional pain. It is the astute clinician who recognizes the plateauing of improvement on postoperative days 3 and 4, the slight increase in abdominal distension, and the failure to regain full bowel function. Unless one "thinks bad thoughts," one will never contemplate that something might be amiss. While a small fever at this time and a change in leukocyte count might be a urinary tract infection or phlebitis from an old intravenous site, the failure to entertain the possibility of an anastamotic leak following a colon resection for diverticulitis or a missed bowl injury following a thoracoabdominal gun shot wound will result in disastrous outcomes (Figure 1). One must be aware of the possibilities that can befall a patient following abdominal trauma or operative intervention. Nowhere in general surgery is the aphorism that *"good clinical*

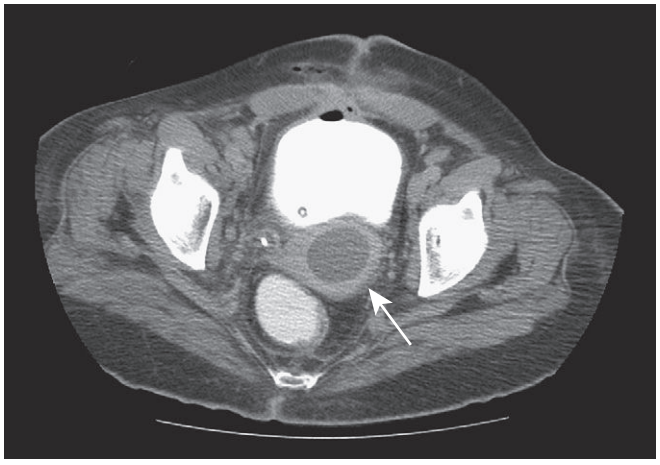

FIGURE 1 Pelvic abscess following multiple bowel resections secondary to a gunshot wound to the abdomen. Note the thick wall and contrast enhancement (*arrow*) that are classic for an abscess. The unilocular presentation and the abscess location make it ideal for percutaneous drainage.

judgment comes from experience and experience comes from bad judgment" more true than dealing with postoperative or posttraumatic abdominal infection. In addition, CT imaging, especially early after operation or injury, may be difficult to interpret or frankly misleading. In these cases, an astute surgeon must look at the CT as either positive or "not positive" rather than negative, and if no other explanation for the infection is identified, the surgeon should urgently reexplore the patient. Waiting until the patient shows signs of organ dysfunction will markedly increase mortality.

It is in the elective surgical population where the presence of an intra-abdominal infection can be most easily diagnosed and treated. These patients are commonly optimized prior to surgery, are not malnourished, and have a typical and well-known course. As outlined, the use of radiographic imaging with CT scanning is often unhelpful prior to postoperative day 5, so clinical judgment is required to ascertain which patients are not progressing in the expected manner. The wound should be examined by experienced individuals at least once daily, if not more frequently. While many superficial wound infections are in fact just that, not uncommonly a wound infection is the tip of the iceberg of a subfascial or intra-abdominal infection. Although with attention to surgical care improvement project (SCIP) guidelines, there has been improvement in the delivery of appropriate prophylactic antibiotics, these interventions have been less uniformly successful in decreasing overall wound infection rates. More importantly one needs to remember that these interventions are not designed to decrease intra-abdominal infections.

Bariatric surgical patients now comprise an increasing number of routine elective cases on the surgical schedule. The presentation of an intra-abdominal catastrophe in this group can be quite subtle, often limited to an unexplained mild tachycardia without abdominal pain. The usual postoperative care of these patients involves defined care plans of early mobilization and oral intake. Deviation from the normal progression, especially in the presence of tachycardia, should prompt rapid investigation for leaks or compromised bowel. Rapid reexploration in the absence of diagnostics before physiologic deterioration will be lifesaving in this group.

MANAGEMENT OF INTRA-ABDOMINAL INFECTIONS

Several factors should come into play once suspicion for an intra-abdominal infection is entertained. These include resuscitation, antibiotic usage, and source control itself. Patients who present with either a suspected or diagnosed intra-abdominal infection should have some form of volume resuscitation. Even without hypotension, there are several reasons why these patients might be volume depleted. These include nausea and vomiting, fluid sequestration within the abdominal cavity or lumen of the bowel, and poor oral intake. As the process progresses, the patient may develop tachypnea, which results in an evaporative fluid loss. By this time, one can often elicit orthostatic hypotension in most patients. Fluid resuscitation should begin with the administration of isotonic crystalloid and in general be guided by evidence of end organ perfusion (adequate mental status, urine output, correction of acidosis). There is no utility-using colloid such as albumin or hetastarch in these circumstances, and some data suggest a worse outcome. Should the patient present with hypotension or evidence of poor perfusion, a more aggressive approach to volume resuscitation should be employed. Our recommendation is to follow the current surviving sepsis guidelines, which include fluid challenges, monitoring/assessment of filling pressures, and the potential use of pressors and steroids.

Early administration of appropriate antibiotics in the course of an infection reduces mortality in the septic patient and should be initiated as soon as a diagnosis of intra-abdominal infection is suspected. While the absolute duration of antibiotic administration is a matter of debate, this therapy should be maintained during the interventions needed to achieve source control. As noted above, there are commonly encountered flora that will depend on the type of peritonitis as well as the presumed location of the infection in the GI tract. This can help dictate antimicrobial therapy. As one moves from the stomach, where gram-positive cocci (streptococci or lactobacilli) predominate, the number and type of bacteria change. The mid- to distal small bowel will still house gram-positive cocci, but enteric gram-negative aerobic and facultative anaerobic bacilli begin to increase in number. The colon will have large numbers of obligate anaerobes. The most common bacteria found in intra-abdominal infections are *E. coli*, *Klebsiella sp.*, *Enterobacter sp.*, *Streptococci* (mostly viridans), *Enterococcus sp.*, and *Bacteroides sp*. It is worth noting that the "expected flora" is altered in patients with previous antibiotic administration or those coming from other health care environments such as nursing homes. In this patient population, the upper GI tract should be considered to have a higher bacterial count that includes Enterobacteriaceae, *Pseudomonas*, and yeast, along with a potential for antimicrobial resistance.

Recommended antimicrobial regimens for mild to moderate community acquired intra-abdominal infections include ticarcillin-clavulanate, cefoxitin, ertapenim, or moxifloxacin as single-agent drugs or combination regimens with metronidazole and cefazolin, cefuroxime, ceftriaxone, levofloxacin, or ciprofloxacin. In those with a high-severity community-acquired infection (i.e., acute physiology and chronic health evaluation [APACHE] >15), and especially those patients who have previously been treated with antibiotics, one should avoid quinolones (high resistance) and think about using single agents such as meropenem, imipenem-cilastin, piperacillin-tazobactam, or ceftazidime or cefepime in combination with metronidazole. These broad-spectrum antibiotics should be tailored once culture and sensitivity reports become available. The duration of antibiotics should be limited to 4 to 7 days unless achieving source control had been difficult. Bowel injuries attributable to trauma that have been repaired in a timely fashion should be treated for no more than 24 hours.

SOURCE CONTROL: OPERATION VERSUS PERCUTANEOUS DRAINAGE ALONE

Source control, the single or multiple interventional processes by which one attains control or elimination of an infection, can potentially be achieved through a nonoperative or operative approach depending on the nature of the disease. There is little if any literature offering Level 1 advice as to the optimum technique under all circumstances. Globally, then, we recommend an appropriate source-control procedure based on the principles of control of ongoing peritoneal contamination, draining infection, and providing restoration of anatomic and physiologic parameters. This procedure can include resection/débridement of nonviable tissue, drainage, diversion, or a combination of each. As detailed below, intervention will then depend on the extent of the underlying process, how sick the patient presents, and resources available. The risk of failure for source control increases in the elderly (>70 years), higher illness severity (APACHE ≥15), delays to intervention, comorbidities, poor nutritional status, and extent of peritoneal involvement.

Once a need for intervention has been established, time to intervention becomes critical. Source control should proceed without delay. While many patients require at least some resuscitation, this should not delay intervention for more than a short time. Patients with severely altered physiology will likely never be resuscitated to "normal" values without source control. In these patients, operative source control may be the only way to halt an ongoing process, and resuscitation should be concomitant with the procedure.

The introduction of image-guided percutaneous drainage of intra-abdominal abscesses in the 1980s revolutionized the treatment

of that disease to the point that it is now the standard of care and the first and best option for many infections. Despite three decades of improvements in imaging technology, the general guidelines for successful drainage have not changed. Absolute necessities include a window in which to drain the collection and material that can be drained though a catheter. Well-localized collections, especially in those patients without diffuse peritonitis, can be managed with a percutaneous drain and appropriate antibiotics. This can even include those with small amounts of localized free air. Examples of infections that are usually amenable and well handled by percutaneous drainage include subphrenic abscesses after splenectomy, pelvic abscess following perforated appendicitis, and diverticulitis with localized abscess (Hinchey class 1b or 2) (Figure 2). Loculated or multiple abscesses are not necessarily contraindications to percutaneous drainage, but these authors have observed patients being treated with three and four and more percutaneous drainages over several weeks when one open operation would have taken care of the problem easier, more expeditiously, and at a lower cost. Patients with poorly localized or diffuse collections, necrotic tissue, or inaccessible collections require open operative intervention. Those patients with diffuse peritonitis or massive amounts of free air require immediate surgery.

The operation performed should be based on the extent of the infection, the organs involved, and the patient's physiologic status. Despite the myriad possibilities in treating intra-abdominal infection, there are several concepts that apply across all diagnoses. The first is that complete identification of the pathology is an absolute necessity to affect proper therapy. It does no one any good to drain the abscess only to miss the necrotic piece of intestine or anastomotic disruption. The groups of patients that require operative intervention are often sicker and more complicated. These cases can be exceedingly challenging, and even senior surgeons can often benefit from another experienced pair of hands in the operating room. Consultation and collaboration with senior partners can also help in the overall intraoperative decision making. Once the anatomic problem is completely identified, the goal is now to achieve source control. As in the severely injured trauma patient, the extent and breadth of the procedure should be dictated by the patient's physiologic status.

In patients with intra-abdominal infection without an obvious GI perforation, unroofing of all abscess cavities and collections is all that is required. Intraoperative cultures should be performed and transported to the laboratory with some expedience. It is always unfortunate to perform these procedures in the middle of the night only to find out that the "negative cultures" of obvious purulence did not make it to the microbiology laboratory until the next day. In patients without any definable residual abscess cavities, there is no need for drains. In fact, drains in this situation are more often associated with subsequent infection than no drainage. In our estimation, the quantity of drains placed often far outweighs the quality of their use. What we mean by this is that because almost all drains are of the closed suction variety, little thought is often given to drain placement, assuming that the suction will allow for proper drainage in all circumstances. While it may be true in concept, it is not always accurate in practice. Bulbs get filled, resulting in a loss of suction; tubing may be kinked by patient positioning or even the dressing.

Additionally, consideration should be given to how the drain is brought out through the abdomen. One must always remember that the drain exit site will ultimately end up several inches more medial when the abdomen is eventually closed. This can result in a loss of the "direct" path of the drain and can decrease efficacy. We believe and teach that placement of drains in a more "gravity-friendly" fashion with more lateral exit tracts will result in shorter and more direct drain paths and can even aid closed suction drainage. In addition, we do not advocate large sump-type drains. These drains often come with filters that are quickly clogged with serum and particulate matter, rendering the sump feature of the drains nonfunctional. If the material is too thick to be drained through a closed suction drain, it is also likely to clog a sump drain. In these circumstances, if sump drainage is employed, we have utilized a short course of continuous irrigation either through one of the sump ports or through a second drain. Lastly, all current drains on the market are made from silicone or a similar nonreactive material. As such, they induce little or no inflammation, and they will not form a tract. While in most cases this is beneficial, there are times where one is relying on the inflammation induced by a latex or rubber drain to "seal the area" and control the infection.

When the genesis of the infection is related to a break in the GI tract, source control involves eliminating or controlling the ongoing contamination. The two overriding concepts in these circumstances are not to make the hole bigger and not to create any new (unnecessary) holes. While on the surface these concepts appear obvious, the compulsion to put "just one stitch" in a leaking anastomosis in the face of gross peritonitis can sometimes be irresistible. The success of this is negligible and will most assuredly lead to further breakdown, a larger hole, and a bigger problem. The complexity of entry into the abdomen itself along with the actual dissection toward the primary pathology should not be underestimated. Creation of inadvertent enterotomies can occur but need to be recognized and treated. The care needed to do these cases cannot be underestimated. In addition, when enterotomies are created, one must critically decide how they should be handled, similarly to the primary pathology.

In most cases, intestinal perforation in the face of peritonitis should be handled by resection. One exception to this is perforated duodenal ulcers, which are treated by graham patch. Perforation in the body of the stomach can be closed primarily followed by imbrication using Lembert sutures because there is abundant gastric tissue to cover a suture line. In the proximal small bowel, resection is usually followed by anastomosis, whereas in the distal small bowel and colon,

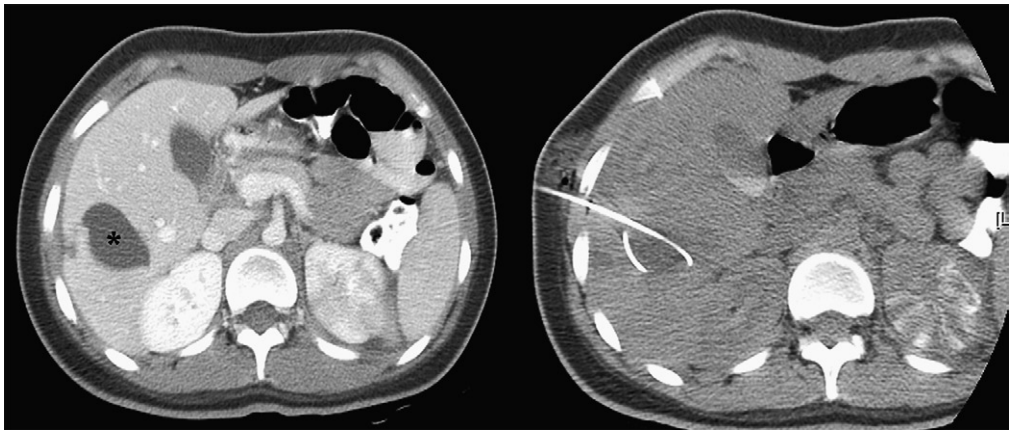

FIGURE 2 Liver abscess (*) following a stab wound to the liver *(left)*. The abscess was successfully percutaneously drained *(right)*.

one must consider the risk to benefit ratio of performing an anastomosis against creation of a stoma. If one chooses to restore intestinal continuity, it is necessary to use bowel that is not involved in the inflammatory process.

While there have been many studies showing equivalence between stapled and hand-sewn anastomosis in elective procedures, there is some suggestion in emergent surgery, and in multiple trauma especially, to suggest that hand-sewn anastomosis may be superior. In any event, when faced with peritonitis and bowel edema, it is our preference to perform only hand-sewn anastomosis. The decision to perform an anastomosis must also take into account the patient's physiologic status and the risk of failing to achieve source control. There is a surgical truism that the anastomosis that is never created will never leak. While a stoma commits the patient to a subsequent operation, surviving intra-abdominal infection and sepsis should be considered a success and an acceptable trade-off. In those patients with gross peritonitis, pressor requirements, and hemodynamic instability, a truncated procedure (i.e., damage control) should be employed. This allows the surgeon to eliminate the source of infection and provide ongoing resuscitation in a more controlled environment such as the intensive care department. During the subsequent operations, hopefully in a much less hostile abdomen, one can plan a more definitive approach to control infection and restore intestinal continuity.

There are also circumstances where a bowel resection or revision of an anastomosis is not possible. Some examples include duodenal stump blowouts, associated phlegmons compromising surrounding vascular structures, or pancreatico-intestinal anastomotic leaks. In these types of cases, the goal is controlling the effluent to create a controlled fistula while allowing the inflammatory and fibrotic process to "scar" over the problem. An important part of the management is the use of latex or red rubber drains placed in the lumen of the intestine. This both allows drainage and enhances the inflammatory process. T-tubes can be particularly useful because they are not prone to inadvertent removal. Liberal use of suction drains in proximity to these processes and placed as outlined above will further capture the effluent not coming through the latex drains. This drain strategy combined with appropriate nutritional support will lead to a controlled fistula that will often allow the clinician to remove the latex drains at much later time when the infection and inflammation has subsided.

Occupational Exposure to Human Immunodeficiency Virus and Other Bloodborne Pathogens

John G. Bartlett, MD

The treatment of human immunodeficiency virus (HIV) has undergone great progress since the introduction of highly active antiretroviral therapy (HAART) in 1996. This has totally changed the prognosis for this disease. At present, HAART has added an average of 43 years to the life of HIV-infected patients; for those who have achieved virologic control, the benefit could be a normal life span. Thus, these patients are likely to have the common medical problems that are found in the general population, such as complications associated with aging, including conditions necessitating surgical intervention. On the basis of the treatments that are currently available to patients with HIV infection, current projections are that patients will soon be in two categories: those who have good virologic control and live a relatively normal life and those whose infections are discovered late or who do not adhere to the medical regimen and have the pre-1996 complications. This chapter reviews some of the progress that has had such a dramatic effect, but the main emphasis is on the management of bloodborne exposures, which is the component that is perhaps most important to surgeons.

PROGRESS IN THE FIELD

Acquired immunodeficiency syndrome (AIDS) was first described in 1981, the putative agent (HIV) was described in 1983, serologic testing became available in 1985, and the effective therapy was established as zidovudine (AZT) in a trial that was completed in 1986. AZT was effective, but the results were temporary as a result of the rapid development of virologic failure and resistance. The beginning of effective therapy was HAART with protease inhibitors, introduced in 1996. Since then, new drugs, concepts of treatment, and simplification of regimens have evolved continuously, and at least 20 large cohorts have been studied to document population-based progress in the field. An assessment in 2012 is that virtually all patients with HIV infection should receive HAART: most commonly with three drugs, usually consisting of two nucleosides and a "third drug" that is either a nucleoside reverse transcriptase inhibitor (NRTI) or a nonnucleoside reverse transcriptase inhibitor, a protease inhibitor, or an integrase inhibitor. The HIV viral load averages 50,000 to 100,000 copies/mL (one copy equals one virion) at baseline; with this therapy, the viral load is expected to decrease to a level below the limits of detection with the standard assay (<50 copies/mL) within 4 to 8 weeks and remain "undetectable" on standard tests if the patient adheres to the regimen. There is good evidence

that this level of viral control actually indicates a total shutdown of the virus, which means no replication and consequently no sequence evolution with development of resistance. The result is total virologic control with clinical stability and immune recovery. The problem associated with this ideal response is that the virus is still present in multiple reservoirs, so that HIV viremia recurs rapidly if therapy is discontinued. Furthermore, such a lapse in treatment is often associated with viral resistance, which necessitates medication changes and fewer future options. The relevance of this outcome to surgical practice is twofold. First, discontinuation of HAART for a surgical procedure increases these risks if caution is not taken, usually with the expert guidance of the HIV healthcare provider. Second, the risk of HIV transmission with occupational exposure is directly correlated with the level of HIV viremia, which is usually high in patients in whom the infection is undiagnosed or untreated or in whom treatment fails.

This information provides an optimistic view of HIV infection and the progress in management. Nevertheless, this is an infection that has not been cured, and researchers seem unlikely to achieve that goal with the drugs currently available and those in development. Another failure has been the ability to prevent transmission of HIV. Thus in the United States (prevalence, 0.3%), there have been an estimated 40,000 new cases every year since 1990. It is now estimated that approximately 1.1 million people live with HIV infection in the United States, and that number is anticipated to increase by approximately 25,000 per year with the dramatic decrease in HIV-related mortality and the continued rates of HIV transmission of about 10,000 per year in the United States. Thus the epidemic seems destined to grow, but patients who are treated have a good chance for a near-normal life expectancy.

Infection with hepatitis B virus (HBV) is also treatable and incurable. Contemporary treatment to reduce HBV viral load includes drugs such as lamivudine, tenofovir, and entecavir. For hepatitis C virus (HCV) infection, the field is rapidly changing, with a large number of new drugs that will substantially change the course of this disease. Unlike HBV and HIV infections, HCV infection can often be cured, and the new drugs are likely to change the epidemiology of this disease completely by 2014.

TABLE 1: Risk of viral transmission with sharps exposure to bloodborne pathogens

Virus	Prevalence (U.S. general population)	Risk of exposure (per 1000)
Human immunodeficiency virus (HIV)	0.3%	3%
MSM	7%	
IDU		
Hepatitis B virus (HBV; HBsAg)	0.1%-0.2%	
MSM	6%-17%	
IDU	7%-10%	
Immigrants from high-risk areas	13%	
HIV-infected patients	7%-10%	
HBeAg positive		22%-30%
HBeAg negative		11%-6%
Hepatitis C virus (HCV)	1.8%	1.9%
People born 1945-1965	3.3%	
MSM	2%-8%	
IDU	60%-90%;	

HBeAg, Hepatitis B "e" antigen; *HBsAg,* hepatitis B surface antigen; *IDU,* injection drug use; *MSM,* men who have sex with men.

OCCUPATIONAL EXPOSURE TO BLOODBORNE PATHOGENS

Three pathogens of major concern include HIV, HBV, and HCV. All three are viremic and can be transmitted by sex or blood exposure. Substantial data document the relative risk of transmission from an infected host with blood exposure in healthcare workers, usually by needlestick injury but also, to a much less extent, with mucous membrane and skin exposure. The relative risk per exposure with sharps injury and the prevalence of each of these three viruses in the general population are noted in Table 1.

The prevalences of these infections in the general population do not necessarily represent their prevalences in hospitals; all three should be substantially higher in hospitals. Furthermore, with regard to hepatitis B, the data refer to the risk of an unvaccinated healthcare worker—a population that, it is hoped, is small.

Occupational Exposure to Human Immunodeficiency Virus

Risk

Analysis of 23 studies of needlestick injuries to healthcare workers from an HIV-infected source patient showed that the rate of HIV transmission in the pre-HAART era was 20 (0.33%) per 6135. With mucosal membrane exposure, the rate was 1 (0.69%) per 143 exposures, and there were no transmissions with 2712 skin exposures.

Through June 2010, there were 57 documented cases of occupationally acquired HIV infection in healthcare workers in the United States. The last report of such a case was in 1999, and there were none that the author is aware of since then. This reporting refers to individuals who had a defined exposure with subsequent seroconversion. There were also 138 cases of "possible occupational transmission" in which the healthcare worker had otherwise unexplained HIV infection. For obvious reasons, the best data are for those with documented exposure and seroconversion. In terms of the injuries that accounted for the 56 cases with available data, 48 resulted from parenteral exposure alone, 5 from mucosal injuries alone, 2 individuals from both, and 1 from an unknown source of exposure. With regard to needlestick injuries, all transmissions have been with a hollow-bore needle; there is no record of HIV transmission with a suture needle, although the Centers for Disease Control and Prevention (CDC) recommend similar management of exposure with either needle type. No HIV transmissions to surgeons have been documented, and the great majority of exposures have occurred in nurses or laboratory technicians.

Analysis of cases with transmission reveals the following exposure-related factors that were correlated with the probability of HIV transmission:

- The depth or severity of the exposure
- The presence of visible blood on the device
- The history that the device had previously been used in the infected patient's vein or artery
- The fact that the source patient died within 60 days of the healthcare worker's exposure

A fifth factor that increased risk was the absence of prophylaxis with antiviral agents. The data were collected in the early phase of the HIV epidemic; progress in managing patients with HIV infection and managing exposures presumably explains the 10-year absence of seroconversions in the more recent experience.

Efficacy of Zidovudine

Several lines of investigation support the role of AZT for exposure to HIV infection. This agent is antiquated, but it is the best studied for the period with the most transmissions.

1. Retrospective analyses of cases show a risk reduction of approximately 80% when standardized for the four variables noted earlier.
2. The effectiveness of AZT in preventing HIV transmission has precedent, according to the early studies of perinatal transmission. The famous AIDS Clinical Trial Group (ACTG) study 076 showed that AZT reduced vertical transmission of HIV by 67%. These data have been substantiated by multiple studies that show consistent results with reductions in perinatal transmission rates from 27% in the absence of antiviral agents to less than 2% when there is virologic control in the maternal source at the time of exposure at birth.
3. There are supporting data from animal models in which both AZT and tenofovir were administered for 1 month, starting either before exposure or up to 24 to 48 hours after exposure.
4. Substantial data show that virologic suppression of HIV virtually eliminates the risk of transmission by sexual contact.

Despite these promising data on the effectiveness of postexposure prophylaxis (PEP), there are at least six cases in which PEP was not successful despite initiation of the treatment within 2 hours of exposure, with regimens that were generally advocated in the pre-HAART era. Moreover, the number of occupationally acquired infections in the United States since 1996 has been reduced to none to two per year.

Management of an Exposure

The first response must be decontamination as quickly as possible. Cutaneous injuries should be washed with soap and water. A visible defect such as an incision wound should be irrigated with saline or a disinfectant. Mucosal surfaces such as the mouth or nose should be flushed with copious amounts of water. Ocular exposures should be irrigated with saline or water. For decontamination, the use of bleach, peroxide, iodophors, or other disinfectants with immediate wound care is satisfactory but not viewed as necessarily an important priority.

Testing the Source

In the absence of recent positive test results, the source should be tested for all three bloodborne pathogens: HIV, HBV with hepatitis B virus surface antigen (HBsAg), and HCV (with anti-HCV). For HIV, the standard is rapid testing, which can detect HIV antibody within 20 minutes. In some patients with very early infection, the HIV viral load is high and seroconversion has not taken place. This means the source patient is antibody negative and has a high viral load. This window is only about 3 to 4 weeks, but it is the period of greatest transmission risk. Contemporary testing options include viral load testing, which requires 2 to 3 days, but newer tests (called fourth-generation tests for both antigen and antibody) provide results in less than 1 hour. These tests have a sensitivity and specificity of approximately 99%. Positive results may be verified with a Western blot test for purposes of HIV management of the source patient, but the early results can be presumed accurate for HIV prophylaxis. In the great majority of cases, negative test results nearly exclude this diagnosis. None of this screening is necessary in a patient known to have HIV infection. In that case, the review should note the recent viral load tests, resistance test results, and the medication record because these may alter drug decisions for antiviral prophylaxis.

The standard practice has been to acquire signed informed consent for testing the source patient. This may be problematic for patients who cannot give informed consent because of concurrent medical conditions. Some states have made allowances to permit obtaining blood from the source patient for HIV testing if the source patient is unable to provide it in the context of occupational exposure, but some states have no such legislation. The CDC and nearly all states have advocated "opt-out testing," which would treat HIV much like other tests, meaning that the patient has the opportunity to decline the test, as with any test or procedure, but there is no requirement for the signed informed consent with counseling. Thus the method of obtaining blood from the source patient for HIV serologic testing may vary substantially on the basis of individual state policy. The occupational health departments of hospitals clearly know the local rules.

Counseling

Healthcare workers must be informed about the risks involved in exposure to HIV, including the facts that (1) the odds of HIV transmission from an HIV-infected source patient are approximately 3 per 1000; (2) if the source patient is not receiving therapy, the healthcare worker does not accept antiretroviral therapy, and (3) the percutaneous injury is "average." With the average type of needlestick exposure to a source patient who is receiving therapy and has a viral load below the limits of detection (i.e., <50 copies/mL), the risk is probably vanishingly small—but it is not zero. This was demonstrated in the studies of perinatal transmission, which also showed a direct correlation between the probability of transmission and the viral load, but some transmission occurred even from women who had very low viral loads. Furthermore, PEP has documented benefit. AZT seems to reduce the probability of seroconversion by 80%, but the current recommendation is for a far more potent regimen; thus the prophylaxis is now expected to be substantially more effective. However, the additional benefit cannot be quantitated.

Timing of Initiation of Antiretroviral Drugs

Studies in macaques show that the earlier treatment is initiated, the more likely it is to be effective. The goal of PEP is to initiate treatment as quickly as possible, preferably within 1 to 2 hours of exposure. According to the CDC guidelines, the allowable window is 36 hours after exposure, but consensus is that earlier is better. In a review of 435 healthcare workers with HIV exposure, the median time from exposure to treatment was 1.8 hours. Even when the source patient's HIV status is unknown, rapid HIV tests enable treatment to begin within the time frame of test results to verify potential exposure. Standard serologic tests usually take 3 to 7 days to analyze, although a negative result of an enzyme immunoassay screening is usually available within 24 to 48 hours and is adequate for the decision to discontinue PEP when a rapid test is not available.

Healthcare Worker Counseling

Healthcare workers should be informed about the following:

1. The risk of transmission according to the data provided earlier, including the risk of seroconversion and the potential effect of PEP, which reduces risk by at least 80%.
2. The effect of time delays on PEP efficacy.
3. Methods to minimize the risk of secondary transmission, meaning "safe sex" or abstention until serologic test results are negative 6 months after exposure. The risk of transmission is greatest in the first 6 to 12 weeks, and many authorities recommend these precautions only through the 3-month test.
4. Description of the PEP regimens and the side effects of the drugs likely to be used.

5. Regardless of the PEP drug decision, there must be follow-up serologic testing at 6 weeks, 3 months, and 6 months. The current recommendation is to repeat serologic testing at 12 months in the healthcare worker who has also acquired HCV with the injury because this may delay the time of HIV seroconversion. Some occupational health departments perform a test at 1 year on all exposed healthcare workers because at least three seroconverted between 6 and 12 months.
6. Female healthcare workers who are not pregnant and have childbearing capacity must be advised that the agents used for HIV prevention are considered safe for use in pregnancy. The only drug that has been traditionally contraindicated is efavirenz, a drug that is not advocated for PEP. In terms of safety of other drugs, the pregnancy registry (*http://www.apregistry.com*) indicates birth defects in 110 of 4391 live births among HIV-infected women receiving antiretroviral drugs during pregnancy. This rate of 2.5/100 is not significantly different from the CDC population-based birth defects surveillance system, which indicates 3.1/100 live births.

Antiretroviral Regimens

Antiretroviral drug recommendations and policies for occupational exposure provided here are based on 2012 guidelines of the New York State AIDS Institute and are as follows:

1. The evaluation is considered urgent with the goal for initiate HAART within 2 hours.
2. If the source patient has a negative result of a test for HIV antibody but is at risk for HIV infection within 6 weeks of the testing, plasma HIV RNA (antigen) and PEP should be given to the healthcare worker within 2 hours of exposure if HIV test results are delayed.
3. The initial regimen should be tenofovir/emtricitabine (Truvada) plus raltegravir. The specific regimen is Truvada (1/day) plus raltegravir (400 mg/day orally) for 28 days. (AZT is no longer recommended because of poor tolerance.)
4. Alternative regimens:
 - If the exposed healthcare worker has renal disease with creatinine clearance rate lower than 50 mL/min, tenofovir disoproxil fumarate (TDF) is contraindicated; an alternative NRTI combination is AZT/lamivudine.
 - If resistance data are available from the source patient, these data should be used in the regimen selection.
 - Poor tolerance is a reason to change regimens. Other agents to consider are atazanavir/ritonavir (ATV/r), darunavir/ritonavir (DRV/r), fosamprenavir/ritonavir (FPV/r), and lopinavir/ritonavir (LPV/r).
 - There needs to be attention to drug interactions.
5. Follow-up monitoring of the exposed healthcare worker, with or without acceptance of HAART prophylaxis, should include HIV testing at 4 and 12 weeks.
6. Potential sources of HIV transmission include not only blood but also semen, vaginal secretions, breast milk, and cerebrospinal, pleural, pericardial and amniotic fluid. (Saliva, sweat, tears, nonbloody urine, and stool are not considered HIV sources).
7. The risk of HIV transmission from an HIV infected source patient in the absence of prophylaxis is estimated at 3 per 1000 with a needlestick exposure and 0.9 per 1000 with a mucocutaneous exposure. Prophylactic AZT reduced these risks by an estimated 80%.
8. The "window" of effective prophylaxis is considered probably closed at 36 hours after exposure. Decisions to start PEP after 36 hours are made a case-by-case basis.

Management of the Injury Site

Sites of skin exposure should be cleaned immediately with soap and water; sites of exposure at mucous membranes, with water flushing.

Source Testing

If HIV status of the source patient is unknown, the following measures should be taken: (1) obtain consent for the HIV test if consent is required according to institutional policy, and (2) use a rapid test if possible. (State laws vary with regard to testing when the source patient refuses or is unable to consent). The rapid test is preferred. If recent HIV acquisition is suspected (within 6 weeks), testing for antigen should be done if the antibody test result is negative (or both should be done simultaneously). Confirmatory tests should be performed if results are positive, but this should not delay prophylaxis. If HAART is given pending testing, it should be stopped when HIV in the source patient is ruled out.

Monitoring the Exposed Healthcare Worker

Baseline: Perform HIV test, (pregnancy test), and obtain chemistry profile and complete blood cell count (CBC).
Day 3: Assess adherence to and tolerance of the treatment regimen.
Week 1: Assess adherence and tolerance.*
Week 2: Assess adherence and tolerance,* and obtain a chemistry profile and CBC.
Week 3: Assess adherence and tolerance.*
Week 4: Assess adherence and tolerance*; obtain a chemistry profile and CBC; and perform an HIV test.
Week 12: Perform an HIV test.

Expert advice is available at the National Clinicians Center PEP Line: 888-448-4911. *Telephone contact or clinic visit.

Expert Opinion

The field of HIV infection has become extremely complicated with the rapid advances since 1995. Many hospitals do not have the available expertise within the occupational medicine department to deal with the complexities of issues and timeliness. Therefore, a CDC recommendation is frequently to seek expert consultation or use of the National Clinicians Center PEP line, which is operational from 9 AM to 2 AM Eastern Standard Time at 888-448-4911. Some common queries include the following situations:

- A delay in exposure report or a decision for PEP after the 24- to 36-hour window of opportunity
- Unknown source of a sharps injury, which must be reviewed on a case-by-case basis
- Use of PEP regimens in patients who are pregnant, potentially pregnant, or breastfeeding
- Resistance of the source virus to antiretroviral drugs
- Toxicity of the PEP regimen in terms of symptom management or decision for different drug regimens

Occupational Exposure to Hepatitis B

The risk of transmission is dependent on the vaccine status of the healthcare worker and the presence or absence of HBV e-antigen (HBeAg) in a patient with HBsAg (see Table 1). Recommendations for PEP are summarized in Table 2. Unvaccinated healthcare workers are highly vulnerable, as indicated in Table 1, and, when the source patient is HBeAg positive, exceptionally so. It is hoped that all healthcare workers, including all surgeons, will have been vaccinated, but rates of protection are somewhat variable. Response to the vaccine is age related; it is 95% for persons vaccinated at 20 to 30 years of age, 86% vaccinated at 40 to 50 years of age, and 45% for those vaccinated when older than 60 years of age. Titers of antibody decrease an average of 10% per year, but prior responders who had a

TABLE 2: Postexposure prophylaxis for hepatitis B*

Antibody status of healthcare worker	Vaccine or source patient status		
	HBsAg positive	HBsAg negative	Unknown
Not immune	HBIG × 1 + vaccine	HBV vaccine	HBV vaccine
Vaccinated responder	No Rx	No Rx	No Rx
Vaccinated nonresponder	HBIG × 1 + vaccine *or* HBIG × 2	No Rx	No Rx; if source patient is at high risk, treat as if HBsAg positive
Vaccinated response unknown	Vaccine booster dose	No Rx	Same as for vaccinated nonresponder
Ongoing vaccination	HBIG × 1 Complete series	Complete series	Complete series

*Adapted from New York State AIDS Institute Guidelines (*http://www.hivguidelines.org*), October 2012.
HBIG, Hepatitis B immune globulin; *HBsAg,* hepatitis B virus surface antigen; *HBV,* hepatitis B virus; *Rx,* treatment.

demonstrated response with an antibody titer exceeding 10 U/mL are probably protected as a result of cell-mediated immunity. It is now common practice to measure antibody response at 1 to 6 months after completion of the three-dose series, but many programs did not do this when the healthcare vaccination programs were initially launched. Currently, for nonresponders, the recommendation is to repeat the vaccination series, and nonresponders have a 55% probability of response with revaccination. The vaccine efficacy is approximately 80% to 95% for all vaccine recipients and 99% for those who have had a documented response.

On the basis of these data, healthcare workers are considered protected if they have been vaccinated and have documented antibody response at any time. If response was never measured, it should be measured in the context of exposure as the basis of subsequent decisions. If the antibody levels are greater than 10 U/mL, the healthcare worker is considered protected. If antibody levels were never measured and are now less than the stated threshold, the healthcare worker must be managed as a "nonresponder." Subsequent management recommendations are provided in Table 2.

Occupational Exposure to Hepatitis C

A review of 25 published studies from 1991 to 2002 indicated that the rate of HCV transmission after a sharps injury from an HCV-infected source patient was 44 (1.9%) per 2357. Cutaneous exposure on intact skin with blood from a contaminated source patient does not appear to confer risk. When a healthcare worker has an exposure to blood or body fluid from a source patient, the institution should follow these guidelines:

1. Wash exposed wounds with soap and water, and flush exposed mucous membranes with water.
2. Evaluate the source patient for HCV infection with HCV antibody.
3. If the source patient is HCV positive, test the source patient for HCV virus with HCV RNA or recombinant immunoblot assay (RIBA), and test the exposed healthcare worker's liver function and HCV antibody level; if the latter result is positive, test for the presence of HCV RNA.

Management guidelines are summarized in Table 3.

Healthcare Worker with Hepatitis C Virus RNA

Refer to a clinician experienced in HCV management.

TABLE 3: Guidelines for hepatitis C exposure

Source patient/healthcare worker	Follow-up
Source patient negative for HCV antibody	No further follow-up
Source patient not available for testing	Exposed healthcare worker: HCV antibody test at 3 and 6 months
Source patient HCV antibody positive and HCV RNA positive	Manage healthcare worker as exposed*
Healthcare worker – HCV negative	Manage healthcare worker as exposed*
Healthcare worker – HCV antibody and HCV RNA positive	Manage healthcare worker as infected

*Postexposure HCV testing in exposed healthcare worker is as follows: In week 4, HCV RNA and liver panel; in week 12, HCV RNA and liver panel; and in week 24, liver panel and HCV antibody testing. If alanine aminotransferase level is elevated at any time, the HCV RNA assay should be repeated, in addition to testing for acute HCV.

Antifungal Therapy in the Surgical Patient

Kieren A. Marr, MD, and Shmuel Shoham, MD

INTRODUCTION

Fungal infections are a major problem in hospitalized surgical patients. The most important infections are invasive and superficial candidiasis and, to a lesser extent, aspergillosis and mucormycosis. Treatment of these infections is the main focus of this chapter. Whereas superficial fungal infections are rarely dangerous, invasive fungal infections continue to be associated with suboptimal outcomes. The reasons for this are related to both host and fungal factors. Patients at risk for developing invasive fungal infections tend to have multiple comorbid conditions and are often critically ill. Moreover, diagnosis of infection can be difficult, and institution of appropriate antifungal therapy is often delayed. With the advent of improved diagnostic modalities and safer antifungal therapy, outcomes are improving (Table 1).

In addition to antifungal chemotherapy, there is often a critical role for surgical management of invasive fungal infections. For example, removal of a potentially infected vascular catheter is frequently necessary in patients with candidemia. Moreover, drainage and/or débridement are often needed in cases of infected fluid collections and invasive tissue disease. In cases of filamentous fungal infections, debridement or excision of infected and necrotic tissue is frequently required in order to control the infection.

Coccidioidomycosis, blastomycosis, histoplasmosis, and cryptococcosis are important fungal diseases. Occasionally, lesions caused by *Coccidioides* and *Blastomyces* require surgical débridement, and patients with high cerebrospinal fluid pressure due to cryptococcosis may need placement of a spinal drain for intracranial pressure management. Because these infections are not typically encountered in a surgical practice, their medical management is not covered in this chapter.

ANTIFUNGAL AGENTS

Polyenes

The polyene class of antifungal agents consists of nystatin and the various formulations of amphotericin B (AmB). These agents work by disrupting the fungal cell membrane and are active against a broad range of clinically important fungi. Neither is absorbed orally. Nystatin is used topically as a solution, powder, or cream for a range of superficial infections such as oropharyngeal, cutaneous, and vulvovaginal candidiasis. AmB is principally used intravenously for systemic infections, but it may be used topically for oropharyngeal and bladder infections and as aerosolized inhalational treatment for prevention of lung infections.

Amphotericin B

AmB is active against a broad array of fungi, including *Candida*, *Aspergillus,* and the Zygomycetes (agents of mucormycosis). AmB is the principal therapy for mucormycosis and as empiric therapy for a suspected disseminated fungal infection when the etiology is unclear. Various formulations are available, including deoxycholate AmB (dAmB), AmB lipid complex (ABLC), and liposomal AmB (L-AmB). Dosing is usually 0.5 to 1.0 mg/kg/d for dAmB and 3 to 6 mg/kg/d for lipid formulations. Higher doses are sometimes used in cases of mucormycosis and for other difficult to treat filamentous fungal infection. AmB may be ineffective due to resistance in infections caused by *Candida lusitaniae, Aspergillus terreus, Fusarium, Scedosporium prolificans,* and *Trichosporon.*

The main drawbacks to AmB are its side effects, which are principally infusion-related reactions and nephrotoxicity. These are less common with the lipid formulations, and we therefore recommend their use over dAmB. Infusion-related toxicities include fevers, chills, myalgias, arthralgias, and occasionally hypotension. These can be prevented or reduced by slowing down the infusion rate and premedicating with acetaminophen. In many patients infusion-related reactions tend to resolve after a few doses. Manifestations of AmB nephrotoxicity include azotemia, hypokalemia, and hypomagnesemia. These are more common with higher cumulative doses of AmB and in patients with preexisting renal disease and/or concomitant

TABLE 1: Patient types and treatment options for adults with fungal infections

Infection	Patient type	Primary treatment/alternative treatment	Length of treatment	Comments
Candidemia	Critically ill, abdominal surgery, cancer chemotherapy, vascular access, burns, parenteral nutrition	**Primary** Caspofungin 70 mg × 1, then 50 mg/d IV Anidulafungin 200 mg × 1, then 100 mg/d IV Micafungin 100 mg/d IV Fluconazole 800 × 1, then 400 mg/d **Alternative** Deoxycholate AmB 0.7-1.0 mg/kg/d IV Lipid AmB 3-6 mg/kg/d IV Voriconazole 6 mg/kg BID × 2 doses, then 3 mg/kg BID	14 days after clearance of blood cultures. Longer if ocular involvement. If possible can switch to oral agent to complete therapy once patient has stabilized.	Remove vascular access devices if possible Do not use fluconazole for patients with neutropenia Evaluate for ocular involvement with fundoscopic examination
Candiduria/UTI	Urinary catheter, diabetes mellitus, kidney transplant recipients	**Primary** Fluconazole 200-400 mg/d **Alternative** Deoxycholate AmB 0.3-0.6 mg/kg/d IV	14 days 7-14 days	Patients with asymptomatic candiduria do not routinely need to be treated. Exceptions are neutropenia or planned instrumentation
Oropharyngeal candidiasis	Immunocompromised, radiotherapy, ill-fitting dentures	**Primary** Clotrimazole 10 mg 5/d PO Nystatin QID PO Fluconazole 100-200 mg/d PO **Alternative** Itraconazole solution 200 mg/d PO Posaconazole 400 mg BID PO Voriconazole 200 mg BID PO Caspofungin 70 mg × 1, then 50 mg/d IV Anidulafungin 200 mg × 1, then 100 mg/d IV Micafungin 100 mg/d IV	7-14 days	Use topical therapy for mild disease; relapses more common with echinocandins
Esophageal candidiasis	Immunocompromised (e.g., advanced HIV)	**Primary** Fluconazole 200-400 mg/d (IV or oral) **Alternative** Echinocandins, itraconazole, or posaconazole (see above for doses)	14-21 days	Relapses may be more common with echinocandins
Vulvovaginal candidiasis	Antibacterial therapy, diabetes mellitus	Topical therapy (e.g., clotrimazole, nystatin, miconazole) Fluconazole 150 mg × 1 PO	Schedules vary by agent	Vulvovaginal candidiasis, even if recurrent, is usually *not* due to an immunocompromised state

Continued

TABLE 1: Patient types and treatment options for adults with fungal infections—cont'd

Infection	Patient type	Primary treatment/alternative treatment	Length of treatment	Comments
Aspergillosis	Abnormalities of neutrophil number or function, structural lung abnormalities, burns	**Primary** Voriconazole 6 mg/kg BID × 2, then 4 mg/kg/d +/– echinocandin **Alternative** Lipid AmB 5 mg/kg/d Caspofungin, anidulafungin (see above for doses), micafungin 100-150 mg/d Posaconazole 800 mg/d in 2-4 divided doses	Length of Rx not clear	Consider monitoring voriconazole and posaconazole levels to help guide therapy
Mucormycosis	Systemic immunosuppression, burns, trauma, near drowning, uncontrolled DM, deferoxamine use	**Primary** Lipid AmB 5-7.5 mg/kg/d +/– echinocandin	Length of Rx not clear	Débridement and excision are often needed If patient is stable, consider switching to posaconazole after 3 weeks AmB

nephrotoxic processes. Giving prophylactic normal saline (0.9% NaCl) at 10 to 15 ml/kg/d and avoiding concomitant administration of nephrotoxic agents can reduce the chance of nephrotoxicity.

Azoles

The azoles are an extremely important class of antifungal agents with activity against a broad range of fungi. These drugs inhibit ergosterol biosynthesis, thereby impairing formation of the fungal cell membrane. Depending on the specific drug, the azoles are available as oral, intravenous, or topical therapy. These agents have the potential for multiple drug interactions via the cytochrome P450 system, and care must be taken when coadministered with other drugs metabolized by these isoenzymes. Important examples include elevation of warfarin, calcineurin inhibitors, and sirolimus levels with concomitant administration of an azole antifungal.

Fluconazole

Fluconazole is the most important azole for surgical patients. It is effective against most species of *Candida,* available in oral and intravenous formulations, and is generally well tolerated. Fluconazole continues to have excellent activity against *C. albicans,* but has variable activity against *C. glabrata*, which can account for up to 25% of candidiasis. It is inactive against *C. krusei*. Fluconazole is a first-line agent for oropharyngeal (100 to 200 mg/d) and esophageal candidiasis (200 to 400 mg/d) and is useful in cases of invasive candidiasis (400 to 800 mg/d; 6 to 12 mg/kg/d) in moderately ill, nonneutropenic patients. Fluconazole is also widely used for prevention of candidiasis in high-risk patients. Dose adjustment is required with renal dysfunction. Fluconazole occasionally causes liver toxicity, gastrointestinal (GI) upset, and rashes and is associated with multiple drug interactions as indicated above.

Voriconazole

Voriconazole is effective against *Aspergillus,* most species of *Candida,* and multiple other filamentous fungi. It is available in oral and intravenous (IV) formulations. Voriconazole is first-line treatment for invasive aspergillosis and can be used in cases of invasive candidiasis. It has excellent bioavailability, allowing for oral administration, but steady-state levels are reached more rapidly with IV loading doses of 6 mg/kg every 12 hours × 2 doses. This is followed by 4 mg/kg twice daily. Oral dosing for most adults is 200 to 300 mg twice daily. Renal adjustment is not necessary, but caution should be used when giving the IV solution in patients with decreased kidney function because the cyclodextrin carrier used in the IV formulation might damage the kidneys.

Voriconazole is associated with multiple adverse reactions, including changes in visual perception, vivid dreams, psychosis, hepatotoxicity, and phototoxicity. Drug levels can vary widely among patients, and this may impact efficacy and toxicity. Therapeutic drug monitoring is increasingly used to ensure that levels are in the acceptable range (troughs of approximately 2 to 5 mg/L). Adverse events are more likely to occur when serum levels exceed 5.5 mg/L. Voriconazole is associated with multiple drug interactions as indicated above.

Posaconazole

Posaconazole is effective against a broad range of fungi, including most species of *Candida, Aspergillus,* and many filamentous fungi, including the Zygomycetes. It is currently only available as an oral suspension, and attainment of steady-state levels can take a week or longer. For this reason it is generally not recommended as first-line therapy for established infections. The dose for invasive fungal infection is 800 mg/d in 2 to 4 divided doses. Total daily doses above 800 mg are poorly absorbed. A new formulation of posaconazole as a tablet and an IV solution are expected to have improved pharmacokinetic parameters and are currently in advanced clinical trials. The most common side effects of posaconazole are GI upset and hepatotoxicity. Posaconazole is also associated with multiple drug interactions as indicated above.

Itraconazole

Itraconazole is of limited importance in surgical patients. It is available as oral tablets and as a cyclodextrin oral solution, which results

in better drug absorption. In some countries itraconazole is also available for IV therapy. The spectrum of activity is similar to fluconazole, but it is also active against some filamentous fungi, including *Aspergillus*. Several factors limit its use, including erratic gut absorption, need for drug-level monitoring, GI upset (particularly with the cyclodextrin solution), hepatic toxicity, and negative inotropic cardiac effects.

Echinocandins

The echinocandins (caspofungin, micafungin, and anidulafungin) are an important class of antifungal agents. They act by inhibition of fungal cell wall formation and have fungicidal activity against almost all *Candida* species (Figure 1). Treatment failures have been reported with *C. parapsilosis*, which has some innate resistance to the echinocandins. Under selective pressure, other species of *Candida* can also become resistant due to mutations. The echinocandins can also inhibit growth of *Aspergillus,* but they do not kill the organism. The echinocandins are extremely well tolerated and have very few drug interactions. They are only available via the IV route. Echinocandins are first-line therapy against invasive candidiasis and may also be used, but are not ideal, for cases of oropharyngeal and esophageal candidiasis. For adults with invasive candidiasis, dosing is micafungin, 100 mg/d; caspofungin, 70 mg loading dose, followed by 50 mg/d; and anidulafungin, 200 mg loading dose, followed by 100 mg/d.

SPECIFIC INFECTIONS

Candidiasis

Candida species are the most important fungal pathogens in surgical patients. These fungi are commensals of the human GI and genital tracts and of the skin. Infections are almost always of endogenous origin, but cross-contamination between colonized patients and/or from health care workers' hands can occur. Invasion occurs when host defenses break down or are breached. *C. albicans* is the most common colonizing and infecting species. The other important species include *C. parapsilosis, C. glabrata, C. tropicalis,* and *C. krusei*. Exposure to antifungal agents and transfer of the yeast among patients via health care workers' hands can alter fungal colonization patterns and subsequent infecting species.

Infection can be broadly divided into mucosal and systemic disease. Oropharyngeal candidiasis tends to occur in patients with abnormal cell-mediated immunity (as in those with advanced human immunodeficiency virus [HIV] and in recipients of corticosteroids). Cutaneous and vulvovaginal candidiasis are sometimes triggered by antimicrobial use and poor glycemic control but also can occur spontaneously. The majority of women with candidal vaginitis are not immunocompromised. Invasive candidiasis tends to occur in those with breached anatomic barriers due to surgery, cytotoxic chemotherapy, or vascular access catheters, and in patients with abnormalities in neutrophil number or function.

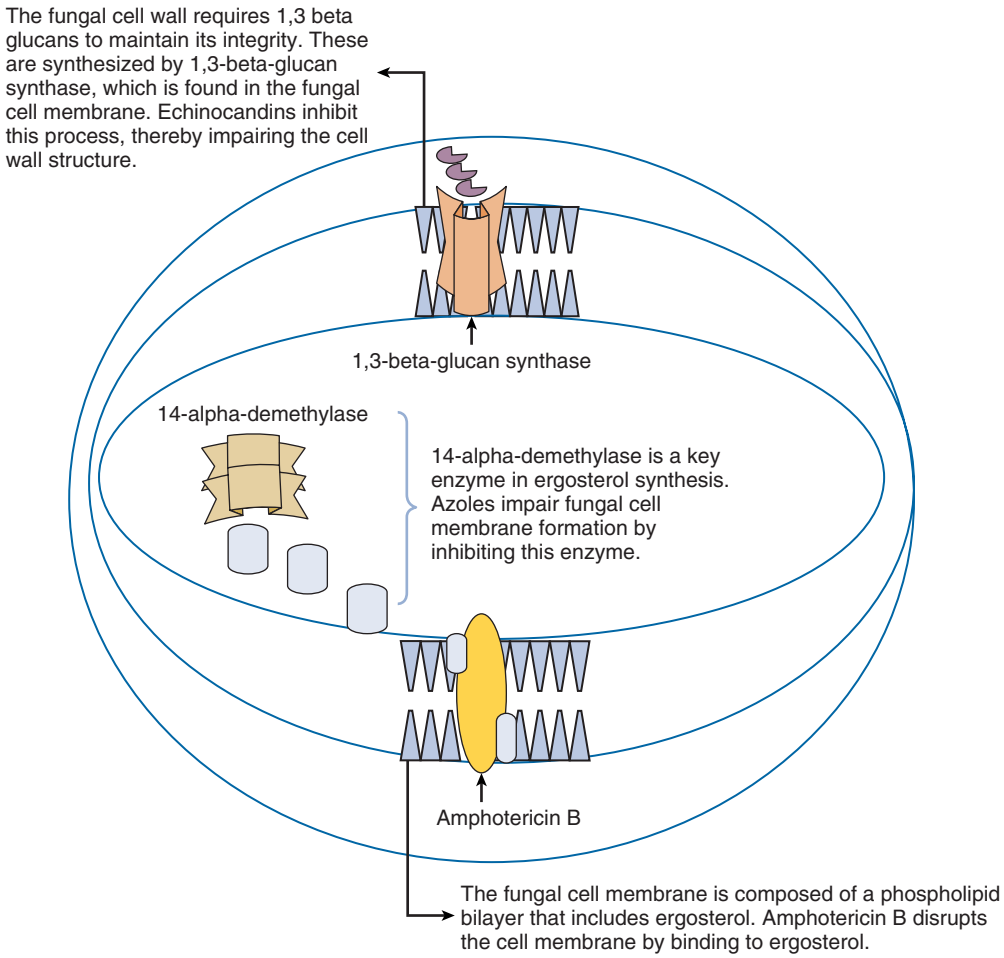

FIGURE 1 Mechanisms of action.

Mucocutaneous Disease

Mucocutaneous fungal infections are very common, and their risk factors (e.g., diabetes mellitus, antibiotic exposure, corticosteroids) frequently overlap with those seen in surgical patients. These infections can cause significant discomfort but are rarely dangerous. Typical sites of infection include the oropharynx (thrush), esophagus, skin, and genitalia. Patients with symptomatic superficial infection should be treated, but because *Candida* species are normal commensals, simply culturing the organism from a superficial surface is not an indication for treatment.

Cutaneous Candidiasis

Cutaneous infections typically involve occluded areas and sites of large skin folds. Candidal intertrigo is a common infection at sites of warm, moist, and macerated skin, such as inframammary and large abdominal folds, the axillae, or groin. Diabetes mellitus, obesity, receipt of antibiotics or steroids, and inflammatory skin diseases are risk factors for such infections. The affected area may be itchy, red, and moist. The skin can be eroded with whitish scaling at the borders. Satellite lesions just beyond the main area's border are common. Diagnosis is generally based on clinical appearance. Superficial candidiasis can be treated with topical therapy. For moist macerated skin, an antifungal powder formulation may be preferable. Nystatin (100,000 units/g) and miconazole (2%) are available as either a powder or cream. A variety of other antifungal creams are also available, including econazole (1%), clotrimazole (1%), butenafine (1%), terbinafine (1%), tolnaftate (1%), and ketoconazole (2%).

Vulvovaginal Candidiasis

Candidal vulvovaginitis is extraordinarily common, and most women will have at least one attack during their lifetime. Risk factors include antibiotics, diabetes mellitus, and pregnancy. Vulvovaginitis may present with local irritation, itching, erythema, vaginal discharge, dysuria, and dyspareunia. Patients will often make a self-diagnosis of "yeast" vaginitis. This can be confirmed by identifying candidal elements (pseudohyphae and blastoconidia) on microscopic evaluation of a 10% KOH treated sample. In cases of vulvovaginal candidiasis, there are multiple intravaginal treatment options, including nystatin tablets (100,000 units/tablet), various azole creams (e.g., daily miconazole 2%, butoconazole 2%, clotrimazole 1%, and terconazole 0.4% and 0.8%), tioconazole 6.5% ointment, miconazole suppositories at 100 and 200 mg, and oral fluconazole 150 mg as a single dose. Some patients with recurrent vulvovaginal candidiasis require long term treatment with oral fluconazole 150 mg weekly or topical clotrimazole twice weekly. Boric acid vaginal suppositories (600 mg twice daily) are an option in recalcitrant cases.

Oropharyngeal and Esophageal Candidiasis

Oropharyngeal candidiasis is mainly a problem in immunosuppressed patients, and particularly in those with advanced HIV. Additional risk factors include extremes in age, poorly controlled diabetes mellitus, nutritional deficiencies, inadequately fitting dentures, systemic or inhaled steroids, radiotherapy, and cytotoxic chemotherapy. Clinical manifestations include thrush, which is characterized by curdlike, white patches on multiple surfaces of the oral mucosa, and erythematous candidiasis (acute atrophic candidiasis), which occurs by itself or in association with the white patches. Symptoms include local pain, burning, and changes in taste perception. Oropharyngeal candidiasis is almost always caused by *C. albicans* and can be treated with topical or systemic therapy. For mild disease, topical therapy tends to suffice. Options include nystatin suspension (100,000 units/mL) 4 to 6 mL four times daily, nystatin pastilles (200,000 units) 1 to 2 pastilles four times daily, or clotrimazole 10 mg troches five times daily. More severe disease may require fluconazole 100 to 200 mg daily. Treatment is typically for 7 to 14 days but may need to be extended, depending on response to therapy.

Esophageal candidiasis is usually associated with high levels of immunosuppression, as in advanced HIV and transplant recipients. Additional risk factors include advanced liver disease, receipt of proton pump inhibitors, and inhaled steroids. Symptoms are usually odynophagia, dysphagia, and retrosternal pain. Concurrent oropharyngeal candidiasis is common but may be absent. Infection is generally limited to the mucosa, but complications include volume depletion and malnutrition due to poor oral intake, esophageal strictures, and even esophageal perforation. Treatment is with oral fluconazole at 200 to 400 mg daily. In cases where the patient is unable to tolerate oral therapy, intravenous fluconazole can be given. Length of therapy is typically 14 to 21 days, depending on response to therapy.

Oropharyngeal and esophageal candidiasis refractory to fluconazole can occasionally develop in highly immunosuppressed and/or azole-experienced patients. This is an unusual situation in a surgical practice. Alternative oral options include itraconazole solution 200 mg/d, voriconazole 200 mg BID, and posaconazole 400 mg BID. These regimens are costlier and potentially more toxic than fluconazole. Furthermore, they may be ineffective due to resistance across the entire azole class. IV antifungal therapy with an echinocandin (micafungin 100 mg daily; caspofungin 70 mg loading dose, then 50 mg daily; and anidulafungin 200 mg loading dose, followed by 100 mg daily) can be effective, but some data suggest higher recurrence rates compared to treatment with an azole. Systemic AmB formulations are another option but can be associated with substantial toxicity.

Patients at significant risk for oropharyngeal candidiasis, such as those receiving cytotoxic chemotherapy, high-intensity immunosuppression, or who have advanced HIV, should be considered for prophylaxis. Topical agents such as nystatin or clotrimazole are generally effective. Systemic fluconazole 100 to 200 mg thrice weekly may also be effective as suppressive therapy in cases of recurrent infection.

Invasive Candidiasis

Invasive candidiasis is the most common serious fungal infection in the surgical population. Infections usually involve the bloodstream and/or intra-abdominal sites, although other organs (e.g., bones, joints, central nervous system) can be involved. Even with intense *Candida* colonization, host defenses must be breached for invasive infection to occur. The main lines of defense are intact GI and skin barriers and effective innate immune responses. Conditions that impact these include gut injury, surgical procedures, severe pancreatitis, thermal injury, vascular access catheterization (particularly if used for parenteral nutrition or hemodialysis), renal failure, corticosteroid use, and neutropenia.

The decision to treat is straightforward in patients with proven established infections. For invasive infection this generally means clinical signs and symptoms compatible with such an infection and material from a normally sterile source (e.g., blood, deep tissue, peritoneal fluid) showing culture or histopathologic evidence for fungal infection. One should never withhold therapy in patients with positive blood cultures because this can be associated with poor outcomes and increased secondary complications. Because symptoms can be nonspecific and blood cultures may be insensitive for detection of invasive candidiasis, treatment is often empiric. Development of prediction rules for invasive candidiasis and the emergence of nonculture techniques, such as serum beta-glucan measurements, are helping to guide initiation of antifungal therapy.

An additional challenge is interpreting the relevance of *Candida* growth in cultures from nonsterile sites. The presence of *Candida* in sputum, skin, and stool cultures suggests yeast colonization, but it does not indicate infection at those sites. Growth of *Candida* species from urinary catheter and abdominal drain cultures may indicate infection but may simply reflect colonization of the medical device.

Colonization with *Candida* at multiple sites in a critically ill patient suggests a high risk for invasive candidiasis. Discerning whether patients with signs and symptoms of sepsis and multiple sites of colonization have fungal infections can be difficult, and empiric therapy should be considered in such situations.

The choice of antifungal therapy depends on the site of infection, patient status, and antifungal susceptibility patterns. The echinocandins (caspofungin, micafungin, and anidulafungin) are the most effective agents for the treatment of candidemia. These agents are fungicidal against most *Candida* species and have an excellent safety profile. The doses are micafungin 100 mg/d; caspofungin 70 mg × 1, then 50 mg daily; and anidulafungin 200 mg × 1, then 100 mg daily. Fluconazole 800 mg (12 mg/kg) × 1, followed by 400 mg (6 mg/kg) daily is another option. Fluconazole should not be used for invasive candidiasis in patients who are neutropenic, unstable, or in whom azole resistance is a possibility. Other options include AmB formulations and voriconazole, but these are associated with more side effects than the echinocandins and fluconazole. Once the *Candida* species has been identified, treatment can be more focused. For infections due to C. *parapsilosis,* fluconazole is recommended because treatment failures can occur with the echinocandins. Fluconazole is active against most *Candida* species, with the exception of many *C. glabrata* and all *C. krusei* isolates. Fluconazole is generally less costly than the echinocandins and available as an oral agent. Patients who are stable and have an isolate that is likely to be susceptible to fluconazole may be transitioned to oral therapy to complete their course of treatment.

Duration of therapy depends on site of infection. Treatment of candidemia should be continued for 2 weeks after clearance of blood cultures and clinical resolution of infection because sites of microabscesses are frequent and not usually symptomatic. Patients with candidemia should be evaluated for dissemination to the eye with a fundoscopic exam, and if there is evidence for chorioretinitis, treatment should be extended to resolution of findings. In cases of endophthalmitis, a vitrectomy and intraocular instillation of an antifungal agent may be needed. The length of therapy for noncandidemic forms of invasive candidiasis is less clear. Treatment of intra-abdominal infections is generally for 2 weeks but may be longer, depending on whether control of the infectious source has been attained. Infections such as osteomyelitis (e.g., poststernotomy *Candida* mediastinitis) and endocarditis generally require surgical management and many months of antifungal therapy.

Candida bloodstream infections often occur in patients with central venous catheters. Obviously infected catheters should be removed. However, it is not always possible to determine whether the catheter served as the primary source of infection, became secondarily infected, or is not infected at all. As a general rule, catheters should be removed. Retention of the catheter can be considered in patients with implanted access devices and candidemia in the setting of cytotoxic chemotherapy and neutropenia. In such patients, the catheter might not be infected.

Candiduria is a common finding in hospitalized surgical patients. Not all patients require treatment, and removal or exchange of a urinary catheter is effective in many cases. Indications for treatment include neutropenia, upcoming urinary instrumentation, and symptomatic disease. Fluconazole at 200 to 400 mg/d may be effective. Treatment of fluconazole-resistant isolates can be challenging because the urinary penetration of voriconazole and the echinocandins is suboptimal. Treatment with systemic or topical AmB is an option, but both are associated with side effects. The echinocandins do not penetrate well into urine but may be effective in cases of renal parenchymal disease.

Antifungal drugs are increasingly used for prevention of invasive candidiasis in high-risk surgical patients such liver, pancreas, small intestine, and lung transplant recipients. The role of antifungal prophylaxis in critically ill adults is evolving. Indications for prophylaxis in this population likely include patients with recurrent gastrointestinal perforations or anastomotic leakages and patients requiring prolonged intensive care unit (ICU) support who possess multiple risk factors for invasive candidiasis.

Filamentous Fungi

Infections due to filamentous fungi such as *Aspergillus*—and to a lesser extent the Zygomycetes *Fusarium, Scedosporium,* and the dark molds—may be encountered in surgical settings. These fungi are present in the environment, and infection can develop after inhalation or direct inoculation from external sources. Patients with abnormal lung anatomy or function may be chronically colonized with *Aspergillus* or other molds, which can then progress to invasive or saprophytic (e.g., fungal ball) disease. Aspergillosis, scedosporiosis, and mucormycosis may be encountered in patients with traumatic injury and in near-drowning victims.

Aspergillosis

Invasive aspergillosis is an increasingly important problem in surgical patients. Risk factors include prolonged and profound neutrophil dysfunction and use of corticosteroids and other immunosuppressive drugs. Because the respiratory tract is the main site of contact with *Aspergillus* spores, patients with significant abnormalities of respiratory tract structure and function, such as those with cystic fibrosis, chronic lung diseases, lung transplantation, and prolonged mechanical ventilation, are also at risk for aspergillosis. Rarely, infection occurs due to direct inoculation of a surgical site or following traumatic injury.

Treatment options for invasive aspergillosis have dramatically expanded in the past decade. Voriconazole at 6 mg/kg every 12 hours × 2 doses, followed by 4 mg/kg twice daily is the treatment of choice. Typically, treatment is initiated with IV voriconazole so as to rapidly achieve therapeutic drug levels. This is then quickly followed by transition to oral voriconazole for ease of administration. Monitoring of voriconazole levels is likely helpful for optimizing care, but its exact role is evolving. Adding an echinocandin to voriconazole may improve outcomes in invasive aspergillosis and has little downside. Treatment with AmB is another option. Prior to the introduction of voriconazole, this was the treatment of choice. This drug remains effective against most clinically relevant species of *Aspergillus*, but it is associated with substantial infusion-related and renal toxicities. Posaconazole is another option, but its role in treatment of invasive aspergillosis is not yet fully defined. Itraconazole has historically been used for mild to moderate cases of aspergillosis, but it use has been mainly supplanted by the newer azoles.

Zygomycetes

Mucormycosis typically affects immunocompromised patients but may also be seen following traumatic injury and near drowning in otherwise normal hosts. Additional risk factors for infections include uncontrolled diabetes mellitus and treatment with the iron chelator deferoxamine. Common sites of infection include the respiratory tract, sinuses, and skin. The infection is angioinvasive and may extend locally to involve adjacent structures (e.g., orbits, brain) and to cause extensive tissue destruction.

Management of mucormycosis generally requires a multidisciplinary approach. This includes correction of metabolic abnormalities (e.g., treatment of diabetic ketoacidosis, discontinuation of deferoxamine), reduction of immunosuppression, and surgical excision or débridement of infected material. This is particularly important if there is angioinvasion or necrosis. A lipid formulation of AmB (e.g., liposomal AmB) at 5 to 7.5 mg/kg/d is the treatment of choice. The addition of an echinocandin can be considered, but data to support this are sparse. Posaconazole may be considered for salvage therapy in patients intolerant to or failing AmB but should not be used as first-line treatment. Posaconazole may also have a role as

maintenance therapy once the patient has received several weeks of AmB and infection is under better control.

CONCLUSIONS

Fungal infections are increasingly encountered in the surgical and critical care settings. Physicians now have unprecedented treatment options for patients with such infections. An understanding of the role of older agents such as fluconazole and AmB and the newer antifungals (e.g., voriconazole, posaconazole, and the echinocandins) is important for successfully managing these patients.

Measuring Outcomes in Surgery

Caprice C. Greenberg, MD, MPH

INTRODUCTION

In the past two decades, an unprecedented focus on the need to measure outcomes in healthcare has resulted from two developments. First, in 1999, the Institute of Medicine (IOM) published its landmark report "To Err is Human" followed closely by "Crossing the Quality Chasm" in 2001. These two IOM reports catapulted the quality and safety issues in the U.S. healthcare system to the forefront of modern day healthcare issues. To improve quality, we must be able to accurately and efficiently measure it; the existing metrics for measuring outcomes, primarily morbidity and mortality, clearly were inadequate, and the required methodologies were underdeveloped.

The second reason for the increasing focus on measurement of outcomes in healthcare is the marked expansion and availability of electronic health information. Increasing numbers of institutions are adopting electronic medical records, and the sophistication of analyses with claims and other administrative data continues to improve. Taken together, the IOM reports and the increasing availability of electronic data have led to an increasing demand from healthcare consumers for the measuring and reporting of outcomes.

DONABEDIAN MODEL OF QUALITY

Although this chapter focuses on measurement of outcomes, the theoretic framework of Avedis Donabedian is important to point out. He believed that in evaluation of quality, structure and process measures must be considered in addition to outcomes. Structure refers to the fixed attributes of a system in which care is provided, such as the facilities, personnel, and policies of a given hospital. Perhaps the most widely recognized structural measure in surgery is volume. Volume is easy to measure, and decades of research document the relationship between higher volume and better outcome. The problem, however, is that the correlation between volume and outcomes is far from perfect. Use of volume to discriminate quality unjustly punishes high-performing, low-volume hospitals and rewards high-volume hospitals regardless of quality. Development of policy to operationalize volume-based referrals has also proven difficult. For example, a volume threshold must be identified to instate volume-based referrals, and the studies that document the volume-outcome relationship have not reported a threshold. The critical ramifications that the value of a volume threshold has for individual hospitals have been shown.

A more direct measure of quality can be achieved with examination of the processes of care. Process measures document whether or not the right thing was done for the right patient at the right time with examination of the proportion of patients who receive a course of treatment that has been associated with improved outcomes. Process measures tend to be more reliable because they are not subject to variations in the risk profile of patients. If a surgeon gives antibiotics to a patient but a surgical site infection (SSI) develops because of uncontrolled diabetes, the surgeon "gets credit" with a process measure based on antibiotic administration but not in an outcome measure of the rate of SSI. Process measures are not without their limitations, however. Determination of the appropriate denominator can be difficult because not all patients should receive all treatments. Process measures also tend to be more difficult to quantify than outcome measures, and access to the required data can be challenging. For example, the required details of care are rarely available in large multiinstitutional data sets. Finally, there is often a lack of high level research to support the link between process measures and improved outcomes, especially those in surgery, which limits the number of process measures that are available.

Figure 1 depicts the relationship between structure, process, and outcome. Structural measures may directly relate to outcomes or may act through their relationship with processes of care. For example, the introduction of bar coding medications (structure measure) has a direct impact on the rate of medication errors (outcome). Increased nurse staffing ratios (structure) on the other hand cannot directly decrease the rate of SSI, but a mechanism can be identified by which an increased nurse to patient ratio (structure) leads to increased compliance with postoperative antibiotic administration (process measure) and ultimately a decrease in the SSI rate (outcome). Figure 2 depicts Birkmeyer's suggestion for the appropriate use of structure, process, and outcome measures based on mortality rate and volume.

Outcomes are the end result of the care that is received and ultimately the quality measures that are the easiest to measure and those that consumers most care about. Outcomes are an especially attractive approach to quality measurement in surgery. An operation is a distinct easily identified intervention and short-term outcomes, including in-hospital measures, are meaningful. For example, complications following a colectomy are much easier to identify in the short term than following a change in a patient's diabetic medication. For these reasons, outcome measures are the focus of the remainder of this chapter.

VARIATION IN OUTCOMES

Surgical outcomes may vary for three important reasons: chance, case mix, and quality of care. The goal in outcome measurement is to isolate the quality of care component, control for case mix, and minimize the influence of chance. Outcomes such as mortality tend to be rare events that can lead to imprecise measures and differences that are that result from chance rather than quality of care. A number of publications have described the issues related to small sample size. Although outcomes tend to be easier to measure and compare than process measures, they are subject to many confounders, such as comorbidity or severity of illness, that can influence how well a patient tolerates surgery. It is important to use statistical techniques that can adjust for these variations in risk in any outcomes analysis to avoid penalizing surgeons or institutions that treat sicker, higher risk cases. Our ability to risk adjust is limited to those characteristics that can be measured and cannot account for unmeasured confounding.

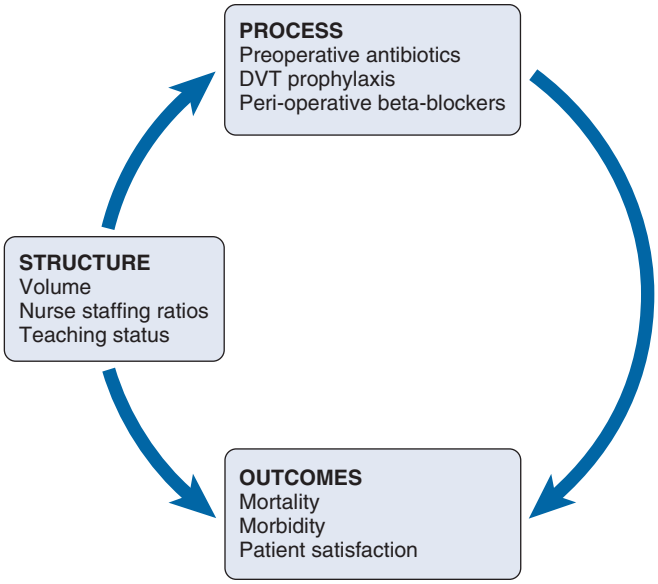

FIGURE 1 The relationship between structure, process, and outcomes. Structure and process measures are dependent on evidence of an impact on outcome. *DVT,* Deep vein thrombosis.

CURRENT MEASURES OF OUTCOMES

Mortality

The most common outcome measure is mortality. Mortality is an unambiguous binary outcome that does not require further definition or clarification. It is easily available in most datasets, including a variety of administrative data sources. It is, however, particularly subject to the two limitations described previously: namely, confounding with the need for case mix adjustment and being a rare event with the associated imprecision in estimates. Most quality reporting that is based on mortality includes techniques for risk adjustment. For example, that National Surgical Quality Improvement Program (NSQIP) collects hundreds of data points per case, including preoperative, intraoperative, and postoperative variables that allow for comprehensive risk adjustment. Figure 3 depicts the impact of risk adjustment on ranking by mortality rate. Because mortality is such a rare event, few institutions have a large enough sample size to reliably use mortality to measure quality. Dimick and colleagues have shown that only coronary artery bypass grafting (CABG) has sufficient volume to reliably use mortality to measure quality. Despite this fact, many reporting systems are moving forward

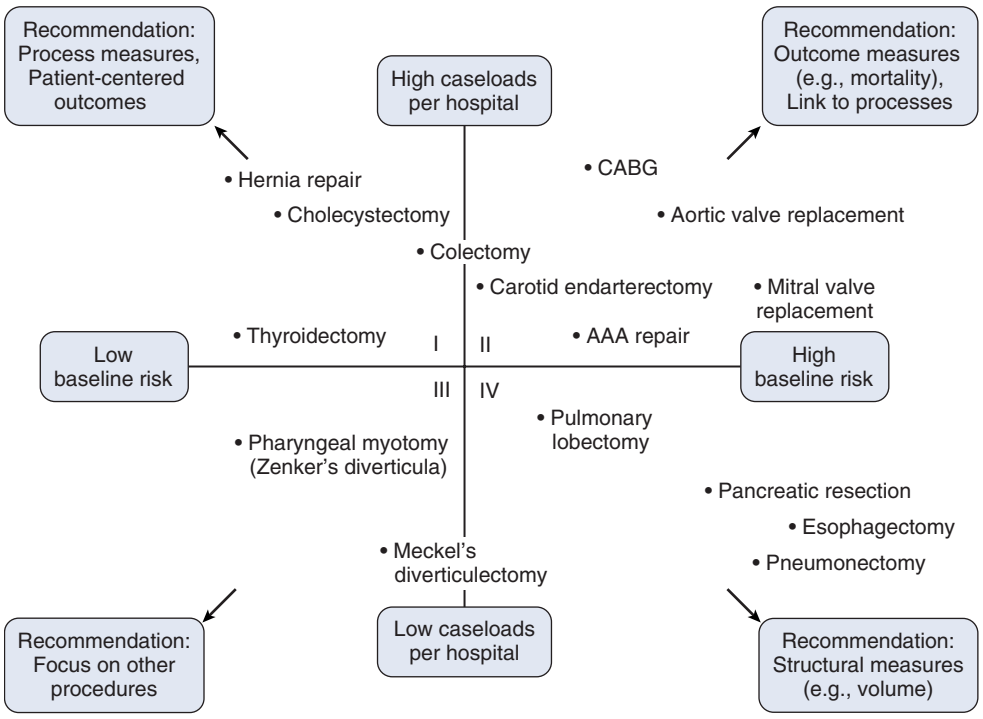

FIGURE 2 Recommendations for appropriate use of structure, process, and outcome measures. *AAA,* Abdominal aortic aneurysm; *CABG,* coronary artery bypass grafting. *(Reproduced from Birkmeyer JD, Dimick JB, Birkmeyer NJO: Measuring the quality of surgical care: structure, process, or outcomes,* JACS *198(4):626, 2004.)*

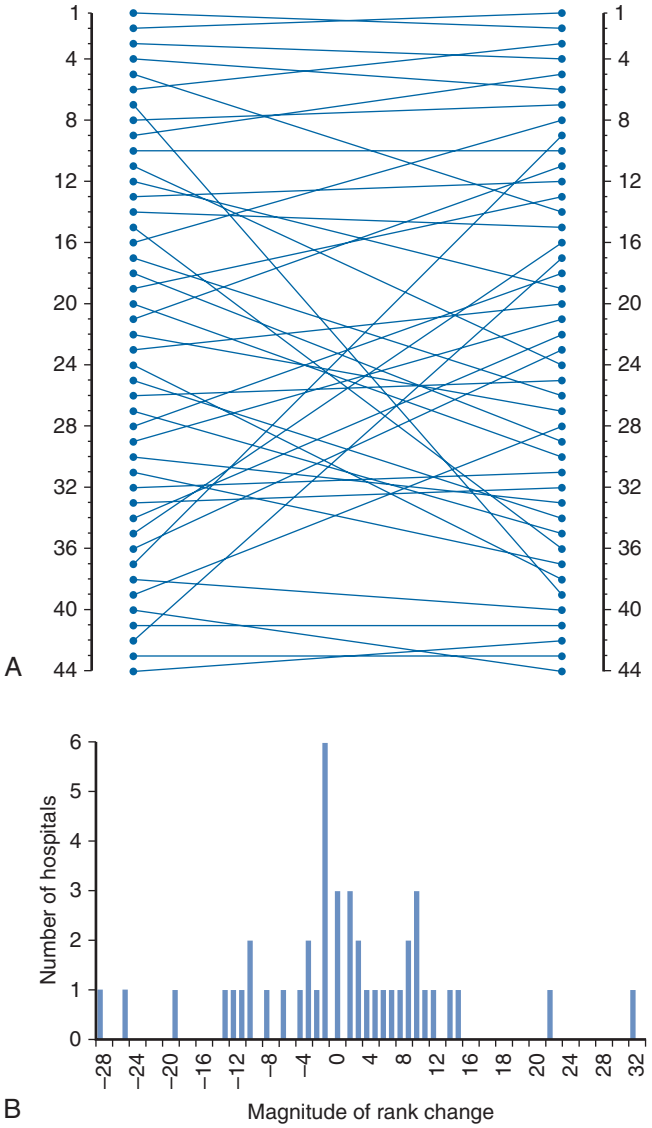

FIGURE 3 The impact of risk-adjustment on rank for mortality measures. **A,** Rankings of 44 hospitals participating in the Department of Veterans Affairs Surgical Risk Study (NVASRS; which became National Surgical Quality Improvement Program [NSQIP]) before (left-hand side) and after (right-hand side) risk adjustment. **B,** The magnitude of the change in rank induced by risk adjustment. *(Reproduced from Khuri SF, Daley J, Henderson W, et al: Risk adjustment of the postoperative mortality rate for the comparative assessment of the quality of surgical care: results of the National Veterans Affairs Surgical Risk Study,* JACS *185(4):315, 1997; and Fink AS: Adjusted or unadjusted outcomes,* Am J Surg *198(Suppl):S28, 2009.)*

with public reporting of risk-adjusted mortality rates without addressing this critical issue.

Morbidity

NSQIP also reports on risk-adjusted measures of morbidity, including overall and specific complication rates. The advantage of this type of outcome reporting is that it tends to be more actionable than mortality rate. Providers can identify the processes of care that influence a given complication rate and design interventions to improve these processes of care. This is especially true for procedure-specific complication rates. For example, if a hospital has a higher than expected rate of SSI after colectomy, several points in the system can be identified for potential intervention. These include the approach to bowel preparation, administration of preoperative antibiotics, management of postoperative antibiotics, temperature regulation in the operating room, glucose control, and sterile technique. Once an aberrant process is identified (i.e., poor compliance with hair removal technique in Surgical Care Improvement Project [SCIP]), an intervention can be devised to improve performance and decrease the complication rate.

Composite Measures

Composite measures have been developed in an attempt to account for the limitations of individual quality measures as discussed previously. A composite measure based on mortality and volume has been proposed by Dimick and colleagues. An observed outcome, such as mortality, is clearly superior to a proxy measure, such as volume, but only to the extent that it is reliable. An ideal measure then uses observed data to the extent that it is reliable and proxy measures only to the extent necessary. Because the reliability of a measure of mortality is primarily determined by case volume, a statistical approach can be used to weight an institution's mortality rate by case volume and then determine the rest of the composite measure by volume. The weight assigned to volume and mortality is individualized for each hospital and each procedure, ensuring that the composite measure is optimized to predict future performance.

Patient-Centered Outcomes

Another approach to improvement of quality measurement is centered on expanding the available measures and focusing on outcomes that are most important to patients. Although morbidity and mortality measures are clearly important, quality of care goes beyond whether the patient lives or dies and whether a complication occurs or not. Surgical treatment can impact many aspects of a patient's life, and these patient-centered outcomes are becoming increasingly important. Patient centeredness was included as one of the six constructs that constitute quality healthcare according to the IOM definition. Patient-centered outcomes research (PCOR) is the study of the relationship between the health outcome and the treatment provided in the context of the patient experience.

A number of patient-centered outcomes can be considered. *Patient satisfaction* is the emotional or cognitive evaluation of a health encounter by patients as defined by their experience. This may include satisfaction with the clinical or technical skill of providers, interactions and communication with providers, accessibility and convenience, and aspects of the setting in which care is provided. Although subjective, patient satisfaction is increasingly used to assess measure performance and is one of the few measures to be collected at the individual surgeon level. In addition, this measure underscores the fact that patients are consumers of healthcare. *Decision regret* is an especially pertinent outcome given the recent increase in shared decision making and preference sensitive care. As patients take a more active role in determining their treatment course, they must remain confident in those decisions and it is important to evaluate remorse or a realization that one should have acted differently. *Health-related quality of life* (HRQL) measures different domains of health such as physical, emotional or social functioning, and can be influenced by both disease and treatment processes. Many previously validated instruments are available, both generic and disease-specific, to measure these patient-centered outcomes.

INTEGRATING OUTCOME MEASUREMENT INTO THE CURRENT PRACTICE OF SURGERY

Benchmarking and Performance Feedback

One of the goals of outcome measurement is to provide a metric to identify areas for improvement and monitor progress. To do this, a given provider or institution must be given a framework in which to interpret the data that are provided. This is often achieved by comparing an individual's performance with the anonymous performance of peers. The difficulty with this is that given the statistical "noise" or unreliability of estimates for outcome measures, most individuals fall within the margin of error. For example, NSQIP provides results as the ratio of the observed to the expected ratio (O/E) of a given outcome (Figure 4). The expected rate is derived with a regression model based on case mix and provides for risk adjustment. If a hospital performs as expected, therefore, the O/E ratio should be 1. If they perform better than expected, the O/E is less than 1; and if they perform worse than expected, it is greater than 1. They also provide 95% confidence intervals; the confidence intervals that are provided must be considered in quality measurement.

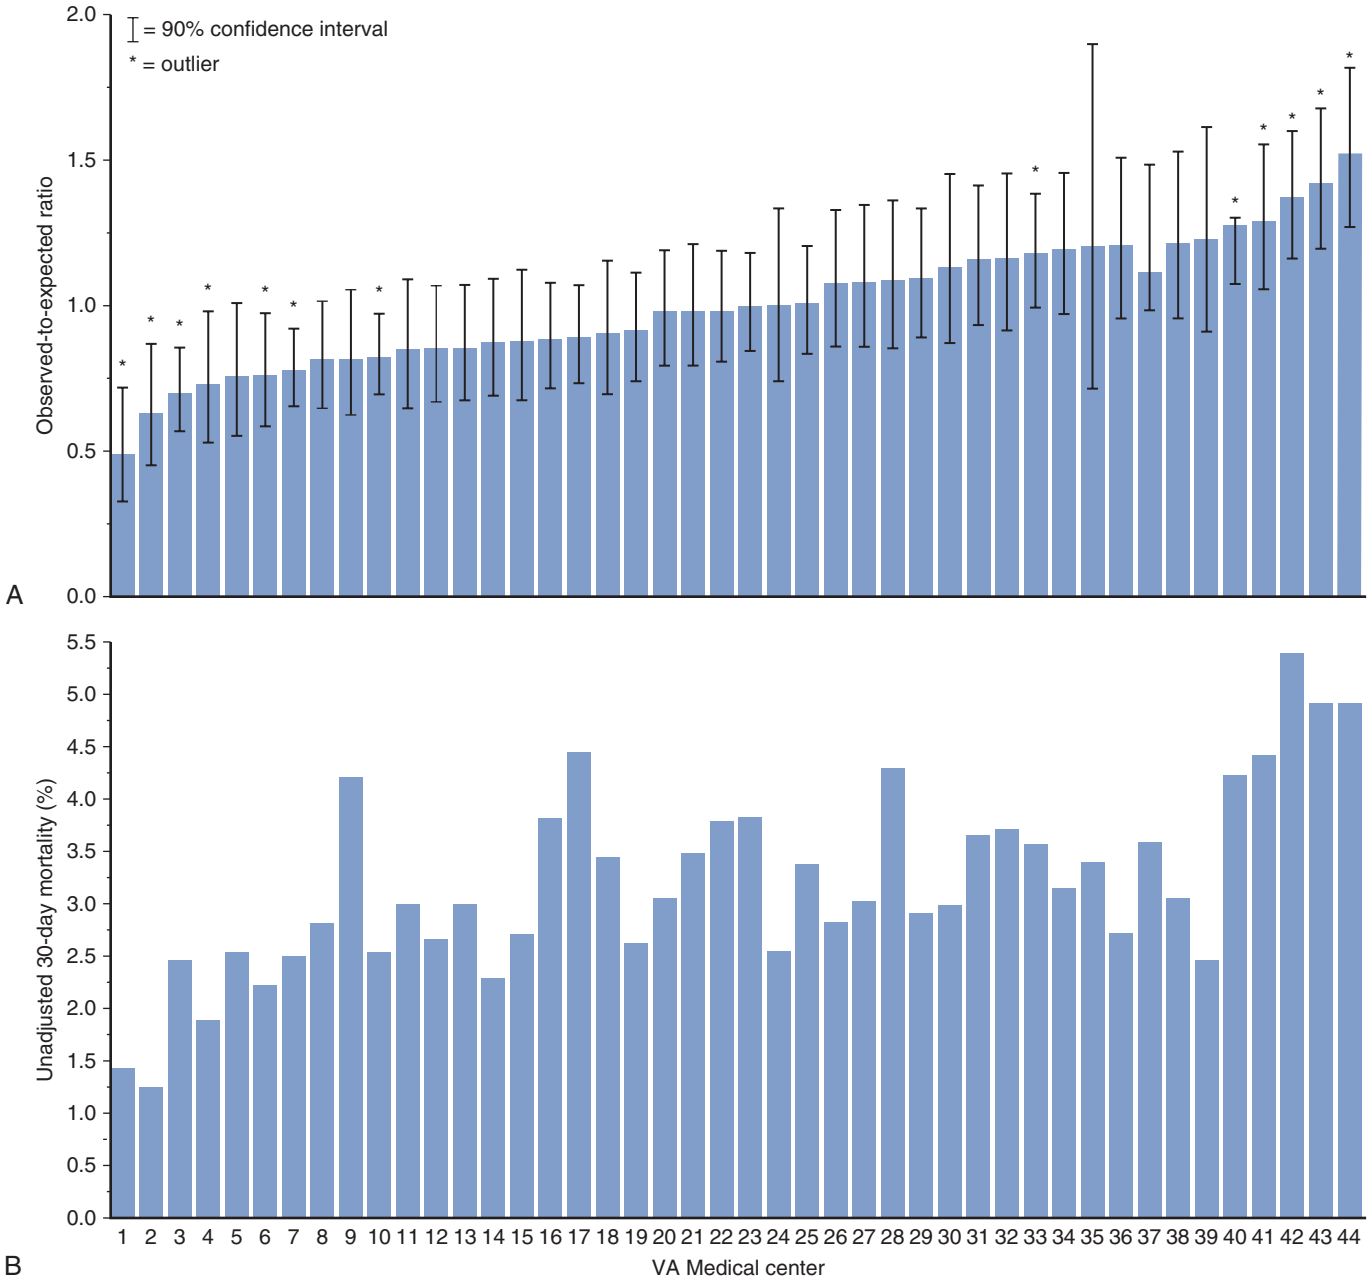

FIGURE 4 Results of the Department of Veterans Affairs *(VA)* Surgical Risk Study (NVASRS; which became National Surgical Quality Improvement Program [NSQIP]). **A,** The importance of considering the 90% confidence interval when interpreting performance. Only the *starred* institutions performed significantly differently than their expected mortality rate. *(Reproduced from Khuri SF, Daley J, Henderson W, et al: Risk adjustment of the postoperative mortality rate for the comparative assessment of the quality of surgical care: results of the National Veterans Affairs Surgical Risk Study,* JACS *185(4):315, 1997.)*

For most hospitals, the confidence intervals cross 1, signifying that their performance falls within the margin of error regardless of where the point estimate lies. However, for high outliers or poor performers, these reports can provide motivation and an estimate of how much improvement is necessary. Another approach is to provide a benchmark based on either national guideline recommendations or the top performers. Although guideline recommendations can provide an objective measure that is stable over time, they are often based on expert opinion and may or may not be achievable. Benchmarks based on top performers can provide a reasonable goal with which individual performance can be compared. For example, SCIP calculates adherence rates for the top 10% of performers in each measure for use as a benchmark.

Quality Collaboratives

Outcome reporting as described previously is an important first step, but it falls short of providing participants with tools to improve performance. To meet this need, a number of regional quality collaboratives have developed across the country. The goal of these collaboratives is not only to share data about outcomes but also to share best practices and provide a forum for learning from other institutions so that performance can be improved. They are usually organized at the state or regional level to allow for regular in-person meetings. Tables 1 and 2 were published in a recent article in the Journal of the American College of Surgeons article that described the success of the Tennessee Surgical Quality Collaborative, which uses NSQIP data. Such significant improvements in outcomes and financial savings have been consistently reported by these collaboratives.

Maintenance of Certification

The American Board of Surgery currently requires that diplomats who certify or recertify after July 1, 2005, participate in Maintenance of Certification (MOC). One of the four core components of MOC is the ability to demonstrate evaluation of performance in practice. Such practice assessment can include participation in a national regional or local surgical outcomes database or quality assessment program, including those sponsored by specialty societies, the American College of Surgeons, regional collaboratives, or other quality improvement programs. For this reason, all practicing surgeons must be familiar with the approaches to outcome and other quality measures, and the limitations to each approach. Because this

TABLE 1: Surgical site infections: change in surgical site infections (SSIs) during the first year of the Tennessee Surgical Quality Collaborative

	Postoperative occurrences per 10,000 procedures		Relative risk (95% confidence interval)
	2009	*2010*	*2010 Compared with 2009*
Deep incisional SSIs	93.6	76.5	0.82 (0.63-1.06)
Organ/space SSIs	157.7	181.2	1.15 (0.96-1.38)
Superficial incisional SSIs	357.6	289.9	0.81 (0.71-0.92)
All SSIs	603.3	546.9	0.91 (0.82-0.99)

TABLE 2: Financial model: savings realized during the first year of the Tennessee Surgical Quality Collaborative

	Postoperative occurrences per 10,000 procedures		Unit costs	Net savings per 10,000 procedures
	2009	*2010*		
Acute renal failure	75.3	56.4	$28,359	$535,985
Graft/prosthesis/flap failure	45.8	18.1	$14,851	$411,373
On ventilator > 48 h	293.6	250.3	$27,654	$1,197,418
Superficial incisional surgical site infection	357.6	289.9	$27,631	$1,870,619
Wound disruption	90.8	59.7	$14,827	$461,120
Full year 2010 savings				$4,476,515
Full year 2010 costs				$2,278,972
Net savings				**$2,197,543**

Reproduced from Guillamondegui OD, Gunter OL, Hines L, et al: Using the National Surgical Quality Improvement Program and the Tennessee Surgical Quality Collaborative to improve surgical outcomes, JACS *214(4):709, 2012.*

is a requirement for board certification, surgeons may as well choose to participate in the outcome measurement and quality improvement programs with the greatest potential to improve their practice.

THE IMPORTANCE OF OUTCOME MEASUREMENT IN RESEARCH

Healthcare is supposed to be evidence based but frequently falls short of this ideal. There is often a lack of data available to inform many healthcare decisions, and the data that do exist are frequently limited in quality. In addition, the high-quality data that do exist may not be applicable to all patients; extrapolation from the select population of participants in a given clinical trial to the heterogenous population in everyday practice is often not possible. Finally, this evidence is often slow to disseminate to practitioners and to be implemented into and change practice. Comparative effectiveness research (CER) and PCOR are gaining traction as new research disciplines that aim to bridge these gaps. The federal government has recently committed significant funds for this type of research because of the potential immediate impact on care. For this reason, practicing surgeons must be familiar with the terms.

Comparative Effectiveness Research

CER compares the outcomes of two alternative approaches to care, either of which has the potential to be best practice, in real world settings. Comparative effectiveness research can be either retrospective or prospective and can include clinical trials as long as they meet the previous considerations. A clinical trial in CER does not contain a placebo arm and has few, if any, exclusion criteria. These types of trials are often referred to as pragmatic or effectiveness trials. The goal of comparative effectiveness research is to increase the evidence available to support healthcare decision making and to streamline the integration of new evidence into everyday practice. By providing increased evidence, CER has the potential to improve our approaches to quality measurement, for example, by providing new process measures.

Patient-Centered Outcomes Research

PCOR is a related discipline. In fact, CER can be considered as one type of PCOR. The Patient-Centered Outcomes Research Institute (POCRI) has developed the following definition: "Patient-Centered Outcomes Research (PCOR) helps people and their caregivers communicate and make informed health care decisions, allowing their voices to be heard in assessing the value of health care options. This research answers patient-centered questions such as:

1. 'Given my personal characteristics, conditions and preferences, what should I expect will happen to me?'
2. 'What are my options and what are the potential benefits and harms of those options?'
3. 'What can I do to improve the outcomes that are most important to me?'
4. 'How can clinicians and the care delivery systems they work in help me make the best decisions about my health and healthcare?'"

One of the goals of PCOR is to engage patients and other stakeholders in the research process and, in particular, in determination of appropriate outcomes. Often in research, we set intermediate outcomes that are easy to measure and compare but that do not have any impact directly on patient care. The goal in PCOR is to ensure that the outcomes of all studies are meaningful and important to patients, including the development of new patient-centered outcome measures.

CONCLUSION

The first step to improving healthcare is to determine what constitutes high-quality care and how best to measure it. In this chapter, the current approaches to quality measurement have been reviewed, with a focus on outcome measures. Although we have come a long way, much still remains to be done. The recent focus on patient-centered outcomes research suggests that there may be political will to support an improved approach to quality measurement. Much of the data required for clinically meaningful measures are currently difficult to capture. As a result, current measures often focus on what can be measured rather than what is most likely to improve quality of care, either because it reflects quality or because it is actionable. Quality measurement in healthcare is still in its infancy. As our ability to handle large amounts of electronic health data continues to improve, as our statistical methodologies become increasingly sophisticated, and as researchers identify new links between the care we provide and the outcomes that are observed, the field of quality measurement will continue to mature. Surgeons must recognize the impact of quality and outcome measurement on their practices and remain abreast of the developments in this important field.

Comparative Effectiveness Research in Surgery

Hugh G. Auchincloss, MD, MPH, and Matthew M. Hutter, MD, MPH

INTRODUCTION

The field of comparative effectiveness research (CER) has experienced unparalleled growth in recent years. This growth represents both an appreciation for the intrinsic value of evidence-based medicine and an acceptance of present and future economic realities. In short, patients deserve to know which treatments are most effective for them, and the healthcare system cannot afford to pay for those that are not. Surgery in particular stands to benefit from CER, and surgeons are positioned to become leaders in this field. Surgery is full of new treatments, techniques, and technology but little guidance as to how and when to adopt them. The result is wide variation in surgical practice among regions, hospitals, providers, and patient populations. Surgeons individually and as a whole must take an active role in grounding the practice of surgery in a solid evidence base. CER is a powerful tool to that end.

WHAT IS COMPARATIVE EFFECTIVENESS RESEARCH?

Two government agencies define CER in a way that illustrates both its breadth and its depth. The Institute of Medicine (IOM) focuses on the expansive mission of CER:

> *"CER is the generation and synthesis of evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat, and monitor a clinical condition or to improve the delivery of care. The purpose of comparative effectiveness research is to assist consumers, clinicians, purchasers, and policy makers to make informed decisions that will improve health care at both the individual and population level."*

The Congressional Budget Office (CBO) provides a more technical definition that speaks to the depth of CER:

> *"As applied in the health care sector, analysis of comparative effectiveness is simply a rigorous evaluation of the impact of different options that are available for treating a given medical condition for a particular set of patients. Such a study may compare similar treatments, such as competing drugs, or it may analyze very different approaches, such as surgery and drug therapy. The analysis may focus only on the relative medical benefits and risks of each option, or it may also weigh both the costs and the benefits of those options. In some cases, a given treatment may prove to be more effective clinically or more cost-effective for a broad range of patients, but frequently a key issue is determining which specific types of patients would benefit most from it."*

CER seeks to determine *which treatment* done on *which patient* is *most effective* at producing *an outcome*. The addition of "and at what cost" to the previous sentence, consistent with the CBO definition of CER, is appropriate but has proven controversial in the United States for reasons to be discussed subsequently. CER can be understood by looking at each of these components individually.

EFFECTIVENESS VERSUS EFFICACY

Efficacy is a measure of the ability of a treatment to produce results under experimental conditions. Effectiveness, in contrast, measures the performance of a treatment in the real world. Not infrequently, efficacy and effectiveness research yield surprisingly different results. For example, tight glucose control in critically ill patients was thought to decrease mortality based on the results of efficacy studies but failed to yield the same results when studied in actual intensive care units.

Both efficacy and effectiveness research have strengths and limitations. Efficacy studies, by virtue of the controlled environment in which they are performed, usually provide clear results and explanations. This clarity, though, comes at the price of generalizability. Practicing clinicians may not believe that the results of such studies are applicable to the conditions in which they practice. In contrast, effectiveness studies tend to produce more ambiguous results. The inherent complexity of the real-world conditions under which these studies are done may make understanding causal mechanisms challenging. However, clinicians may find the results of these studies more immediately relevant to their own practice.

WHICH TREATMENT?

Generally speaking, CER is a head-to-head comparison of two or more alternative treatment strategies. Treatment strategy in this context may mean comparison of a new drug or procedure with standard of care, a medical treatment with a surgical one, or different conditions of healthcare delivery. When the treatment strategies compared are similar, CER tends to produce results that are easy to accept, at least from a statistical standpoint. As the differences between treatments grow, research methods must become more rigorous to generate valid conclusions.

In its simplest form, CER in surgery compares two similar procedures or protocols. An example is comparison of open with laparoscopic repair of primary unilateral inguinal hernia (as with Neumayer in the *New England Journal of Medicine* in 2004) or albumin with saline solution for the resuscitation of critically ill patients (as in the Saline versus Albumin Fluid Evaluation [SAFE] study from 2004).

Pitting a medical therapy against a surgical one is more complex. For example, a 2012 *New England Journal of Medicine* study conducted jointly by the Society of Thoracic Surgeons (STS) and the American College of Cardiology Foundation (ACCF) found that older patients with multivessel coronary disease who underwent coronary artery bypass grafting had a long-term survival benefit compared with those who underwent percutaneous catheter-based intervention. The methodologic debate sparked by this study is perhaps a cover for a more passionate political debate occurring behind the scenes, which serves as a reminder that CER can create a minefield when professional interests are at stake.

CER may also compare the setting in which treatment occurs. Birkmeyer and colleagues have shown that certain high-risk operations like esophagectomy and pancreaticoduodenectomy are performed with lower overall mortality at high-volume institutions compared with low-volume institutions. Similar studies have compared outcomes based on hospital resources, surgeon age, individual surgeon volume, and involvement of surgical trainees. All of these studies fall under the umbrella of CER.

WHICH PATIENTS?

The characteristics of individual patients are important to CER in two fundamental ways. First, because of the real-world nature of CER studies, they often feature groups of patients who differ in significant ways. Statistical methods must be used to balance these differences and minimize their impact on the outcome. Second, the outcome of a treatment strategy depends in part on the group of patients to which it is applied. Studies often seek either by design or in retrospect to identify subgroups in which a treatment is particularly beneficial or harmful.

Balancing two or more groups of patients with dissimilar characteristics is one of the foremost challenges of CER. Patients may differ in age, demographics, diagnosis, comorbidities, severity or stage of illness, or concurrent procedures. When these differences impact the outcome independently of the treatment studied, they are known as confounders. Randomization, as in a prospective clinical trial, balances known and unknown confounders evenly between treatment arms. In an observational study, a researcher can only hope to acknowledge the uneven distribution of known confounders and adjust for them with statistical methods. Multiple such methods exist, including stratification, multiple regression modeling, and the use of propensity scores.

Stratification is the simplest method of balancing known confounders. If the study population is large enough, it can be divided into blocks based on known confounders, and the analysis can be conducted within each block. For example, the population could be divided into three blocks based on age group and then further divided into six blocks based on patient gender. The resulting analysis would compare young women only with young women, and so on. This method yields results that are easy to interpret, but its usefulness is limited to large populations with few confounders. With small populations or multiple confounders, stratification leads to inadequate power (i.e., the ability of a study to detect a difference when one really is present).

Multiple regression modeling is a more sophisticated and commonly used method of adjusting for confounders. Multiple regression modeling is a three-step process. First, the researcher determines which factors other than the treatment in question contribute to the outcome. Second, a statistical model is constructed that describes the outcome as a function of those factors and the treatment. Lastly, the model is used to adjust for the effect of the other factors, leaving behind only the effect of the treatment. Multiple regression models can be used to adjust for multiple confounders simultaneously without a significant loss of power. Most statistical software programs are equipped with a model-building function that makes this method accessible to researchers with a basic knowledge of statistics.

The use of propensity scores and propensity matching is an alternative to multiple regression modeling that has recently experienced an exponential growth in popularity. This method is based on two assumptions: first, in an observational study, a patient is more likely to have received one treatment versus another based on that patient's characteristics; and second, random chance explains why two patients with similar baseline characteristics may undergo different treatments. A propensity score is a measure of the likelihood of a patient receiving a specific treatment. It is the product of a multiple regression model that uses patient characteristics as predictors and treatment strategy as the outcome. Propensity scores can be used in a variety of ways but are most commonly used to match patients who underwent different treatments but, based on having the same propensity score, can be said to have similar baseline characteristics. Propensity matching is often advertised as a method of creating a randomized trial out of observational data. In reality, it suffers from the same limitations as multiple regression modeling, namely an inability to control for unknown confounders.

At first glance, these methods of adjustment appear to be formulaic and objective. In fact, the process is highly subjective. The researcher chooses which of the methods to use. Beyond this, the researcher chooses which confounders need to be adjusted for and what form those confounders should take. For example, most surgeons agree that a study comparing two types of hernia repair should be adjusted for patient weight. Is it sufficient to divide patients into obese versus nonobese? Or should body mass index (BMI) be retained in the model in continuous numeric form? Is the difference between a BMI of 25 and a BMI of 30 the same as that between 30 and 35 or that between 60 and 65? And what should be done with underweight patients? The answers to these questions are determined by the researcher and can have profound impact on the results of the study. Ideally, the plan for adjustment is made in prospective fashion based on previous studies, sound clinical judgment, and preliminary sense of the architecture of the data. However, even with experienced and thoughtful researchers, the results of observational studies should be examined critically for residual confounding.

CER can also identify groups of patients who, based on their characteristics, may benefit from a treatment strategy. These may be discovered during subgroup analysis of a larger study or, indirectly, through studies designed to determine which factors predict a certain outcome after a treatment. For example, the National Emphysema Treatment Trial (NETT), published in the *New England Journal of Medicine* in 2003, was a randomized controlled trial to evaluate lung volume reduction surgery in patients with chronic obstructive pulmonary disease (COPD). As a secondary goal, the study sought to identify patient characteristics that were associated with a good outcome after lung volume reduction surgery (LVRS). Indeed, although the overall benefit of LVRS remains unclear, in patients with predominantly upper lobe emphysema and low exercise tolerance, it appears to confer a significant improvement in survival and quality of life. Studies that look for predictors of an outcome after treatment indirectly address a similar question. The NETT protocol, for example, was informed by a series of earlier studies that showed upper lobe emphysema to be a predictor of good functional outcome after lung volume reduction surgery. Although these studies do not directly compare one treatment with another, they provide the foundation for future studies that do.

WHICH OUTCOME?

The effectiveness of one treatment versus another is measured in its ability to generate a desirable outcome, avoid an undesirable one, or some combination of the two. There are many such outcomes to choose from, including morbidity and mortality, freedom from disease or symptoms, cost, and quality of life. The choice of which to use depends on a combination of clinical relevance and practical considerations.

Mortality is an obvious choice. Death as an outcome has inherent face validity (everyone usually agrees it is something to be avoided). Its measurement is unambiguous. It is accurately recorded, and when it is unrecorded, it is frequently obtainable through publicly available resources like death certificates. Mortality, though, is an insensitive measure of effectiveness, particularly in surgery. Because mortality associated with most surgeries is thankfully quite low, it is seldom a useful method for discriminating one treatment strategy from another. Short-term mortality as an outcome in CER is therefore limited to studies regarding high-risk procedures or studies focusing on the delivery of healthcare at the hospital or regional level. Long-term survival and disease-specific survival may be more useful but are harder to reliably measure.

Morbidity, in contrast, is a frequent occurrence after most procedures and so is commonly used as an outcome in CER. Measures of morbidity, though, are more subjective than mortality. Even straightforward events like postoperative urinary tract infection may be defined in multiple ways. In addition, although some postoperative events clearly are worse than others, less clear is how to incorporate

this subjective ranking into objective data. Composite measures of morbidity may help to address some of these inherent deficiencies.

Procedure-specific outcomes such as recurrence after hernia repair or continence after ileorectal anastomosis are favored by surgical researchers because of their clinical relevance. Measurement of these outcomes can be a subjective and resource-intensive process. Years may be needed to observe a difference in graft patency after two competing methods of lower extremity revascularization, for example. In addition, more often than not, the success of a procedure cannot be determined with one outcome measure alone. The success of bariatric surgery is a function not just of weight loss but of also of improvement in comorbidities and quality of life. Quantifying these outcome measures in a universally accepted fashion is challenging.

Specific groups of researchers tend to have outcomes that are of particular interest to them. Hospital administrators and insurance companies may focus on outcomes of efficiency such as length of stay, use of resources, or readmission rates. Health economics research deals in constructs such as the incremental cost effectiveness ratio. Countless other measures exist that may be relevant in certain contexts.

Lastly, patient-centered outcomes have assumed a prominent position in CER. Broadly speaking, these are outcomes that are important to patients but, because of the difficulty of quantifying and measuring them, have historically received little attention. Despite the challenges associated with comparing treatments based on constructs such as quality of life, improved functionality, and patient experience, this is likely to be an area of significant growth for CER in surgery in the future.

HOW IS COMPARATIVE EFFECTIVENESS RESEARCH DONE?

CER can take many forms, including reviews of the existing literature, observational studies, or randomized controlled trials. Each has strengths and weaknesses with regard to feasibility, relevance, and quality of evidence produced. (In simplified terms, evidence is often classified into several levels, with level I reserved for randomized controlled trials, level II for observational studies, level III for case studies and literature review, and level IV for expert opinion. These levels remain in common usage, although the most recent recommendation of the U.S. Preventative Services Task Force [USPSTF] is to classify evidence as "good," "fair," and "poor." These levels are distinct from the USPSTF's "grades," which are for use by clinicians regarding clinical practices; Tables 1 to 3).

The simplest method of CER is review of the existing literature. This may take the form of a meta-analysis or a literature review. The primary advantage of a review of existing literature is that it is cheap and can be done relatively quickly. The drawbacks are numerous. No studies regarding the effectiveness of many treatments. When these studies do exist, reconciling differences in their methodology can be challenging. Finally, there is the possibility of publication bias (i.e., the tendency of journals to publish positive studies but not negative ones). Despite these limitations, a comprehensive review of existing literature should be the initial step in all CER.

Observational studies are the most common form of CER. These vary greatly in size and complexity, ranging from case reports and case series to massive cohort studies and large national database projects. Observational studies are limited by the inability to control for unknown confounders. However, they have the advantage of being both relatively easy to perform and immediately applicable to clinical practice. The ability to perform high-quality observational studies in surgery has been aided greatly by the growing availability of large administrative and clinical databases. Administrative databases, including Medicare claims data and national registries such as the Healthcare Cost and Utilization Project Nationwide Inpatient Sample (HCUP-NIS), are publically available and contain millions of patient records. They can be a robust source of information for researchers skilled in navigating their complexity. However, administrative data, which exist primarily for the purpose of billing, can be highly variable depending on the provider or the hospital in which they are recorded. Moreover, they lack the rich clinical context that can be found in databases like the American College of Surgeons National Surgical Quality Improvement Project (ACS-NSQIP), the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP), the American College of Surgeons National Trauma Data Bank (ACS-NTDB), the Society of Thoracic Surgeons (STS) Adult Cardiac Surgery, Congenital Heart Surgery, and General Thoracic Surgery Databases, and the Scientific Registry of Transplant Recipients (SRTR). These databases have been developed on the initiative of surgeons and provide a unique opportunity to examine clinical questions on a national scale.

TABLE 1: Levels of evidence

Level	Type of evidence
Ia	Evidence from meta-analysis of randomized controlled trials
Ib	Evidence from at least one randomized controlled trial
IIa	Evidence from at least one controlled study without randomization
IIb	Evidence from at least one other type of quasiexperimental study
III	Evidence from nonexperimental descriptive studies, such as comparative studies, correlation studies, and case-control studies
IV	Evidence from expert committee reports or opinions or clinical experience of respected authorities

Adapted from Agency for Healthcare Research and Quality 1992 guidelines.

TABLE 2: Quality of evidence

Quality of evidence	Definition
Good	Evidence includes consistent results from well-designed, well-conducted studies in representative populations that directly assess effects on health outcomes
Fair	Evidence is insufficient to assess the effects on health outcomes because of limited number of power of studies, important flaws in their design or conduct, gaps in the chain of evidence, or lack of information on important health outcomes
Poor	Evidence is insufficient to assess the effects on health outcomes because of limited number or power of studies, important flaws in their design or conduct, gaps in the chain or evidence, or lack of information on important health outcomes

From U.S. Preventive Services Task Force's Guide to clinical preventive services, 2010-2011. http://www.ahrg.gov/clinic/pocketgd.htm.

TABLE 3: Grade for practice recommendations

Grade	Definition	Suggestions for practice
A	The USPSTF recommends the service. There is high certainty that the net benefit is substantial.	Offer or provide this service.
B	The USPSTF recommends the service. There is high certainty that the net benefit is moderate, or there is moderate certainty that the net benefit is moderate to substantial.	Offer or provide this service
C	*Note: The following statement is undergoing revision.* Clinicians may provide this service to selected patients depending on individual circumstances. However, for most individual without signs or symptoms, there is likely to be only a small benefit from this service.	Offer or provide this service only if other considerations support the offering or provide the service in an individual patient.
D	The USPSTF recommends against the service. There is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits.	Discourage the use of this service.
I Statement	The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of the service. Evidence is lacking, of poor quality, or conflicting, and the balance of benefits and harms cannot be determined.	Read the clinical considerations section of the USPSTF Recommendation Statement. If the service is offered, patients should understand the uncertainty about the balance of benefits and harms.

USPSTF, U.S. Preventative Services Task Force.
From U.S. Preventive Services Task Force, Grade definitions, updated July 2012, http://www.uspreventiveservicetaskforce.org/uspstf/grades.htm.

Randomized controlled trials (RCTs) have typically been thought of as efficacy rather than effectiveness research as described previously, which has led some researchers to suggest a new emphasis on "practical" clinical trials. These trials would retain the methodologic rigor of classic RCTs but accrue patients in liberal fashion and compare treatments in the form that clinicians are likely to encounter them, making their results more readily applicable to clinical practice.

COMPARATIVE EFFECTIVENESS RESEARCH IN THE NATIONAL AND INTERNATIONAL SPOTLIGHT

In the past decade, CER has become a national priority in the United States. This interest has been sparked by patients as they become increasingly savvy consumers of healthcare, clinicians who recognize the need to provide the highest quality care, and policymakers who see CER as a way to rescue the healthcare system from the staggering cost of unproven or ineffective treatments. Federal funding for CER is at its highest point ever.

The modern era of federally funded CER began in 2003 with the Medicare Modernization Act. This authorized the Agency for Healthcare Research and Quality (AHRQ; established in 1989 as a branch of the Department of Health and Human Services) to spend $50 million per year on research with focus on "outcomes, comparative clinical effectiveness, and appropriateness of health care items and services." In 2005, AHRQ used that funding to establish the Effective Health Care Program (EHC). EHC is tasked with providing systematic reviews of the existing literature regarding the clinical effectiveness of treatments. When that evidence does not exist, two related programs, Developing Evidence to Inform Decisions about Effectiveness (DEcIDE) and the Centers for Education and Research on Therapeutics (CERTS), perform original studies. AHRQ received additional funding for CER through the American Recovery and Reinvestment Act of 2009. In 2010, the Patient Protection and Affordable Care Act established the Patient-Centered Outcomes Research Institute (PCORI). PCORI's mission is to sponsor CER with a focus on patient-centered outcomes. Federal funding for CER has come with strings attached, though: PCORI and AHQR are expressly forbidden from sponsoring or conducting research regarding cost effectiveness. The bill includes the following: "The [PCORI] … shall not develop or employ a dollars per-quality adjusted life year (or similar measure that discounts the value of a life because of an individual's disability) as a threshold to establish what type of health care is cost effective or recommended. The Secretary shall not utilize such an adjusted life year (or such a similar measure) as a threshold to determine coverage, reimbursement, or incentive programs …" This underscores the unease that many policymakers, clinicians, and patients feel regarding the potential misuses of CER.

By European standards, federal involvement in CER in the United States remains superficial. In the United Kingdom, the National Institute for Health and Clinical Effectiveness (NICE) has existed as a branch of the National Health Service (NHS) since 1999 and is explicitly involved in CER, including cost effectiveness. NICE conducts CER on all treatments covered by the NHS. The results are presented in terms of cost versus potential benefit, and the findings directly influence coverage decisions by the NHS. Likewise, the Insitut Für Qualitat und Wirtschaftlichkeit im Gesndheitswesen (IQWiG) is officially an independent institution, but its sole contractor is the German government. Since 2004, it has been conducting CER, including cost effectiveness, and its recommendations frequently inform coverage decision. In France, the Haute Autorié de Santé (HAS) was established in 2004 to determine the cost versus benefit implications of emerging treatments. Like IQWiG, it is an independent body, but its recommendations are usually accepted.

CONTROVERSY

Critics of CER argue that the growing national obsession with comparative effectiveness stifles innovation and prevents personalized medicine. They reason that every advance in medical therapy goes

through an experimental period. Submission of a new treatment to the rigors of CER before it is has found a proper application and been mastered by a number of clinicians ensures that the deck is always stacked in favor of the status quo. In addition, critics fear certain treatments that produce disappointing results on a large scale will never be given the chance to connect with the small subgroup of patients in which they are effective. Supporters counter that CER provides a context in which innovations that are truly effective are able to gain immediate traction and that identification of subgroups of patients in which treatments are effective is one of its chief strengths.

Always, though, the debate returns to the issue of cost. Those opposed to active government involvement in CER cite both an existential fear of government interference in the healthcare decisions of individuals and the pragmatic fear of healthcare rationing. These views were well articulated by Newt Gingrich during a debate with Sir Michael Rawlins, the chairman of NICE, in the pages of *The Economist*: "What happens when a drug is more effective than another but costs three times as much? To make this decision, government must weigh the cost it will bear with your quality of life. Do you want government to decide that the more expensive drug isn't worth the cost for you to have less pain and suffering?" For those on the other side of the debate, the issue is not whether healthcare resources should be rationed but how. Healthcare dollars are a finite resource, and CER provides a context for rationally allocating them. Rawlins responds to Gingrich's query with one of his own: "On what basis should nations use their resources to treat ill-health in a manner that is fair to all?" CER, he suggests, is the answer. The paradox of the 2010 Affordable Care Act, which draws what many believe is an artificial distinction between comparative effectiveness and cost effectiveness, reflects that this debate is far from over.

FUTURE DIRECTIONS

The role of CER is expanding in two directions. At the top, it is becoming an increasingly important part of the debate about the future of healthcare. Surgeons as a group need to be well versed in its methods, strengths, and limitations if they want to maintain control over their profession. The real strength of CER, though, is in the way in which it comes to strengthen the most fundamental element of medicine: the patient-doctor relationship. The future of surgery is one in which surgeon and patient together are able to make informed decisions about which treatment strategy to pursue based on the surgeon's expertise and the patient's profile, disease process, and expectations. CER provides the context for that clinical encounter.

Surgical Palliative Care

Geoffrey P. Dunn, MD, FACS

Surgical palliative care is the treatment of suffering and the promotion of quality of life for seriously or terminally ill patients under surgical care. The conceptual framework for surgical palliation has antecedents in the history of surgery and the hospice concept of care introduced by the late Dr. Cicely Saunders. The hospice concept she introduced in the 1960s was subsequently modified and expanded to apply to individuals with longer term prognoses, including those choosing to continue disease-directed treatment.

Several core values of surgical culture, including nonabandonment and preservation of hope, are consistent with the essence of palliative care as it has developed around the globe as a standard of care for advanced and terminal illness. The indication for palliative care in surgical practice is based on the patient and the patient's family's desire for relief of distress in any of its forms and the wish to improve the quality and promise of life regardless of diagnosis or prognosis. The choice of therapy is based on the ability of the treatment to meet the agreed upon goals of care, not its impact on the underlying disease process.

In 2005, The American College of Surgeons' Board of Regents endorsed the *Statement of Principles of Palliative Care* drafted by its Task Force on Surgical Palliative Care and Committee on Ethics (Box 1). In 2006, the National Quality Forum (NQF) established its *National Framework and Preferred Practices for Palliative and Hospice Care* based on consensus guidelines submitted by the leading five hospice and palliative care organizations. In 2009, the Accreditation Council for Graduate Medical Education (ACGME) recognized hospice and palliative medicine as a subspecialty of 11 parent boards, including the American Board of Surgery.

The primary target for palliative intervention is distress, not disease. To consistently dissect out this target, a conceptual model for pain and suffering is necessary. Useful models of pain and suffering widely recognized in clinical palliative care are Cicely Saunders's model of "Total Pain" and Eric Cassell's concept of suffering. Saunders's model outlines four cardinal dimensions of pain (physical, social/economic, psychologic, and spiritual) that in aggregate are referred to as "total pain" and that contribute to suffering. Cassell described suffering as the feeling that arises from a threat to integrity (wholeness) of the person. The elements of personhood include an individual's past, present, and future; social role; private life; and a transcendent dimension. Suffering is not relieved until the threat to personhood has passed or is diminished.

Principles of communication with individuals receiving palliative care are analogous to the right conduct of an operation: creation of the right physical and social context, assessment of the individual's preparedness, permission to proceed, definitive action, acknowledgment of the impact of the action on the recipient, closure, and follow-up.

Surgical palliative care assessment includes identification of previous illness and treatments, sources of pain in all dimensions, sources of personal strength, liabilities, and individual values and wishes (Table 1). Decision-making capacity, surrogacy, and advance medical directives are addressed at this time. *Relief of pressing symptoms should be done before or concurrently with assessment.* Patient's goals of care that emerge from this discussion set the parameters for the surgeon's involvement. In cases in which operative intervention is anticipated, preoperative anesthesiology consultation is helpful in planning of intraoperative and perioperative analgesia (especially if use of an epidural catheter is desired), in review of patient goals of care in light of what anesthesia expertise can offer, and in reconsideration of existing "do not resuscitate" (DNR) orders.

As a general rule, physical symptom relief takes immediate priority of action over intervention for nonphysical distress, even if nonphysical issues are ultimately more important to the patient. Symptom management is the work of palliative care and requires an interdisciplinary approach. A strong liaison with clinical pharmacists is particularly helpful because of the effectiveness of pharmacotherapy for the most common symptoms and the frequency of adverse drug reactions, including costs, that add to total symptom burden. Tables 2, 3, and 4 show medications and their conversions commonly used for control of major symptoms encountered during palliative care in the hospital setting. For nonphysical symptoms, the surgeon's role is to identify, triage, and refer appropriately and promptly.

The importance of collegiality with individuals entrusted with spiritual care of the individual cannot be overemphasized, particularly if spiritual anguish is the predominating form of the patient's distress. Despite differences in faith and values, "moral friendship," a concept proposed by clergyman and surgeon Daniel Hall, between surgeon and patient is *usually* possible and remains one of the worthiest goals of care. One can conceive of situations in which the moral perspectives of physician and patient are sufficiently opposed that a mutual accommodation might not be possible in the setting of the clinical relationship. Table 5 outlines specific ethical concerns frequently encountered in surgical palliative care.

Palliative care service consultation should be sought out to complement surgical expertise, especially when the nonphysical symptom burden is high and clarification of goals is difficult in the face of rapidly progressing or critical illness. Palliative care consultation services, which are increasingly available in the United States, have been shown to improve symptom control, enhance patient and family satisfaction, lower costs, and even improve survival. Surgeons should be mindful of the option of hospice referral for patients with an estimated survival of 6 months or less if the illness pursues its usual

BOX 1: Statement of principles of palliative care

- Respect the dignity and autonomy of patients, patient surrogates, and caregivers.
- Honor the right of the competent patient or surrogate to choose among treatments, including those that may or may not prolong life.
- Communicate effectively and empathically with patients, their families, and caregivers.
- Identify the primary goals of care from the patient's perspective, and address how the surgeon's care can achieve the patient's objectives.
- Strive to alleviate pain and other burdensome physical and nonphysical symptoms.
- Recognize, assess, discuss, and offer access to services for psychologic, social, and spiritual issues.
- Provide access to therapeutic support, encompassing the spectrum from life-prolonging treatments through hospice care, when they can realistically be expected to improve the quality of life as perceived by the patient.
- Recognize the physician's responsibility to discourage treatments that are unlikely to achieve the patient's goals, and encourage patients and families to consider hospice care when the prognosis for survival is likely to be less than half a year.
- Arrange for continuity of care by the patient's primary or specialist physician, alleviating the sense of abandonment patients may feel when "curative" therapies are no longer useful.
- Maintain a collegial and supportive attitude toward others entrusted with care of the patient.

From Task Force on Surgical Palliative care: Statement of principles of palliative care, Bull Am Coll Surg *90(8):34-35, 2005.*

BOX 2: Prognostic indicators

General Indicators of Poor Prognosis

- Functional ability: single most important predictive factor
- Median survival of 3 mo: Karnofsky ≤ 50 or ECOG ≥ 3
- Additional evidence: unintentional progressive weight loss, >10% over prior 6 months; serum albumin, <2.5 g/dL (not to be used in isolation from other factors)

Cancer-Related Indicators of Poor Prognosis

- Patients with solid tumors typically lose 70% of functional ability in last 3 mo of life
- If >50% of time is spent sleeping or lying down and is increasing, median survival is 3 mo, less with increasing symptoms, especially dyspnea
- Most solid tumors that progress through 2 rounds of chemotherapy: <6 mo
- Hypercalcemia: 8 wk (except newly diagnosed myeloma or breast cancer)
- Pericardial effusion: 8 wk
- Carcinomatous meningitis: 8-12 wk
- Multiple brain metastases: 1-2 mo without radiation; 3-6 mo with radiation
- Malignant ascites or pleural effusion: <6 mo
- Most metastatic solid cancers, acute leukemias, high-grade lymphomas not on chemotherapy: <6 mo

ECOG, Eastern Cooperative Oncology Group.

course without further attempts to reverse it. Referral can follow operative palliation of symptoms but should not be made until the patient or surrogate has had a chance to become aware of a prognosis of 6 months or less. (Boxes 2 and 3 and show estimates for prognosis and referral criteria for palliative care and hospice services.)

Palliative surgery is currently moving away from its earlier definition of noncurative intervention to the more affirmative concept of deliberate symptom control and restoration of quality of life. This transition has been guided by increased emphasis on determination of personal relevance for symptom relief (patient-centered), minimization of morbidity, improvement in nonphysical domains, and durability of symptom relief.

Considerations for palliative surgery include the expected course of the disease, the psychology of the patient, the effectiveness of the given operation, and the capacities of the surgeon/surgical team. Therapeutic benefit from palliative surgery must achieve symptom control, durability of symptom control, and symptom control with minimal morbidity (including social morbidity of hospitalization of an individual during the last weeks of life). Major operative complications dramatically worsen the prospects of achieving durable symptom relief up to the time of death.

Although life expectancy of less than 2 months has been suggested as a contraindication for palliative surgery, prognostication by physicians is notoriously inaccurate, especially if the symptom is the reason for loss of function rather than progression of disease.

For major palliative intra-abdominal procedures, such as malignant bowel obstruction, generally agreed upon relative contraindications include diffuse intraperitoneal carcinomatosis, palpable multiple intra-abdominal masses, multiple liver metastases, extraabdominal metastases, pleural effusions, multiple sites of partial

BOX 3: Palliative care consultation indications and Medicare Hospice Benefit eligibility

Palliative Care Consultation

- Patient has an illness typified by progressive deterioration and worsening symptoms, often ending fatally.
- Patient has limiting/threatening conditions with declining functional status, mental or cognitive function.
- Suboptimal control of pain or other distressing symptoms.
- Patient/family would benefit from clarification of goals and plan of care, or resolution of ethical dilemmas.
- Patient/surrogate declines further invasive or curative procedures, preferring comfort-oriented symptom management only.
- Patients on medical/surgical or critical care units who are expected to die imminently or shortly after hospital discharge.
- Bereavement support of hospital workers, particularly after the death of a colleague under care.

Eligibility for Medicare Hospice Benefit

- Patient is eligible for Medicare Part A.
- Two physicians must certify that patient has a condition with a prognosis that is associated with a survival of 6 months or less if the illness pursues its natural course.
- Patient (surrogate if patient not competent) must sign form electing hospice benefit.
- Hospice care must be provided by a Medicare-certified hospice program.

Courtesy of Robert A. Milch, MD, FACS, Buffalo, NY.

TABLE 1: Palliative care staging

Domain	Assessment questions to ask the patient
Illness/ treatment summary	Tell me what you know about your illness. Could you give me an account about your illness and treatment you have had until now? Tell me what stands out in your memory (about your illness, about treatment to date). I will review (have reviewed) your medical history in your chart, but I am really interested in hearing about it from your point of view.
Physical symptoms	How long have you had (symptom)? Are you having this (symptom) all the time or on and off? How would you describe what you are feeling? Is the (symptom) staying the same, getting better, or getting worse? On a scale (provide a scale), what is the lowest you have been in the past day? The highest? Where are you now? In which number range would you be satisfied? Do you notice any change depending on what you are doing? Does anything make the (symptom) better? Worse? Is it (symptom) keeping you from sleeping (etc)? To what extent does the (symptom) interfere with what you want to do? Is the (symptom) causing problems in your relations to others? Have any treatments helped your (symptom)? How much? What do you think is causing it (symptom)? What does it (symptom) make you think about? Does it (symptom) frighten you? Why?
Psychologic symptoms	Does everything happening make any sense to you? What do you think will happen next? How has your illness affected your life? How would you describe your mood? What do you see as the biggest problem facing you now? What frightens you most about your illness? How well do you think you are coping now? Do you feel depressed? Have you ever thought of taking your life? Do you have a plan? Have you been sad? Frightened? Anxious? Are you afraid of being a burden to others? How have you handled tough times in your life previously? Who do you turn to for support in tough times?
	Have you ever had problems with depression, alcohol, or other psychologic difficulties before your illness? Did you ever have treatment for these? Are you afraid we won't be there when you need us?
Spiritual issues	Do you consider yourself a religious or spiritual person? How important is your faith or belief in your life? Do you belong to a community of faith? Is there a group of people particularly important to you? What sustains your hope? Do you have religious or spiritual beliefs that help you through difficulty? What gives your life meaning? Does your faith influence your feelings about your illness? Your surgery? Do you see any possible conflicts between your healthcare and your beliefs? Do you have any specific observances or rituals we should be mindful of during your care (here)?
Social context	Can you tell me about other people in your everyday life, at work, at home, etc?
Communication preferences	Is it your preference to be alone or have someone close to you present when we discuss important matters? Is there anyone with whom you would like me to discuss your care? If I am approached by family members with questions about your situation, do I have your permission to discuss it? To what extent? Would an interpreter be helpful? (Professional interpreters, not family or friends, and definitely not children, are recommended.)
Decision making	Who will make decisions about your medical care if (when) you are not able to?
Practical concerns	When you are ready for home, will your home be ready for you?
Anticipatory planning	Have you given any thought of what comes after your hospitalization? What plans have you made for your future? Are there things you need to know right now for planning for the future? Would it be helpful for us to schedule a meeting with us and your family to plan your future treatment and care?

From Nine dimensions of palliative care assessment identified in EPEC, American Medical Association's Education for Physicians on End-of-life Care, 1999.

TABLE 2: Pharmacopoeia for management of persistent pain

Symptom	Medication and usual starting doses (adults)
Mild persistent pain, VAS 1-3	Acetaminophen: 325-650 mg PO qid • Maximum dose: *3000 mg/24 h; use less (<2400 mg) with concomitant use of alcohol or other hepatotoxic drugs (cytochrome P450 inducers). Care must be taken to identify total daily intake of acetaminophen in other prescription and nonprescription preparations. Aspirin: 600-1500 mg PO qid • Gastropathy, decreased platelet aggregation. Choline magnesium trisalicylate (Trilisate): 750-1500 mg PO bid • Little effect on platelet aggregation. Ibuprofen (Advil, Motrin): 200-400 mg PO qid • Maximum dose: 3200 mg/24 h. Gastropathy, nephropathy, decreased platelet aggregation. Naproxen (Naprosyn): 250 mg PO bid • Usual adult dose: 500-1000 mg/24 h (maximal: 1300 mg/24 h). • Nonsteroidal antiinflammatory drugs are most useful with an inflammatory component of pain and can be used concomitantly with opioids that exploit this property. All of these agents have a maximal therapeutic dose, unlike opioids. They are not benign drugs, particularly for the elderly, and may be less safe than the use of opioids. Patients at increased risk of NSAID-induced renal dysfunction include the elderly and those with preexisting renal dysfunction, congestive heart failure, hepatic dysfunction, hypovolemia, and concomitant nephrotoxic drug use. Good hydration and dose reduction minimizes risk. • Major complications are not necessarily preceded by minor ones. Naproxen and ibuprofen have the safest cardiovascular risk.
Moderate to severe persistent pain, VAS 4-10; VAS 7-10 is a *pain emergency*	Hydrocodone (Vicodin, Lortab): 5-10 mg PO q3-4h • Hydrocodone in tablet form is only available compounded with acetaminophen or ibuprofen. Caution is used with escalating because of ceiling dose of acetaminophen and ibuprofen. Oxycodone: 5-10 mg PO q3-4h (moderate pain); 10-30 mg PO q4h (severe pain) • Compounded form (Percocet, Tylox) used only for moderate cancer pain because of dose-limiting toxicities of acetaminophen and aspirin (Percodan). Single-entity oxycodone can be used for moderate and severe cancer pain because it has no ceiling dose. • Available in immediate-release (Roxicodone) and controlled-release (OxyContin) forms. • Immediate release forms include a solution, concentrate (20 mg/mL), and tablet. IV form is not available. • Slow-release form can be given rectally. Slow-release preparations should never be crushed or cut. Morphine: 15-30 mg PO q3-4h; 10 mg IV q3-4h • The gold standard. Most flexible opioid for dosing forms. • Caution with use in elderly patients and patients with renal insufficiency. • Controlled release forms (MS Contin, Oramorph, Kadian) available and can be given rectally. Kadian can be opened and given via a PEG tube. Avinza capsules can be opened and the pellets sprinkled on applesauce, swallowed whole without chewing. Hydromorphone: 4-8 mg PO q3-4h; 1.5 mg IV q3-4h • Useful in patients with renal failure and for subcutaneous infusions. Fentanyl, transdermal: 12 μg/h patch q72h • Not for acute pain management. Should not use more than 12 μg patch in opioid-naive cases. Prolonged duration of effect may require close monitoring for up to 12-24 h once patch is removed if patient has excessive dose. Methadone: 5-20 mg PO q4-8h; 2.5-10 mg IV q4-8h • Not a first-line agent, although very effective, especially for pain with a neuropathic component. Very inexpensive. Flexible: can be given PO, IV, SQ, PR, SL, and vaginally. • Its long half-life makes dosing more difficult than with alternative opioids, and close monitoring is required when initiating and when making dosage adjustments. • Numerous medications, alcohol, and cigarette smoking can alter its serum levels. • Physicians who write methadone prescriptions *for pain* should specify this indication. Methadone use for drug withdrawal treatment requires special licensure. • Consultation with pain management, clinical pharmacists, or palliative care/hospice services skilled in methadone use is recommended for surgeons inexperienced with methadone.

TABLE 2: Pharmacopoeia for management of persistent pain—cont'd

Symptom	Medication and usual starting doses (adults)
	General comments: • Opioid analgesics are the agents of choice for severe cancer-related pain. Oral administration is the preferred route. There is no reason to use the painful and occasionally morbid intramuscular route. • Respiratory depression is most likely to occur in opioid-naive cases with significant pulmonary disease or obstructive or central sleep apnea. It is always preceded by sedation. Reversal with naloxone should be reserved for life-threatening respiratory depression or hypotension, not sedation or confusion. Sedation is a common side effect when initiating opioid therapy. Tolerance to this usually develops within a few days. • Initiate bowel stimulant prophylaxis for constipation when prescribing opioids unless contraindicated. • Management of moderate to severe persistent pain requires familiarity with approximate equivalent doses of differing opioids. See Table 4 (e.g., morphine 30 mg orally is equianalgesic to hydromorphone 7.5 mg orally) and the conversion between parenteral and oral dosing (e.g., morphine 30 mg PO is equianalgesic to 10 mg IV, IM, or SQ). • Adjuvant or coanalgesic agents are drugs that enhance analgesic efficacy of opioids, treat concurrent symptoms that exacerbate pain, or provide independent analgesia for specific types of pain (e.g., a tricyclic antidepressant [secondary amine; i.e., desimpramine]) for treatment of neuropathic pain. Coanalgesics can be initiated for persistent pain at any VAS level. Gabapentin is commonly used as an initial agent for neuropathic pain. • There is no place for meperidine (Demerol), propoxyphene, or mixed agonist-antagonist agents (Stadol, Talwin) in management of persistent pain. • Codeine is of limited use for persistent pain because of increasing untoward side effects for doses above 65 mg with plateau of analgesic effect. 7% of white patients genetically lack the capacity to convert codeine to morphine, which accounts for most of its analgesic effect. Compounding with acetaminophen imposes a ceiling for use, unlike uncompounded opioids. • Invasive techniques (axial analgesia, neurolytic blocks) should be considered at the outset of pain management in pain emergencies (VAS 9-10).
Constipation prophylaxis	Docusate sodium (Colace): 100 mg PO q d • Stool softener. Give with stimulant laxative and titrate up PRN. Increasing opioid dosage requires up titration. Sennosides (Sennakot): 15 mg PO q d • Combination products with docusate and sennosides are available (Senekot-S, Peri-Colace). Bisacodyl: 2 tabs PO q d or 1-2 suppositories q d Sorbitol 70% solution: 15 mL PO or PR q d • Use for exacerbations of constipation in patients already on bowel regimen. General • Avoid bulk-forming laxatives because of their propensity to form bowel concretions in underhydrated, debilitated patients. • Nausea and anorexia are frequent presentations of opioid-induced constipation.

bid, Twice a day; *IV,* intravenous; *NSAID,* nonsteroidal antiinflammatory drug; *PEG,* percutaneous gastrostomy tube; *PO,* orally; *PR,* per rectum; *PRN,* as needed; *qh,* every hour; *qid,* four times daily; *SL,* sublingual; *SQ,* subcutaneously; *VAS,* visual analogue scale.
*American Liver Foundation.
The medications listed are meant to give the surgeon a rough idea of the commonly used medications and their usual starting doses. These are not recommendations for specific patients. Considerable variability of response requires individualizing dosing and titration to effect.
Dosing recommendations from Miaskowski C, Cleary J, Burney R, et al: Guideline for the management of cancer pain in adults and children, APS Clinical Practice guidelines series, no. 3, *Glenview, IL, 2005, American Pain Society, pp. 51-68.*

TABLE 3: Approximate opioid equivalences for management of moderate to severe pain

Analgesic	IM, SQ, IV route (mg)	Oral route (mg)
Morphine	10	30
Hydromorphone	1.5	7.5
Oxycodone	Not available	20
Fentanyl	10 µg IV ≈ 1 mg IV morphine 25 µg/h patch q72h ≈ 50 mg oral morphine/24 h	
Methadone	Ratios relative to methadone depend on the dose of the previous opioid	<1000 mg daily oral morphine equivalent *and* <65 years old: 10:1 ratio (oral morphine:oral methadone). <1000 mg daily oral morphine equivalent *but* ≥65 years old OR >1000 mg but less than 2000 mg daily oral morphine equivalent regardless of age: 20:1 ratio (oral morphine:oral methadone). >2000 mg daily oral morphine equivalent regardless of age: consider higher ratio such as 30:1 (oral morphine:oral methadone). Methadone has a variable and long half-life. Dosing interval every 8-12 h.

IM, Intramuscular; *IV,* intravenous; *SQ,* subcutaneously.
These are not recommendations for specific patients. The interindividual and intraindividual variability to opioids requires individualizing dosing and titration to effect.
From Friedman LL, Rodgers PE: Pain management in palliative care, Clin Fam Pract *6:371-393, 2004.*

TABLE 4: Pharmacopoeia for management of selected nonpain symptoms

Dyspnea	Hydrocodone (Vicodin, Lortab): 5 mg PO q4h • Use in opioid-naïve patient for mild dyspnea. • May use an equivalent dose every 1-2 h for breakthrough dyspnea. • Syrup preparations of hydrocodone without acetaminophen (Hycodan) are available. Hydrocodone compounded with acetaminophen limits its dosing because of acetaminophen's ceiling. • Useful agent if cough accompanies dyspnea. Morphine: 5 mg PO q4h; 1.5 mg IV q4h • Use in opioid-naïve patient with severe dyspnea. • May use an equivalent dose every 1-2 h for breakthrough dyspnea. • When 24-h requirements are determined and condition is stable, conversion to a controlled-release formulation is possible. Oxycodone: 5 mg PO q4h • Use in opioid-naïve patient with severe dyspnea. • May use an equivalent dose every 1-2 h for breakthrough dyspnea. • When 24-h requirements are determined and condition is stable, conversion to a controlled-release formulation is possible. Hydromorphone: 1 mg PO q4h; 0.2 mg IV q4h • Use in opioid-naïve patient with severe dyspnea. • May use an equivalent dose every 1-2 h for breakthrough dyspnea. General comments: • Doses can be titrated up 50%-100% every 24 h as needed. • For patients already receiving opioids, increase baseline opioid dose by 25%-50% and titrate as with opioid-naïve patients. • In severe pulmonary disease, start with half of the previous doses and up titrate no more than 25% every 24 h. • Extreme caution should be used with use along with anxiolytics for dyspnea because of additive sedating effect and potential for respiratory depression. Anxiety accompanying dyspnea often resolves with effective relief of dyspnea using opioids. • Hypoxemia ≠ dyspnea. In situations in which life prolongation is not desired, oxygen supplementation is not needed in nondyspneic hypoxemic patients. Oxygen saturations and arterial blood gases are not needed under these circumstances and confuse the goals of care. Oxygen supplementation should be given only if it relieves symptoms.

TABLE 4: Pharmacopoeia for management of selected nonpain symptoms—cont'd

Nausea/vomiting	Prochlorperazine (Compazine): 5-10 mg PO/IV/PR qid Promethazine (Phenergan): 0.25-1 mg/kg PO/IV/PR q4h • Avoid: very sedating, increased risk of respiratory depression with other CNS depressants. Can cause dystonia. Metoclopropamide (Reglan): • Contraindicated in bowel obstruction. May be useful in reversing early, partial malignant bowel obstruction when used with other agents. • Avoid use with other agents with potential extrapyramidal side effects. Haloperidol (Haldol): 0.5 mg PO q8h; 0.25 mg IV/SQ q8h • Can cause dystonia. For dystonia, use diphenhydramine. (Benadryl): 1 mg/kg PO/IV; or benztropine (Cogentin): 0.02-0.05 mg/kg PO up to 4 mg • IV dosing can cause hypotension, although haloperidol is generally well tolerated by the infirm. • Can cause prolongation of QT interval on ECG. Ondansetron (Zofran): 0.15 mg/kg/dose PO/IV q6h (maximal, 8 mg) • Specific for chemotherapy-induced nausea. No evidence that its efficacy exceeds other antiemetics for other etiologies of nausea. Dexamethasone: 4-10 mg PO/SQ/IV, loading; then 2-4 mg bid • Useful for nausea from elevated intracranial pressure and has appetite-stimulating properties. Also helpful for reducing pain from hepatic capsular distention. • Can be used as adjunct to pharmacologic management of malignant bowel obstruction. • Side effects (mood swings, GI hemorrhage, myopathy) should not be overlooked, even in patients with very limited prognosis. Olanzapine: 2.5-5 mg PO/SL q12h and 2.5-5 mg SL q6h PRN up to 20 mg/d • Can be used for nausea and vomiting unresponsive to haloperidol. • Side effects: somnolence, postural hypotension, constipation, dizziness, restlessness, and weight gain. Scopolamine: 0.5 mg per transdermal patch changed q72h; 0.006 mg/kg/dose q6h IV/SQ • Useful for nausea and vomiting triggered by vestibular stimulation (motion sickness) or hypovolemia. • Helpful for reducing terminal secretions (i.e., "death rattle") • Anticipate dry mouth and, occasionally, confusion.
Malignant bowel obstruction "Pharmacologic nasogastric tube"	Antisecretory agent (glycopyrrolate, scopolamine, octreotide); Centrally acting antiemetic (haloperidol, chlorpromazine); Opioid (morphine, hydromorphone): • This combination of agents can be given to control the symptoms associated with inoperable MBO without nasogastric suctioning. For intractable symptoms on combination therapy, consider placement of PEG. Octreotide, which is expensive, is reserved for high-volume emeses and should be initiated only when opioid and a centrally acting antiemetic fail to control obstructive symptoms. Dexamethasone: • May reverse early, incomplete MBO in conjunction with a peristaltic agent (metoclopropamide, amidotrizoate).
Anxiety/restlessness	Lorazepam (Ativan): 0.5 mg PO q4h PO/SL/PR
Delirium, moderate	Haloperidol (Haldol): start at 1-2 mg PO/SQ qh until calmer, then 1-2 mg PO/SQ qid or bid Chlorpromazine (Thorazine): 25-50 mg PO/IV/PR qh until calmer, then 25-50 mg PO/IV/PR qid or bid • Benzodiazepines (diazepam, lorazepam) can worsen delirium. • Address and treat reversible causes of delirium (i.e., hypercalcemia, dehydration with opioid metabolite accumulation).
Delirium, severe, agitated	Haloperidol: combined with midazolam as an hourly infusion • Requires monitoring. Lorazepam: 1-2 mg PO/SL/IV qh Chlorpromazine: 100 mg qh PO/IV/PR Propofol (Diprivan): highly effective sedation, although its use is limited to closely monitored settings

Continued

TABLE 4: Pharmacopoeia for management of selected nonpain symptoms—cont'd

	General: • Sedation may worsen mental clouding seen in delirium but should be mentioned as the necessary cost of preventing bodily injury from thrashing or psychologic distress of the patient and caretakers. • In very rare cases of refractory severe symptoms in the last hours/days of life, deliberate sedation to the point of unconsciousness (palliative sedation) can be considered in consultation with medical ethics and palliative care specialist.

bid, Twice a day; *CNS,* central nervous system; *ECG,* electrocardiogram; *GI,* gastrointestinal; *IV,* intravenous; *MBO,* malignant bowel obstruction; *PEG,* percutaneous gastrostomy tube; *PO,* orally; *PR,* per rectum; *PRN,* as needed; *qh,* every hour; *qid,* four times daily; *SL,* sublingual; *SQ,* subcutaneously.
The medications listed are meant to give the surgeon a rough idea of the commonly used medications and their usual starting doses. These are not recommendations for specific patients. Considerable variability of response requires individualizing dosing and titration to effect.

TABLE 5: Common ethical issues in surgical palliative care

Issue	Commentary
Disclosure of bad news	Broad legal and ethical consensus supporting disclosure of bad news *when permitted* by patient or surrogate. No evidence that disclosure of bad news "takes away hope" if conveyed gently and in the spirit of nonabandonment. Empathic truth telling fosters trust that is the basis of hope.
Perioperative DNR orders	The American College of Surgeons, the Association of Operating Room Nurses, and the American Society of Anesthesiologists position papers condemn policies requiring automatic cancellation of existing DNR orders for patient undergoing anesthesia based on the principle of patient autonomy. All recommend preoperative discussion ("required reconsideration") during which patient or surrogate confirms patient's treatment goals and limits of care, including revision or implementation of a DNR order, risks of patient's care plan, and recommendations by anesthesiologist and surgeon. During this discussion, the anesthesiologist and patient can set the parameters for resuscitation for the procedure itself and in the recovery room.
Withhold/withdraw life support	The withholding and withdrawal of medical treatments are considered legally and ethically equivalent and are based on the right to bodily integrity. It is generally more difficult to withdraw a life-supporting treatment once it has been started than to not initiate it at all. A surrogate's persistent reluctance to consider termination of life support is usually related to the fear that of "killing the patient" or fear that withdrawing life support causes suffering. Legally and ethically, termination of undesired medical treatment of the properly informed and uncoerced patient/surrogate is not considered homicide or suicide.
Aggressive symptom management	Aggressive symptom management of unbearable symptoms is a moral imperative if effective treatment is available, even at the risk of hastening or causing death, as long as causing death is not the intention of treatment. The risk of hastening death is present with any surgical treatment for serious illness, including attempts to cure. In situations in which rapid escalation of dosing is necessary to relieve intractable severe symptoms (pain, dyspnea, agitated delirium) in the imminently dying patient, the Rule of Double Effect, broadly accepted by ethicists, is invoked. RDE is comprised of these elements: • The act must be good or morally neutral. • Bad effects are foreseen but not intended. • A good end cannot justify a bad means. • The risk/benefit ratio must be reasonable.
Terminal sedation	Rarely indicated in palliative care. Reserved for severe, intractable symptoms when death is imminent. The goal of palliative sedation is to use the minimal amount of sedation necessary to relieve severe physical symptoms to the point of unconsciousness, if necessary, not deliberate induction of coma or hastening of death. Consultation with ethics committee, neuropsychiatric consultant (to determine competency), and palliative care specialist are recommended.

DNR, Do not resuscitate; *RDE,* Rule of Double Effect.

obstruction or prolonged transit time of contrast on intestinal radiographs, ascites, cachexia or hypoalbuminemia, advanced age, poor performance status, recurrence after recent laparotomy for malignant obstruction, previous abdominal radiation therapy, and disease refractory to chemotherapy.

The availability of stenting, minimally invasive procedures, laparoscopic approaches, and improved adjuvant chemoradiation and radiation therapies have increased flexibility in relieving symptoms related to obstruction, pain, bleeding, fistula, and contaminated wounds. Many of the principles and interventions useful for the palliation of malignant disease can be applied to nonneoplastic disorders encountered in surgical practice, such as chronic pancreatitis, congestive heart failure, and chronic liver failure.

Patient self report is the gold standard for outcomes measurement after palliative treatment. Numerous validated measuring instruments exist, some of which offer multiple languages and disease-specific modules with ongoing updates. Some of the more commonly used questionnaires include the Functional Assessment of Cancer–General Version (FACT-G), the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire-Core 30 (EORTC QLQ-C30), and the McGill Quality of Life Questionnaire (MQOL).

Access to bereavement services is a critical component of surgical palliative care, not only for patients and families but also for hospital caregivers. Hospital-based bereavement services, including pastoral care departments and family support services, have been shown to affect long-term psychosocial functioning of surviving family members and decisions about organ donation. Surgeons may also benefit from these services as they seek the balance between aloofness and overwhelming emotion in response to serial losses. Recognition that one's status as a surgeon does not inure the surgeon from the impact of loss is crucial for adapting to the responsibilities of surgical palliative care.

Cardiovascular Pharmacology

Jay G. Shake, MD, MS, FACS, and David P. Ciceri, MD

OVERVIEW

An understanding of the pharmacologic means of manipulating the cardiovascular system is essential for all of those involved in the care of surgical patients. Many patients who present for elective noncardiac surgery have significant cardiovascular comorbidities, especially ischemic heart disease and hypertension, which need careful perioperative management. Dysrhythmias are common, particularly in patients who have undergone thoracic surgery or are critically ill. Many patients with low cardiac output states and shock need support with vasoactive medications with inotropic or vasopressor activity.

TACHYARRHYTHMIAS

Narrow QRS Dysrhythmias

Narrow QRS dysrhythmias are common in patients after noncardiac surgery. They are particularly common after thoracic surgery and in hemodynamically unstable conditions. In addition, patients frequently have development of sinus tachycardia, which can increase risk in patients with ischemic heart disease and compromise cardiac function in patients with stenotic valvular heart disease or severe systolic or diastolic dysfunction. The first perioperative priority in a patient with sinus tachycardia is to ensure an adequate circulating blood volume and optimal analgesia. Agents to control the elevated heart rate may be considered in patients at increased cardiac risk once the patient's volume status has been assessed and pain is relieved.

After surgery, the patient may have a variety of narrow QRS tachydysrhythmias that include atrial fibrillation, accelerated junctional rhythms, and paroxysmal supraventricular tachycardia, but the most common is atrial fibrillation. The first critical step in management of a patient with atrial fibrillation is to assess whether the ventricular rate response and loss of atrial contribution to ventricular filling is causing significant hemodynamic compromise or severe cardiopulmonary symptoms (ischemic chest pain, dyspnea, etc.). If the patient's condition is severely compromised, the patient needs prompt treatment with electrical cardioversion. The patient with an unstable condition should undergo light sedation if the cardiac and pulmonary status allows. Some patients' clinical conditions do not tolerate sedation. The patient should undergo synchronized cardioversion at 120 to 200 J with a biphasic waveform defibrillator. The practitioner should ensure that synch is selected before each attempt at cardioversion because the defibrillator defaults back to the defibrillation mode after each electrical discharge. Unfortunately, many patients with hyperadrenergic postoperative conditions who develop atrial fibrillation and are hemodynamically unstable do not respond to synchronized cardioversion. These patients need to be supported with additional volume (if necessary) and the administration of an alpha-adrenergic vasopressor like norepinephrine or phenylephrine. The authors' opinion is that once blood pressure has stabilized, patients should receive intravenous (IV) amiodarone while electrolyte disturbances such as hypokalemia, hypomagnesemia, and any evidence of myocardial ischemia are corrected.

Patients with more stable conditions with atrial fibrillation should be treated in a stepwise fashion. The ventricular rate should be controlled with a parenteral beta-blocker (metoprolol, atenolol, or esmolol) or the calcium channel blocker diltiazem. A beta-blocker is preferred if patients have ischemic heart disease, particularly if they were on a beta-blocker in the preoperative period. On occasion, digoxin may be useful as a second additional agent in a patient with inadequate rate control with either a beta-blocker or diltiazem. The digoxin loading dose should be decreased by a third to a half if the

patient is going to receive amiodarone (discussed subsequently) because amiodarone increases the serum digoxin level.

The second clinical question in a patient with atrial fibrillation after rate control has been achieved is whether to attempt to restore sinus rhythm. In ambulatory patients, the trend over the past few years has been to concentrate more on rate control and anticoagulation therapy rather than repeated attempts at electrical or chemical cardioversion. The authors' practice is to be more aggressive at attempting to restore sinus rhythm in patients in the immediate postoperative period. Many of these patients with even more stable conditions have some adverse hemodynamic effects from atrial fibrillation, and restoration of sinus rhythm in less than 24 to 48 hours avoids the issue of systemic anticoagulation therapy to avoid stroke in patients who have recently undergone surgery.

Beta-blockade can be effective as a postoperative prophylactic therapy in patients at high risk for atrial fibrillation. The beta-blocker needs to be given continuously (esmolol) or on a scheduled basis (metoprolol up to 15 mg IV every 4 to 5 hours) as tolerated, and it should be administered parenterally in patients with uncertain gastrointestinal function. Amiodarone is usually the preferred antiarrhythmic agent once atrial fibrillation has occurred. The conventional loading dose is 150 mg IV over 10 minutes. Critically ill patients frequently need higher loading doses, and the authors administer up to 450 mg IV over 45 minutes in sequential boluses if the patient does not convert to sinus rhythm. The patient then receives a continuous infusion of amiodarone at 1 mg/min for 6 hours followed by an infusion of 0.5 mg/min. The amiodarone infusion can be converted to the enteral route once gastrointestinal function is ensured. Nowadays, administration of any other antidysrhythmic agent to acutely ill patients with atrial fibrillation is uncommon, unless under the specific direction of a consultant. If the patient with a more stable postoperative condition persists in atrial fibrillation for 12 or more hours, despite amiodarone and correction of electrolyte abnormalities, electrical cardioversion should at least be considered. Systemic anticoagulation therapy to prevent stroke needs to be considered in patients who persist in atrial fibrillation for longer than 48 hours. The potential benefit of anticoagulation therapy has to be weighed against the bleeding risk in each individual patient.

Wide QRS Dysrhythmias

Wide QRS dysrhythmias are much less common in patients after surgery. The most common is monomorphic ventricular tachycardia, but patients may also have torsades de pointes, one form of polymorphic ventricular tachycardia. Other possibilities include a wide QRS in patients with preexisting conduction disturbances or a rate-dependent bundle branch block. The appropriate first therapy for a patient with a hemodynamically unstable condition with ventricular tachycardia is synchronized cardioversion with 100 to 200 J with a biphasic waveform defibrillator. If the defibrillator does not synchronize, the patient should receive 200 J in the defibrillation mode. The patient should receive a loading dose and infusion of amiodarone as described previously for atrial fibrillation with a hemodynamically stable condition despite the monomorphic wide QRS tachycardia or after successful cardioversion. If the patient is pulseless, a 300 mg amiodarone bolus should be administered during attempts at resuscitation. On occasion, lidocaine is administered to a patient with monomorphic ventricular tachycardia with failure to respond to amiodarone. The treatment of a patient with a hemodynamically stable condition with torsades de pointes is different and deserves special mention. Any precipitating drugs are discontinued first. The patient is treated with parenteral magnesium (1 to 2 g over 30 to 60 seconds; may be repeated in 3 to 5 minutes) even with normal serum magnesium levels. The patient should be watched closely for signs of weakness because hypermagnesemia can depress neuromuscular function. If torsades persists, the heart rate between bursts of torsades should be increased to 90 to 110 bpm because that shortens the QTc interval and suppresses the rhythm disturbance. This is most frequently accomplished by pacing.

BRADYDYSRHYTHMIAS

Bradydysrhythmias can occur after surgery, but they are less common. In a patient who is not severely hypoxemic, bradycardia frequently results from medications. All agents that have negative chronotropic activity or that block conduction through the atrioventricular (AV) node need to be temporarily held and later, if still indicated, cautiously resumed. The first agent that should be given to treat symptomatic bradycardia is atropine. The dose is 0.5 mg IV repeated as needed every 3 to 5 minutes to a maximum of 3 mg. If atropine is ineffective, the patient should receive an infusion of either dopamine (2 to 10 μg/kg/min) or epinephrine (0.03 μg/kg/min starting dose). Pacing is also an excellent therapeutic option for patients with symptomatic bradycardia. The different options for pacing a patient after surgery include transcutaneous, transvenous, epicardial (cardiac surgery), and esophageal (intubated) pacing.

CONTROL OF CARDIAC AND SYSTEMIC VASCULAR PERFORMANCE

Control of Preload

Restoration and maintenance of an adequate intravascular volume to ensure optimal filling of the left and right ventricle is essential to the care of all ill patients. Surgical patients present and have a wide array of disturbances of hypovolemia from ongoing bleeding, ongoing loss of asanguineous fluid, vasodilation, and altered vascular permeability. The fluids that should be administered differ from patient to patient based on the clinical setting but most frequently consist of some combination of isotonic crystalloids, 5% albumin, and, when necessary, blood products. Historically used pressure parameters such as the central venous pressure (CVP) and pulmonary capillary wedge pressure (PCWP) have been repeatedly shown to be not useful in prediction of intravascular volume or response to a subsequent fluid bolus. Fortunately, the use of dynamic parameters (pulse pressure variation, stroke volume variation, etc.) and dynamic parameters shown with ultrasound scan (echocardiography) have been shown to be excellent predictors of fluid responsiveness in many clinical settings. An important caveat to remember is that 50% of all patients with unstable conditions in the intensive care unit (ICU) respond to fluid therapy alone. It is also essential to recognize when additional fluid administration is no longer helping and may even be harming the patient and to redirect efforts to resuscitate the patient.

Control of Myocardial Contractility

Assessing and optimizing intrinsic myocardial performance never occurs in a clinical vacuum. Each patient may have significant alterations in rate, rhythm, atrioventricular synchrony, preload, and systemic and pulmonary vascular resistance that need to be addressed. These dynamic abnormalities need to be continuously reassessed and acted on.

Left Ventricular Failure

Both acute and chronic systolic left ventricular dysfunction and failure are common in the most ill of surgical patients. Many patients presenting for elective or urgent surgery have moderate or severe chronic systolic heart failure and are on a complex medical regimen that can include angiotensin-converting enzyme inhibitor,

angiotensin receptor blocker, beta-blockers, diuretics, and aldosterone receptor antagonists. Some of these medications need to be administered intravenously during the perioperative period, be held at times, and have the dose frequently adjusted.

Chronic Systolic Heart Failure

Beta blockade should be cautiously maintained during the perioperative period in patients with heart failure on chronic beta-blocker therapy, particularly if the patient is hypotensive or is suspected of having a compromised cardiac output. Use of a low dose of parenteral medications (esmolol, 50 to 100 μg/kg/min; metoprolol, 5 to 10 mg IV every 4 to 6 hours) may be necessary in patients in whom the gastrointestinal route is unavailable or unreliable. Beta blockade needs to be held in patients with hypotension, with ongoing severe problems with hypovolemia, or with decompensated heart failure. They should be cautiously reintroduced at very low doses once the patient's condition has stabilized.

Although it is still an area of controversy, the preoperative administration of either angiotensin-converting enzyme inhibitors or angiotensin receptor blockers may result in significant hypotension after the induction of general anesthesia. These medications are commonly held the morning of surgery in many practices for this reason. If hypotension does occur, the administration of vasopressin IV at a dose of 0.03 to 0.04 units/min may be very effective at restoring the blood pressure to normal levels. These medications need to be resumed after surgery, however, at reduced doses and cautiously in patients who have experienced any hemodynamic difficulties. Parenteral enalaprilat can be useful in patients who cannot receive enteral mediations. A reasonable starting dose is 0.625 mg IV every 6 hours. The dose is increased if tolerated every third or fourth dose to a maximum of 2.5 mg IV every 6 hours. Combination therapy with intravenous hydralazine and nitrates can be used instead of resuming an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker in patients with development of renal insufficiency in the perioperative period.

Fluid and diuretic therapy in patients with severe systolic left ventricular failure who undergo major surgery can be very challenging. These patients need similar amounts of volume and blood component therapy during the initial perioperative period compared to their healthier counterparts. The left ventricle with systolic dysfunction does not continue to increase stroke volume in response to progressive fluid challenges as in patients with normal ventricular function. Furthermore, a patient with poor ventricular function has rapid decompensation with hypovolemia resulting in an inadequate preload. One must anticipate the need for diuretics the second or third postoperative day in the patient with heart failure to clear the sodium and fluid administered during the initial perioperative period. Mobilization of fluids and the need for diuresis may be delayed if the patient has had significant hemodynamic instability. The authors' practice is to initially use intravenous loop diuretics because of the wide range in oral bioavailability seen in patients with these agents. The initial dose should be at least what the patient's chronic prehospital dose had been and may need to be increased if there has been a decline in renal function. A continuous infusion of a loop diuretic (furosemide 0.1 mg/kg/h, increased every 2 hours to a maximum of 0.4 mg/kg/h if necessary) after a loading dose (typically 0.1 mg/kg bolus) may be needed if the patient does not respond to intermittent dosing. Higher doses of furosemide, in association with severe fluid overload in the setting of acute kidney injury or end-stage renal disease, may prompt one to consider use of another form of volume removal such as ultrafiltration. As always, one must ensure an adequate circulating blood volume, cardiac output, and blood pressure before attempting diuresis in an ill patient.

Acute Systolic Heart Failure

Acute systolic heart failure occurs most commonly as a result of decompensation of preexisting severe heart failure or because of a myocardial ischemic event. When acute systolic heart failure occurs in the perioperative setting, it is essential to ensure an optimal intravascular volume and to maintain or restore sinus rhythm and atrioventricular synchrony whenever possible. Echocardiography is desirable to exclude a previously unrecognized valvular abnormality or less common pathology such as hypertrophic cardiomyopathy and to assess the severity of left ventricular dysfunction. Depending on the clinical situation or new finding, the input of a consultant service such as a cardiologist may be advisable.

Vasoactive agents (Table 1) need to be used in patients in whom hypotension or inadequate perfusion persists despite an adequate blood volume and sinus rhythm. Although no proven outcome benefit is found in this setting, the authors routinely use hemodynamic monitoring in these patients to allow logical selection of agents and their titration to achieve reasonable hemodynamic goals. Fortunately, a number of minimally invasive hemodynamic monitors can be rapidly put into use to guide therapy along with echocardiography. On occasion, a pulmonary artery catheter may also be placed to guide therapy.

The goals of the vasoactive agents (Table 2) are to improve myocardial contractility enough to achieve an adequate stroke volume and cardiac output and to avoid provoking myocardial ischemia and to minimize increases in heart rate. At the same time, an adequate

TABLE 1: Commonly used inotropic and vasopressor medications

Medication	Dose range	Mechanism	Indications
Norepinephrine	1-20 μg/min	α_1, α_2, β_1	Inotrope and vasoconstrictor
Epinephrine	1-20 μg/min	α_1, α_2, β_1, β_2	Inotrope and vasoconstrictor
Dopamine	1-20 μg/kg/min	α_1, α_2, β_1, β_2, dopamine	Inotrope and vasoconstrictor
Dobutamine	2-20 μg/kg/min	β_1, β_2	Inotrope and vasodilator
Phenylephrine	20-200 μg/min	α_1	Vasoconstrictor
Isoproterenol	1-20 μg/min	β_1, β_2	Inotrope and chronotrope
Milrinone	0.25-0.75 μg/kg/min	Phosphodiesterase 3 inhibitor	Inotrope and vasodilator
Vasopressin	0.01-0.04 U/min	Vasopressin V_1 and V_2 receptors	Vasoconstrictor in catecholamine-resistant shock

TABLE 2: Effects of adrenergic and vasopressin receptor subtypes on cardiovascular system

Receptor	Location	Effect
α_1	Systemic arterioles (abdominal viscera, coronary, skin, skeletal muscle), veins, pulmonary arterioles	Vasoconstriction
α_2	Presynaptic and postsynaptic sympathetic nerve terminals, central nervous system	Vasodilation
β_1	Heart	Inotropy, chronotropy, dromotropy
β_2	Systemic arterioles (abdominal viscera, coronary, skeletal muscle), veins, pulmonary arterioles	Vasodilation
Dopamine	Systemic arterioles (abdominal viscera, renal, coronary)	Vasodilation
V_1	Vascular smooth muscle	Vasoconstriction
V_2	Renal distal convoluted tubule and collecting duct	Antidiuresis

blood pressure needs to be restored (mean arterial pressure, ≥65 mm Hg) and unnecessary increases in afterload, which impair left ventricular function with systolic dysfunction, avoided.

Dobutamine (5 to 15 μg/kg/min) is the agent most commonly used to enhance myocardial contractility in the setting of an adequate or normal blood pressure and low stroke volume in patients with systolic dysfunction. It is a moderately potent beta 1 agonist and has variable and usually modest effects on vascular tone, although significant hypotension can occur, particularly in patients with unrecognized hypovolemia. The tendency for dobutamine to cause increases in heart rate and provoke tachyarrhythmias is probably less than other agents in most clinical settings. Dopamine (5 to 20 μg/kg/min) has been the agent that has historically been used in the setting of hypotension and low stroke volume from systolic heart failure. In older studies, dopamine has been shown to worsen myocardial ischemia; it can cause increases in heart rate and tachyarrhythmias, but it can achieve the immediate hemodynamic goals in many patients. Many practitioners consider the addition of dobutamine to dopamine for additional inotropic support if necessary once an adequate blood pressure has been restored. The SOAP II trial was a large multicenter trial of patients in shock randomized to receive either dopamine or norepinephrine for hemodynamic support. Overall, no difference was found in mortality, but the patients who received dopamine had a twofold increase in the rate of development of atrial fibrillation (22% vs 11%). Of concern, in the a priori subgroup analysis of patients with cardiogenic shock, patients who received dopamine had a higher mortality than did those who received norepinephrine. Dopamine may still be the agent initially used in many practices in these patients, but the authors more commonly use the combination of norepinephrine and dobutamine. The substitution of epinephrine may be needed for severe tachycardia or tachyarrhythmias from dopamine or the hypotension associated with dobutamine use.

Another class of agents that may be beneficial in patients with systolic heart failure is the parenteral phosphodiesterase inhibitors. These agents are potent inodilators that cause both significant increases in myocardial contractility and vasodilation in the systemic and pulmonary vascular beds. Milrinone is the agent most commonly used, with a loading dose of 50 μg/kg over 10 minutes followed by an infusion of 0.125 to 0.75 μg/kg/min (standard starting dose, 0.375 μg/kg/min). Many times, it is best to omit the loading dose or to fractionate it and administer it much more slowly in patients with marginal hemodynamics. Milrinone may result in significant hemodynamic improvement in euvolemic or hypervolemic conditions with systolic dysfunction. Administration of a beta adrenergic agonist, like dobutamine or epinephrine, which acts by increasing cyclic adenosine monophosphate (cAMP) production, to a patient receiving milrinone can result in a synergistic increase in contractility. Disadvantages of milrinone are its relatively long half-life (2½ hours in patients with congestive heart failure [CHF]) and its accumulation in patients with renal insufficiency. Support of excessive vasodilation with an agent like norepinephrine for a period of time is not uncommon.

Acute Myocardial Ischemia

The hemodynamic management of patients with left ventricular systolic failure from acute myocardial ischemia is similar to that outlined previously. Minimization of increases in heart rate and myocardial oxygen demand to as great an extent as possible is of paramount importance. These patients should receive an aspirin and a statin (HMG-CoA reductase inhibitor) as soon as possible. Beta-blockade should be considered once patients have been weaned from inotropic and vasopressor support. An unfractionated heparin infusion or other anticoagulant therapy may be considered in some patients, with the potential benefit always weighed against the risk of surgical bleeding. Cardiology consultation should be obtained, and angiography should be considered for those patients with a large area of the left ventricle at risk, hemodynamic instability, and recurring or unremitting symptoms.

Right Ventricular Failure

Successful management of the patient with severe right ventricular failure can be tremendously challenging. One of the first critical aspects is determination of whether a significant contribution from an elevated pulmonary vascular resistance can dramatically worsen right ventricular function. If biventricular failure is being driven by a failing left ventricle, then initial efforts should be directed at restoring left ventricular function. If elevated pulmonary pressures and right ventricular failure are found and left ventricular function appears adequate, then therapy to decrease elevated pulmonary artery pressures can cause significant improvement. Initial attempts should be made to correct hypercapnia, hypoxemia, and severe acidosis because all cause an increase in pulmonary artery pressure. Also, excessively high tidal volumes and unnecessary levels of positive end-expiratory pressures (PEEP) should be avoided. Systemic administration of vasodilators may lower pulmonary artery pressures but can result in significant systemic vasodilation and profound hypotension. Inhaled vasodilators, such as nitric oxide, prostacyclin, or prostaglandin E1 (PGE1), can cause significant decreases in elevated pulmonary artery pressures with minimal or no adverse systemic hemodynamic effects. One needs to be vigilant so that the inhaled vasodilator therapy is not inadvertently interrupted, especially during patient transport, which may result in rapid deterioration in right ventricular function. Right ventricular function should also be supported with judicious fluid administration and vasoactive support. Adequate systemic blood pressure (mean arterial pressure [MAP], ≥65 mm Hg) and right ventricular perfusion pressure have to be

maintained to allow right ventricular function, and the use of a vasopressor like norepinephrine may be necessary. Right ventricular preload has to be adequate, but overdistension causes right ventricular function to decline precipitously. Assessment of right ventricular preload is challenging because neither CVP nor the assessment of right ventricular area with echocardiography accurately predicts right ventricular preload or fluid responsiveness. Once an adequate systemic blood pressure has been restored, addition of dobutamine, epinephrine, or milrinone to improve right ventricular contractility may be beneficial.

Left Ventricular Diastolic Dysfunction

Patients with significant left ventricular diastolic dysfunction, even in an ambulatory outpatient setting, can be challenging. Very little definitive data are available to help guide management, even though it is a very common clinical problem. These patients are commonly treated with diuretics to manage symptoms, and at times, patients may be on a combination of angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, beta-blockers, and calcium channel blockers, despite the lack of good outcome data. In the perioperative setting, one can anticipate that the patient will poorly tolerate hypovolemia and reduced preload but also be at risk of volume overload and pulmonary edema. Expert perioperative fluid management is extremely important, and once again, the need to administer diuretics to these patients on postoperative day 2 or 3 should be anticipated. These patients benefit significantly from maintaining or restoring sinus rhythm and atrioventricular synchrony. Beta-blockers and negative chronotropic calcium channel blockers like diltiazem may be helpful in some patients.

Control of Afterload

The most common condition in the surgical patient associated with an abnormal vascular resistance is vasodilated shock, which is most commonly caused by sepsis (septic shock). Although not as common, spinal cord injury, hepatic failure, adrenal insufficiency, anaphylaxis, postcardiotomy hypotension, and severe inflammation in the absence of infection are other causes of vasodilated shock seen in surgical patients. Fortunately, besides the obvious differences in etiology, many of the principles of hemodynamic management are similar. First, vasodilation occurs in both the arteriolar resistance and the venous capacitance vessels. The potential blood volume expands significantly and needs to be aggressively restored. Isotonic crystalloids, 5% albumin, and if necessary, in a bleeding or extremely anemic patient, blood products should be used for fluid therapy in septic patients. Hydroxyethyl starch preparations and hyperoncotic albumin should not be given to septic patients. Second, septic patients in particular have alterations in permeability and the function of the interstitium, which cause continued loss of intravascular fluid until the inflammation begins to abate.

The use of vasoactive medications is necessary to support many patients with septic shock. The two agents that have been used most commonly in this setting are dopamine and norepinephrine. The SOAP II trial, which compared the use of these two agents in almost 1000 patients in septic shock, found no difference in mortality but a twofold greater incidence of atrial fibrillation in patients given dopamine infusions. In addition, several systematic reviews, published after that landmark trial, suggest a higher mortality in patients treated with dopamine. Norepinephrine (starting dose, 0.03 μg/kg/min) should be the initial vasoactive agent used in most patients with septic or vasodilated shock while an adequate intravascular volume is ensured. Considerable research has been done in the past 15 years and has shown that a large number of patients with vasodilated shock from septic shock or after cardiopulmonary bypass have a relative vasopressin deficiency state. Administration of vasopressin to these patients in physiologic replacement doses (0.03 to 0.04 units/min) allows a significant lowering of the doses of other vasoactive medication and a reduction in duration of vasoactive drug administration. The VASST trial was a large multicenter trial that looked at the outcomes of patients with septic shock who had initially responded well to moderate doses of norepinephrine. The patients were randomized to then receive vasopressin or placebo in addition to norepinephrine. The required dose of norepinephrine was decreased in those patients who received vasopressin, but no difference in mortality or other outcomes was found. The authors usually only consider adding vasopressin to patients in septic shock after reaching modest to high doses of norepinephrine (>0.1 μg/kg/min).

There has been growing recognition over the past decades that significant myocardial dysfunction is very common in patients with septic shock. At least one third of adults with septic shock have low or low normal cardiac outputs despite restoration and maintenance of an adequate intravascular volume. Common practice is administration of dobutamine (5 to 15 μg/kg/min) in addition to norepinephrine to improve cardiac performance to patients with severe myocardial depression. This approach has been consistently associated with improved survival rates in moderately sized studies compared with historical controls. One recent study looked at effects on outcome in 300 patients with septic shock randomized to receive norepinephrine plus dobutamine or epinephrine. They found a small increase in serum lactate levels in patients randomized to receive epinephrine, which resolved after 24 hours despite continued therapy, and no differences in mortality or other outcomes. Epinephrine should probably be considered a viable second-line agent in patients who are not responding adequately to norepinephrine or who have significant myocardial dysfunction.

Problems with excessive afterload can occur in surgical patients with hypertension (discussed subsequently) or, on occasion, low cardiac output states because of left ventricular systolic dysfunction and normal or elevated systemic blood pressure. In these patients, a vasodilator or inodilator may be an elegant choice to reduce vascular resistance and improve stroke volume and cardiac output without increasing myocardial oxygen demand. Sodium nitroprusside may be a good first choice for these patients because of its very short half-life (2 minutes), which makes it easy to titrate or discontinue. After an adequate preload is ensured, the initial dose used in these patients should be low (0.3 μg/kg/min) and very slowly increased. Once the patient has shown a good response and a stabilized condition, they can be transitioned gradually to a different regimen of scheduled vasodilator medications. Milrinone may be an acceptable initial choice in similar patients.

TREATMENT OF SYSTEMIC HYPERTENSION

Many useful medications can be successfully used to control systemic hypertension in the perioperative setting. One of the first principles is to avoid placing patients at risk from intentional or inadvertent discontinuation of chronic antihypertensive medications (frequently from continuing enteral medication with gastrointestinal tract dysfunction or ileus). The most critical of these medications are beta-blockers, especially in patients with known or at risk for ischemic heart disease. Perioperative beta-blockade for reduction of cardiac risk (discussed subsequently) is a topic in evolution, but all available data indicate that chronic beta-blocker therapy should not be discontinued. As previously mentioned, the major exception is in the setting of severe hemodynamic compromise and hypotension. All other patients should receive their chronic beta-blocker therapy as tolerated. If gastrointestinal function is not certain, then the patient should receive scheduled intravenous beta-blocker therapy. A reasonable goal is to target a heart rate of less than 80 bpm and avoid any hypotension. Failure to continue chronic

beta-blocker therapy exposes the patient to a significant risk of a perioperative myocardial ischemic event or dysrhythmia, especially atrial fibrillation. Patients should be transitioned to their chronic enteral antihypertensive medication regimens as their gastrointestinal tract function improves.

Labetalol is a mixed alpha and beta adrenergic agent that has been used very successfully in many perioperative settings. No data are available to suggest that it should be used in patients on chronic beta-blocker therapy in the perioperative setting, however. Labetalol has been used successfully in beta-blocker naïve patients, particularly in patients who have neurotrauma or who have undergone neurosurgery because it does not cause cerebral vasodilation. Initial doses should be low (10 to 20 mg IV) and can be increased as tolerated. Patients with euvolemic, hemodynamically stable conditions with severe hypertension may be treated with more conventional doses of labetalol (test dose, 20 mg; followed by 40 and 80 mg boluses every 10 minutes to a maximum of 300 mg).

Vasodilator medications can be useful antihypertensive medications in the perioperative setting. Parenteral medications that are administered with a continuous infusion include nitroglycerin, sodium nitroprusside, nicardipine, clevidipine, and fenoldopam. Nitroglycerin and sodium nitroprusside are both cerebral vasodilators and should not be used in patients at risk for intracranial hypertension in the absence of an intact neurologic examination or intracranial pressure monitoring. Nitroglycerin is a fairly ineffective antihypertensive agent in most patients and is commonly used primarily for its antiischemic effects. Sodium nitroprusside is an effective antihypertensive agent, but it exposes the patient to the risk of cyanide toxicity because each molecule of nitroprusside disassociates to release 5 molecules of cyanide. The authors always mix thiosulfate with nitroprusside (100 mg thiosulfate to 1000 mg nitroprusside). Thiosulfate is a sulfur donor that is needed by the enzyme rhodanase to metabolize cyanide. Thiosulfate administration significantly reduces the risk of cyanide accumulation.

Nicardipine and clevidipine are parenteral dihydropyridine calcium channel blockers that have been used in the perioperative setting. Nicardipine (initial dose, 5 mg/h; titrated to maximal dose, 15 mg/h) has been shown to be effective in hypertensive emergencies and in a number of perioperative settings, particularly in neurosurgical cases. Nicardipine's half-life with infusions of usual duration is approximately 45 minutes, so there is a somewhat greater need to anticipate the change in blood pressure and adjust the dose accordingly than with agents with a very short half-life such as nitroprusside. Nicardipine can then be transitioned to its oral formulation. Nicardipine and labetalol alone or in combination are the current preferred agents in neurosurgical and neurotrauma cases. Very little published data look at clevidipine in noncardiac surgery patients at this time; for that reason, this agent is not routinely used in postoperative patients yet, despite its promise.

Fenoldopam is a dopaminergic 1 receptor agonist that is an effective parenteral antihypertensive agent and that has been investigated in multiple cardiac and noncardiac studies. In clinical trials, doses from 0.01 to 1.6 μg/kg/min have been used. In addition, multiple studies have examined the effect of fenoldopam on perioperative renal injury in cardiac surgery, aortic, major vascular, and transplant surgery cases. Benefit is suggested in current systematic reviews, but the benefit may be small and there is no consistently demonstrated effect on renal replacement therapy or survival. Large, multicenter, and appropriately powered trials are needed to confirm or refute this potential benefit.

Other antihypertensive agents used in the perioperative setting are angiotensin-converting enzyme inhibitors (discussed previously), which are available in a parenteral formulation; intravenous hydralazine; and transcutaneous and oral clonidine. Intravenous hydralazine is inexpensive and moderately effective. Its utility is limited by its variable onset to peak effect, antihypertensive efficacy, and duration of action. A reasonable starting regimen is 10 to 20 mg every 4 to 6 hours, which can be increased incrementally to a maximum of 40 mg every 4 hours. One situation in which hydralazine may be particularly useful in combination with nitrates is in patients with CHF from systolic left ventricular dysfunction and renal insufficiency who cannot be treated with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers. Clonidine is used primarily in the perioperative setting in those patients who are taking the medication chronically to prevent clonidine withdrawal syndrome and severe hypertension. Clonidine can also be used as an adjunct in the treatment of several different withdrawal syndromes.

Diuretics can play a role in the management of the patient with perioperative hypertension. Patients on chronic diuretic therapy need to have diuretic therapy resumed after the initial recovery period. This may need to occur sooner in patients with evidence of volume overload or pulmonary edema.

PHARMACOLOGIC REDUCTION OF PERIOPERATIVE CARDIAC RISK

Pharmacologic approaches to reduce perioperative cardiac risk, in patients with known or suspected ischemic heart disease, have been an area of intense investigation for the past 15 years. The enthusiasm for widespread use of perioperative beta-blockade based on initial studies in patients at high risk has been tempered by the recognition that this therapy may cause harm as well as benefit. In patients at lower risk, perioperative beta-blockade may still slightly decrease perioperative cardiac risk, but at the cost of a greater number of strokes and overall higher mortality. In brief, careful patient selection is of paramount importance when considering use of perioperative beta-blocker therapy. First, patients on chronic beta-blocker therapy with known or at significant risk for ischemic heart disease should not have beta-blockers withdrawn during the perioperative period. Second, patients undergoing major or moderate surgery should undergo an evaluation of cardiac risk. Multiple tools are available, but a simple tool that has been well validated is the revised cardiac risk index. It consists of six factors: high-risk surgical procedures (intraperitoneal, intrathoracic, or suprainguinal vascular), history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, diabetes requiring preoperative treatment with insulin, and a preoperative serum creatinine value of more than 2.0 mg/dL. Perioperative beta-blockade should be considered in patients with two or more cardiac risk factors who are undergoing major surgery. Patients with one or no cardiac risk factor who have not chronically been treated with beta-blockers should not be treated with perioperative beta-blockade. The beta-blocker therapy should ideally be initiated 2 weeks before surgery and titrated at a heart rate of 60 bpm with an acceptable blood pressure and then continued with parenteral agents, if necessary, in the immediate postoperative period. The beta-blocker therapy should be continued at least until hospital discharge and preferably to a follow-up appointment with the patient's primary care provider because of increased cardiac risk. If a patient has multiple revised cardiac index risk factors but has not been placed on outpatient beta-blocker therapy, the authors consider initiating parenteral beta-blockers carefully just before surgery and continuing that therapy throughout the perioperative period. In this circumstance, the authors attempt to maintain a heart rate of less than 80 and avoid any instance of hypotension.

Growing evidence shows that therapy with statins is associated with improved cardiovascular outcomes and that statin therapy should not be withdrawn in the perioperative settings. Statin therapy should be continued until the time of surgery and resumed as quickly as possible after surgery. Patients need to be on statin therapy for a minimum of 2 weeks before surgery to accrue benefit. This is an active area of research, and newer data and recommendations continue to emerge.

Glucose Control in the Postoperative Period

Raminder Nirula, MD, and Meghan Lewis, MD

INTRODUCTION

Glycemic control has been a goal in postoperative care since the realization that diabetes mellitus was associated with postoperative complications. Although this association is presumably the result of perioperative hyperglycemia, the long-term effects of hyperglycemia lead to comorbidities such as coronary artery and peripheral vascular disease, which contribute to suboptimal postoperative outcomes. Postoperative hyperglycemia in patients without diabetes has also been linked to poor postoperative outcomes and may represent the body's stress response altering carbohydrate metabolism. Hemorrhage and tissue injury cause increased glucose production and impaired insulin sensitivity mediated largely through the release of adrenalin, although the exact mechanisms are numerous and complex. In addition, the perioperative administration of adrenergics or steroids confounds the relationship between hyperglycemia and outcome. Hyperglycemia, in turn, increases both infections and inflammatory mediators and alters wound healing and repair. Perioperative glycemic control, therefore, carries the potential to affect patient outcome and hospital resource utilization.

INDICATIONS

The association between postoperative hyperglycemia and poor outcomes has been well studied after cardiac surgery, hepatectomy, colectomy, and other general and vascular surgeries. This relationship has also been reported in septic, critically ill, and trauma patients. Tight glucose control then intuitively seems to be indicated for all of these patient populations. Indeed, tight glucose control has shown benefits in these populations; however, hypoglycemia has been reported from overly zealous hyperglycemia protocols.

Tight glucose control is indisputably indicated after cardiovascular surgery. The cardiac literature has reported improved outcomes with tight postoperative glucose control since the 1990s. Patients with tighter glucose control have been shown to have lower rates of superficial and deep wound infections, among other complications, after surgery. In 2011, a meta-analysis of randomized controlled trials comparing tight glucose control with conventional glucose control after cardiac surgery showed that tight glucose control reduced intensive care unit (ICU) mortality, incidence of atrial fibrillation, need for epicardial pacing, duration of mechanical ventilation, and ICU length of stay.

Other critically ill surgical patients have benefited from tight glucose control. A landmark randomized controlled trial in 2001 reported a statistically significant reduction in morbidity and mortality (4.6% compared with 8%; $P = 0.04$) in surgical intensive care unit (SICU) patients treated with strict maintenance of a normal blood glucose (defined as 80 to 110 mg/dL instead of 180 and 200 mg/dL in the control group). Reduced morbidity in the tight glucose control group was attributed to a reduction in bloodstream infection, acute renal failure, red cell transfusion, incidence of critical illness polyneuropathy, and need for mechanical ventilation.

Postoperative euglycema may be indicated in all postoperative patients. In 2008, a retrospective review of the National Surgical Quality Improvement Program (NSQIP) data of nearly 1000 patients who underwent general or vascular surgery identified elevated postoperative glucose as a strong independent predictor of postoperative pneumonia, wound infection, urinary tract infection, and sepsis within 30 days of surgery. In 2012, another retrospective analysis of the Veterans Affairs Surgical Quality Improvement Program (VASQIP) data determined that patients with postoperative hyperglycemia after elective colectomy had an increased risk for surgical site infections, respiratory complications, operative reintervention, myocardial infarction, cardiac arrest, venous thromboembolism, and mortality. Although hyperglycemia was linked to worse outcomes in these studies, one cannot assume, based on these studies alone, that glucose homeostasis necessarily translates into a reduction in these infectious complications, as the hyperglycemia may be a marker of the severity of illness or the magnitude of the surgical insult rather than a direct contributor to the postoperative complications.

Hyperglycemia from parenteral nutrition, particularly during the initiation period when the body has yet to adapt to the intravenous glucose infusion, requires correction. A randomized controlled trial of 248 gastrectomy patients who needed parental nutrition showed a significantly reduced overall postoperative complication rate with intensive glucose control (13.6% compared with 25.2%; $P = 0.024$).

TECHNIQUES

Because of the multifactoral and complex nature of postoperative hyperglycemia, tight glucose control during this time period can be an extremely difficult task. Intravenous insulin infusion is perhaps the most precise way to quickly adjust blood glucose levels after surgery because of its rapid action. A continuous insulin infusion, however, requires frequent blood glucose measurements and close monitoring, which leads to increased costs and use of resources. For this reason, the alternative of a sliding scale of subcutaneously administered insulin is the most common method used after surgery. This method, however, frequently achieves suboptimal glucose control. Alternative strategies for improved postoperative glucose control are an important area of current research.

Long-acting insulin for improved glucose control has been evaluated after surgery, specifically in patients with a preoperative diagnosis of diabetes mellitus. In a randomized controlled trial of 100 patients with diabetes, those treated with basal bolus glargine (supplemented with glulisine given before meals) had better glucose control than those treated with a conventional sliding scale. As predicted, the patients receiving glargine were also found to have a lower number of postoperative complications, such as wound infections. Regarding the complications of this therapy, the authors reported a higher incidence of hypoglycemia in the glargine group; however, no significant difference was found in severe hypoglycemia episodes between the two groups (blood glucose levels, <40 mg/dL).

Glucose and insulin administration with maintenance of normoglycemia (GIN therapy) is an alternative to the standard titratable insulin infusion. This is a technique of perioperative glucose control where insulin is infused at a preemptive constant rate and dextrose is titrated to a goal serum glucose concentration. The technique has been advocated by some and has shown acceptable safety and efficacy in small trials. The goal of this therapy is complete suppression of endogenous insulin production with a constant infusion of insulin. This allows easier maintenance of blood glucose levels because the dextrose infusion rate can be adjusted to exactly match the patient's glucose utilization rate (removing the variable of insulin resistance).

Another proposed mechanism for tight control of postoperative glucose levels is an artificial pancreas. These devices measure blood glucose levels and automatically infuse regular insulin into the bloodstream to maintain glucose control. In 2012, a prospective randomized study reported superior glucose control in 17 patients with the artificial pancreas compared with 15 patients using a conventional sliding scale after elective pancreatic resection. Devices such as these appear effective; however, widespread utilization may be cost prohibitive.

One final consideration for control of postoperative glucose levels is avoidance of excessive intravenous glucose infusion. This can be accomplished with the use of enteral feeds, preferentially whenever possible. Patients fed parenterally have poorer glycemic control and associated worse outcomes. The addition of even small amounts of ("trophic") enteral feeds for patients receiving parenteral nutrition after surgery has shown numerous benefits, including reduced blood glucose concentrations and reduced insulin resistance.

RESULTS

As evidence of improved outcomes with tight postoperative glucose control has become more compelling, postoperative glucose management protocols have been implemented. Protocols can help improve compliance and render results of new therapies more easily measurable. Standard insulin infusion protocols are now ubiquitous; however, newer insulin-resistance-guided (IRG) protocols may be preferred. These IRG protocols have shown superior glucose control in patients after cardiovascular surgery, including increased time in the normoglycemic range, reduced time to the first glucose measurement in the target range, and decreased episodes of both hyperglycemia and hypoglycemia. IRG protocols are created from a collection of insulin titration curves. Each patient is assigned to one of several columns and then treated with a protocol based on the patient's own predicted level of insulin resistance. The column for the patient is then adjusted as needed based on both planned treatments and the patient's response.

The ideal target range for blood glucose levels after surgery is yet to be determined. Strict glucose control (80 to 110 mg/dL) was strongly advocated after van den Berghe's study in 2001 showed a benefit for this level of glycemic control. Since that time, however, a number of studies refuted this recommendation based on the consequences (hypoglycemia) associated with strict glucose control. The NICE-SUGAR trial, published in the *New England Journal of Medicine* in 2009, challenged the notion of tight postoperative glucose control. This international randomized controlled trial of 6104 patients showed *increased* mortality in patients managed with tight glucose control (target blood glucose range, 81 to 108 mg/dL) compared with more conventional control (≤180 mg/dL). Although the authors were not able to definitively identify the cause of increased mortality, significantly more episodes of severe hypoglycemia (<40 mg/dL) occurred in the tight glucose control group compared with the conventional group (6.8% versus 0.5%; $P < 0.001$). The conclusion was a caution against controlling postoperative glucose levels too tightly.

SUMMARY

Patients are at risk for hyperglycemia after surgery because of the body's response to the stress of surgery. Postoperative hyperglycemia has been associated with increased morbidity and mortality in numerous surgical subpopulations, likely as a result of infectious and inflammatory effects. Tight glucose control has shown benefit after surgery; however, it must be balanced against the costs and consequences of such therapy. The ideal target blood glucose range, and the best method for glucose control, is yet to be determined.

Postoperative Respiratory Failure

Lena M. Napolitano, MD, FACS, FCCP, FCCM

INTRODUCTION

Postoperative pulmonary complications (PPCs), particularly postoperative pneumonia and acute respiratory failure, are a significant cause of morbidity and mortality in surgical patients. Every effort should be made to prevent PPCs; therefore, surgeons must be acutely aware of patient-related, procedure-related, and laboratory test risk factors in the preoperative period (Table 1).

If these PPC risk factors are identified preoperatively, then all efforts to provide specific interventions to reduce the risk for PPCs should be implemented (Table 2). Preoperative efforts include smoking cessation at least 8 weeks prior to surgery and optimization of chronic pulmonary diseases, including asthma and chronic obstructive pulmonary disease. Intraoperative strategies to reduce the risk for PPCs include using a laparoscopic approach if possible, consideration of regional anesthesia and analgesia, and use of short-acting neuromuscular blockade. Postoperative strategies for PPC prevention focus on adequacy of pain control, increasing lung volume, pulmonary toilet, and preventing aspiration using selective gastric decompression. Lung expansion interventions via deep-breathing exercises, incentive spirometry, and positive pressure strategies have shown variable benefit in reducing the occurrence of PPCs.

ACUTE RESPIRATORY FAILURE

Acute respiratory failure (ARF) is respiratory system failure or dysfunction resulting in abnormalities of gas exchange, including oxygenation and/or carbon dioxide elimination. Common etiologies in surgical patients include pneumonia, atelectasis, aspiration, pulmonary edema, and acute respiratory distress syndrome (ARDS) and pulmonary embolus (Table 3 and Figure 1). Mechanical ventilation and noninvasive ventilation are the primary therapies for treatment of ARF.

CLASSIFICATION AND EPIDEMIOLOGY

ARF is classified as either hypoxemic or hypercapnic. Severe hypoxemic ARF should raise concern for possible ARDS.

- ***Hypoxemic respiratory failure*** (type I), defined as arterial partial pressure of oxygen (PaO_2) <60 mm Hg on room air, is the most common form of respiratory failure, and hypoxemia is a major immediate threat to organ function.
- ***Hypercapnic respiratory failure*** (type II) is defined as arterial partial pressure of carbon dioxide ($PaCO_2$) of >50 mm Hg on room air.
- ***Acute lung injury (ALI) and ARDS*** (see definitions in Table 4) are syndromes of acute hypoxemic respiratory failure that arise from *direct* (pulmonary) or *indirect* (extrapulmonary) insults (Table 5) that induce pulmonary inflammation, damage the cells of the alveolar-capillary membrane, and lead to severe ARF. A new definition for ARDS (Berlin definition) has been recently proposed (Table 6), which classifies ARDS into mild, moderate, and severe categories and includes specific amounts of positive end-expiratory pressure (PEEP) at which the ratio of PaO_2 to fraction of inspired oxygen (FiO_2) is calculated.

ARDS and ALI are associated with pathologic changes in the lung with diffuse alveolar damage that includes alveolar flooding, characteristic hyaline membranes, resulting in the loss of the gas exchange and barrier functions of the lung as a result of injury to the endothelial and epithelial layers of the alveolar-capillary membrane. Parenchymal injury is not a truly "diffuse" process and has significant regionalization of the inflammation, injury, and subsequent mechanical abnormalities. This heterogeneity can have significant impact on a mechanical ventilation strategy since there is preferential delivery of ventilatory breaths to pulmonary regions with higher compliance and lower resistance (i.e., the more normal regions) rather than to diseased parenchyma resulting in potential regional overdistension. ARDS stages include exudative, proliferative, and fibrotic phases.

ARF TREATMENT: NONINVASIVE VENTILATION

Noninvasive ventilation (NIV) provides positive pressure ventilator support without the need for an invasive airway. NIV should be considered first-line therapy in ARF due to chronic obstructive pulmonary disease exacerbation, since it is associated with decreased mortality rates, decreased need for intubation, decreased complications, and reduced length of hospital stay. Similarly, NIV is an effective and safe treatment for adult patients with ARF due to acute cardiogenic pulmonary edema; a systematic review of 21 studies documented that NIV was associated with reduced hospital mortality and endotracheal intubation and reduced length of stay in the intensive care unit (ICU).

NIV as a weaning strategy for intubated patients with ARF uses early extubation with immediate application of NIV. A recent systematic review of 12 trials documented that NIV significantly decreased mortality, ventilator-associated pneumonia, ICU and hospital length of stay, and total duration of mechanical ventilation. The role of NIV for treatment of ARF due to severe exacerbations of asthma is less clear; thus, NIV should be used with caution and with careful monitoring for need for intubation. NIV can also be used to treat ARF caused by other conditions, such as severe pneumonia or obesity hypoventilation, and to improve respiratory outcome in post-surgical patients.

ARF TREATMENT: INTUBATION

- Endotracheal intubation is required, and the orotracheal route is recommended with direct laryngoscopy or the GlideScope (Verathon, Bothell, Wash) versus awake fiberoptic intubation for patients with potential difficult airway. Short-acting sedative/hypnotics with neuromuscular blockade are required in awake patients. Caution should be used with propofol (which can cause significant hypotension) and etomidate (which is associated with adrenal insufficiency), particularly in elderly patients and patients with hypotension or hemodynamic instability.
- Chest radiograph should be obtained to confirm position. The endotracheal tube should be inserted to approximately 23 cm in men and 21 cm in women (measured at the incisor). Cuff pressures should be monitored and closed-circuit suction catheters used.

TABLE 1: Patient-related, procedure-related, and laboratory risk factors for postoperative pulmonary complications

Factor	Strength of recommendation*	Odds ratio
Patient-Related Risk Factor		
Advanced age	A	2.09-3.04
ASA Class ≥ II	A	2.55-4.87
CHF	A	2.93
Functionally dependent	A	1.65-2.51

- Sedation is required for endotracheal tube and mechanical ventilation tolerance, and intravenous infusions of short-acting narcotics and sedatives are used most commonly. A sedation scale should be used to reduce sedation to the least amount required. As soon as gastrointestinal tract function is confirmed, a transition to enteral narcotics and sedatives can be made. Emerging data document that benzodiazepines are associated with increased delirium; thus, caution should be used with these agents, particularly in the elderly and in those critically ill patients with organ dysfunction or failure.

TREATMENT: VAP PREVENTION

- All efforts to prevent ventilator-associated pneumonia (VAP) should be implemented immediately after intubation and initiation of mechanical ventilation. The key components of the ventilator bundle for VAP prevention are the following:
 - Elevation of the head of the bed
 - Daily "sedation vacations" and assessment of readiness to extubate (spontaneous awakening trial and spontaneous breathing trial [SAT/SBT])

TABLE 2: Specific interventions to reduce the risk for postoperative pulmonary complications (PPCs)

Risk reduction strategy	Strength of evidence*	Type of complication
Postoperative lung expansion modalities	A	Atelectasis, pneumonia, bronchitis, severe hypoxemia
Selective postoperative nasogastric decompression	B	Atelectasis, pneumonia, aspiration
Short-acting neuromuscular blockade	B	Atelectasis, pneumonia
Laparoscopic (vs open) operation	C	Spirometry, atelectasis, pneumonia, overall respiratory complications
Smoking cessation	I	Postoperative ventilator support
Intraoperative neuraxial blockade	I	Pneumonia, postoperative hypoxia, respiratory failure
Postoperative epidural analgesia	I	Atelectasis, pneumonia, respiratory failure
Immunonutrition	I	Overall infectious complications, pneumonia, respiratory failure
Routine total parenteral or enteral nutrition†	D	Atelectasis, pneumonia, empyema, respiratory failure
Right heart catheterization	D	Pneumonia

*A, good evidence that the strategy reduces the risk for PPCs and benefit outweighs harm; B, at least fair evidence that the strategy reduces the risk for PPCs and benefit outweighs harm; C, at least fair evidence that the strategy may reduce the risk for PPCs, but the balance between benefit and harm is too close to justify a general recommendation; D, at least fair evidence that the strategy does not reduce the risk for PPCs or harm outweighs benefit; I, evidence of effectiveness of the strategy to reduce the risk for PPCs is conflicting, of poor quality, lacking, or insufficient or the balance between benefit and harm cannot be determined.

†Evidence remains uncertain (strength of evidence I) for severely malnourished patients or when a protracted time of inadequate nutritional intake is anticipated.

From Lawrence VA, Cornell JE, Smetana GW: Strategies to reduce postoperative pulmonary complications after noncardiothoracic surgery: systematic review for the American College of Physicians. Ann Intern Med *144:596–608, 2006.*

TABLE 3: Common etiologies of acute respiratory failure and indications for mechanical ventilation

Etiologies of respiratory failure	Indications for mechanical ventilation
• Exacerbation of chronic obstructive pulmonary disease • Respiratory muscle fatigue • Neuromuscular diseases • Obtundation or coma • Pneumonia • Sepsis • Acute respiratory distress syndrome (ARDS)	• Apnea or respiratory arrest • Tachypnea (respiratory rate >30 breaths per minute) or bradypnea • Vital capacity <15 mL/kg, <1.0 L or <30% predicted • Minute ventilation >10 L/min • Hypoxemia • Hypercarbia

- Daily oral care with chlorhexidine gluconate
- Peptic ulcer disease prophylaxis
- Deep venous thrombosis prophylaxis

- Weaning of mechanical ventilation should be initiated to allow spontaneous breathing as soon as possible. A paired SAT/SBT should be performed in all patients on mechanical ventilation since it is associated with improved outcomes with reduced mortality rates, increased ventilator-free days, and reduced ICU and hospital lengths of stay.
- Other evidence-based strategies for VAP prevention can be considered in ICUs with a high prevalence of VAP, including continuous aspiration of subglottic secretion tubes, the use of silver-coated endotracheal tubes, and selective oral decontamination or digestive tract decontamination.

TREATMENT: MECHANICAL VENTILATION

- Effective strategies in mechanical ventilation must ensure adequate oxygenation and alveolar ventilation and reduce work of breathing without ventilator-induced lung injury (VILI).
- The treatment for hypoxemic ARF (type I) is to improve oxygenation and reverse or prevent tissue hypoxia by achieving adequate oxygen delivery to tissues with a goal of arterial oxygen saturations higher than 90% on the lowest FiO_2 concentration possible. The treatment of failure to ventilate—that is, hypercapnic ARF (type II)—is to increase alveolar ventilation by achieving adequate minute ventilation.

TABLE 4: The American-European Consensus Conference (AECC) definition of ALI and ARDS developed in 1994

ALI Criteria	Timing: acute onset Oxygenation: $PaO_2/FiO_2 \leq 300$ mm Hg (regardless of PEEP level) Chest radiograph: bilateral infiltrates seen on frontal chest radiograph Pulmonary artery wedge: ≤ 18 mm Hg when measured or no clinical evidence of left atrial hypertension
ARDS Criteria	Same as ALI except: Oxygenation: $PaO_2/FiO_2 \leq 200$ mm Hg (regardless of PEEP level)

ALI, Acute lung injury; *ARDS,* acute respiratory distress syndrome; *FiO_2,* fraction of inspired oxygen; *PaO_2,* arterial partial pressure of oxygen; *PEEP,* positive end-expiratory pressure.

TABLE 5: Clinical disorders associated with the development of ARDS

Direct insult pulmonary	Indirect insult extrapulmonary
Common	**Common**
Aspiration pneumonia Pneumonia	Sepsis Severe trauma Shock
Less Common	**Less Common**
Inhalation injury Pulmonary contusions Fat emboli Near-drowning Reperfusion injury	Acute pancreatitis Cardiopulmonary bypass Transfusion-related acute lung injury (TRALI) Disseminated intravascular coagulation Burns Traumatic brain injury Drug overdose

TABLE 6: New acute respiratory distress syndrome "Berlin" definition 2012

Acute respiratory distress	Syndrome (ARDS)
Timing	Within 1 week of a known clinical insult or new or worsening respiratory symptoms *(New addition, AECC stated "acute onset" with no definition)*
Chest imaging	Bilateral opacities on chest radiograph or chest computed tomographic scan *(No change from AECC definition)*
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload *(No change from AECC definition, but removed pulmonary artery wedge pressure criterion from definition given declining use of PA catheters)*
Oxygenation	
Mild	PaO_2/FiO_2 ratio 201-300 mm Hg with PEEP or CPAP ≥ 5 cm H_2O *(The term "acute lung injury, ALI" in AECC definition was removed, and added a minimum level of PEEP)*
Moderate	PaO_2/FiO_2 ratio 101-200 mm Hg with PEEP ≥ 5 cm H_2O
Severe	PaO_2/FiO_2 ratio ≤ 100 mm Hg with PEEP ≥ 5 cm H_2O

AECC, American-European Consensus Conference; *CPAP,* continuous positive airway pressure; *FiO_2,* fraction of inspired oxygen; *PA,* pulmonary artery catheter; *PaO_2,* partial pressure of arterial oxygen; *PEEP,* positive end-expiratory pressure.
Adapted from: The ARDS Definition Task Force, Ranieri VM, Rubenfeld GD, et al: Acute respiratory distress syndrome: the Berlin definition. JAMA *(23):2526-2533, 2012:doi:10.1001/jama.2012.5669.*

- Mechanical ventilation can lead to additional lung injury, that is, VILI. VILI mechanisms include barotrauma, diffuse alveolar injury resulting from overdistension (volutrauma), injury caused by repeated cycles of recruitment/derecruitment (atelectrauma; Figure 2), and the most subtle form of injury related to the release of local mediators in the lung (biotrauma).
- Variables that can be adjusted for mechanical ventilation include the following:
 - Mode of ventilation
 - Tidal volume (Vt)
 - Respiratory rate (RR)
 - Supplemental oxygen (FiO_2)
 - Inspiration/expiration ratio (I:E)
 - Inspiratory flow rate
 - Positive end-expiratory pressure (PEEP)
 - Trigger sensitivity (effort required to trigger the ventilator to deliver a breath)
 - Rise time (determines speed of rise of flow or pressure in each breath)
 - Temperature and humidity of inspired air
- Oxygen uptake via the lungs is dependent on both PaO_2 (FiO_2, alveolar pressure) and ventilation-perfusion matching (reversing atelectasis, reducing intrapulmonary shunting). To improve oxygenation, three main strategies are utilized:
 - Increase FiO_2. High levels (>50%) have been associated with oxygen toxicity, absorptive atelectasis, and other issues.
 - Increase mean alveolar pressure by increasing mean airway pressure (increase PEEP or increase I:E ratio, increase inspiratory time).
 - Recruitment maneuver with PEEP (i.e., 30 cm H_2O PEEP for 30 seconds, 40 cm H_2O PEEP for 40 seconds, or pressure control RM with high PEEP 40, low PEEP 20, respiratory rate 10-20, I:E 1:1, with mean airway pressure 30 for 2 minutes)
- Ventilation describes carbon dioxide elimination via the lungs and is largely dependent on alveolar ventilation. Alveolar ventilation = respiratory rate × (tidal volume − dead space). To improve CO_2 elimination:
 - Increase minute ventilation (increasing tidal volume or respiratory rate).

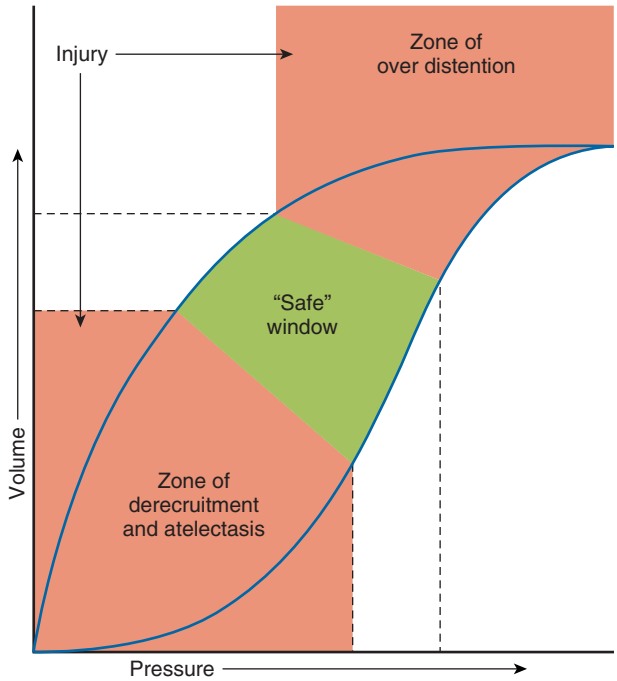

FIGURE 2 Pressure-volume curve of a moderately diseased lung, such as in ARDS. Two hazard zones exist: overdistension and derecruitment/atelectasis. Higher end-expiratory pressures and small tidal volumes are needed to stay in the "Safe" window. High-frequency oscillatory ventilation may have a larger margin of safety in keeping the lung open within the desired target range and avoiding alveolar overdistension. *ARDS,* Acute respiratory distress syndrome. *(Reprinted with permission from Imai Y, Slutsky AS: High-frequency oscillatory ventilation and ventilator-induced lung injury.* Crit Care Med *33(3 Suppl):S129–S134, 2005.)*

MODES OF MECHANICAL VENTILATION

- Controlled mechanical ventilation is commonly used initially to ensure adequate alveolar ventilation and arterial oxygenation and reduce work of breathing and further lung damage. Recent studies suggest a benefit when early conversion to spontaneous breathing modalities during mechanical ventilation is employed. Therefore, spontaneous breathing is desired whenever possible.
- Mechanical positive pressure ventilation can be delivered via a volume or pressure target.
- No single mode of mechanical ventilation for ARF is superior in terms of clinical outcomes.

Volume Modes

Tidal volume is set and airway pressure is variable. The airway pressure will be variable based on the rate of delivery of the tidal volume, pulmonary compliance (plateau pressure), and airway resistance (peak pressure). This variability in airway pressure may result in barotrauma if high peak airway pressures occur.

Controlled Mechanical Ventilation (CMV): Set respiratory rate and tidal volume to achieve an exact minute ventilation; does not allow patient interaction. CMV may result in diaphragmatic inactivity, promoting atrophy and contractility dysfunction in this important inspiratory muscle, so it is not commonly used.

Assist-Control Ventilation (ACV): A commonly used mode of mechanical ventilation that is patient-triggered or time-triggered, flow-limited, and volume-cycled. The tidal volume of each delivered breath is the same, whether triggered by the ventilator or the patient. The ventilator delivers breaths in coordination with the respiratory effort of the patient. If a patient triggering event does not occur in a set time interval, then the ventilator will deliver a breath similar to control mode. This allows for patient participation with regard to breath initiation. ACV is associated with low work of breathing, as every breath is supported and tidal volume is guaranteed.

Synchronous Intermittent Mandatory Ventilation (SIMV): The ventilator delivers both mandatory (set rate, tidal volume) breaths delivered in coordination with the respiratory effort of the patient and pressure support (set pressure) breaths to support spontaneous breathing. Most SIMV modes will default to a control-mode setting in the event that the patient does not trigger the ventilator in a certain time window around the preset respiratory rate. Synchronization of the tidal volume delivery with the patient's inspiratory effort attempts to limit barotrauma that may occur with nonsynchronized intermittent mandatory ventilation when a preset breath could be delivered to a patient who is already maximally inhaling (breath stacking) or is forcefully exhaling.

Pressure Modes

Airway pressure is set and tidal volume is variable. The tidal volume will be affected by any factor that changes the airway pressure, including thoracic compliance and pulmonary resistance, and by the inspiratory time. As the lung inflates, the inspiratory flow tapers; this results in a more homogenous gas distribution throughout the lungs. Since tidal volume is variable in pressure control modes, a sudden decrease in pulmonary compliance can cause a rapid reduction in tidal volume and minute ventilation, resulting in acute respiratory acidosis. This mode necessitates close monitoring of the minute ventilation and possible intrinsic PEEP or auto-PEEP (Figure 3).

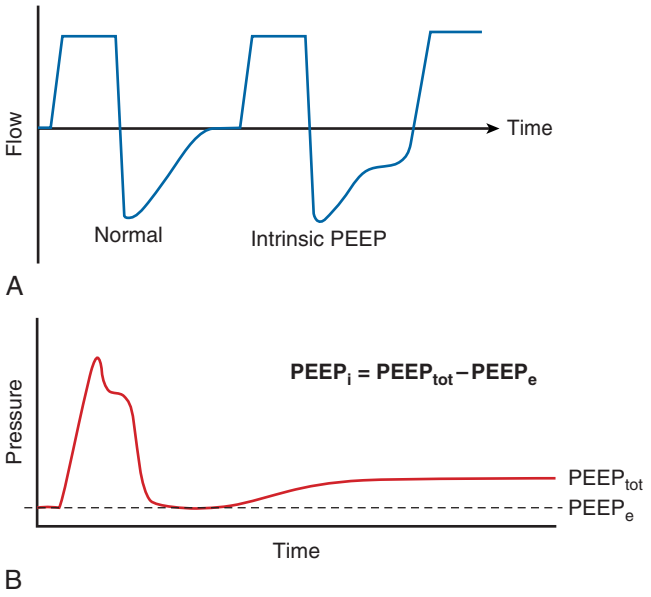

FIGURE 3 Intrinsic PEEP or auto-PEEP. **A,** Examination of the flow-time curve from the ventilator gives an indication that there is intrinsic PEEP but does not give an indication of the magnitude. The patient does not need to be apneic. **B,** A quantitative measurement of intrinsic PEEP can be obtained in an apneic patient by using the expiratory pause hold control on the ventilator. This allows equilibration of pressures between the alveoli and the ventilator, allowing the total PEEP to be measured. The value for total PEEP can be read from the PEEP display. Intrinsic PEEP = Total PEEP—Set PEEP. *PEEP,* Positive end-expiratory pressure.

Pressure Control Ventilation (PCV): Set an inspiratory pressure and inspiratory time rather than tidal volume and inspiratory flow rate. Tidal volume is dependent on set pressure, inspiratory time, and patient's compliance or resistance. In patients with hypoxemic ARF or ARDS, changing from a volume control mode to a pressure control mode may result in lower peak airway pressures.

Pressure Support Ventilation (PSV): Breaths are assisted by a set inspiratory pressure, which is delivered until inspiratory flow drops below a predetermined threshold (e.g., 25% of peak flow). Respiratory rate and tidal volume are determined by the patient. PSV can be a stand-alone mode or can function with SIMV (PSV only with spontaneous breaths). Apnea alarms are required to ensure patient safety. Some ventilators may have a set backup intermittent mechanical ventilation rate in case spontaneous respirations cease. PSV has been advocated to limit barotrauma and decrease the work of breathing. PSV is also used at low levels (5 cm H_2O) during spontaneous breathing trials.

Pressure-Regulated Volume Control (PRVC) or Volume Control Plus (VC+): Automatically adjusts inspiratory pressure in response to dynamic changes in patient mechanics to guarantee a set tidal volume in a pressure-control breath. Constant pressure is applied throughout inspiration (like pressure control), but the ventilator will adjust the inspiratory pressure with each breath (compensating for changes in airway resistance and compliance) to deliver a set tidal volume. PRVC is a patient-triggered or time-triggered, pressure-limited, time-cycled mode.

Airway Pressure Release Ventilation (APRV): This is an inverse-ratio pressure mode of mechanical ventilation that alternates between high PEEP (generally set between 25 and 30 cm H_2O) and low PEEP (usually 0 cm H_2O), with a longer inspiratory

time (time-high), I:E commonly 7:1 to 10:1, and a very short expiratory time or "release" (time-low). APRV is an excellent treatment for severe hypoxemia as it achieves high mean airway pressures, resulting in improved alveolar recruitment without high plateau pressures. Tidal volume is determined by the difference between high PEEP and low PEEP. Spontaneous breathing can occur, and APRV is well tolerated hemodynamically and in terms of patient comfort with minimal sedation.

Bilevel or Biphasic Ventilation: Similar to APRV, mandatory breaths are pressure controlled, and spontaneous breathing can occur at time-high or time-low (Figure 4). Spontaneous breaths may be pressure supported. Compared to APRV, bilevel time-low is generally longer, which allows for more spontaneous breaths during time-low.

ADVANCED MODES OF MECHANICAL VENTILATION IN THE ICU

Newer modes of mechanical ventilation are focused on improving the patient-ventilator interface, resulting in decreased ventilator dyssynchrony and improved patient comfort, allowing greater time in spontaneous breathing.

Proportional Assist Ventilation (PAV): During PAV, the airway pressure is proportional to the instantaneous effort of the patient and is amplified according to the patient respiratory mechanics (pulmonary compliance and airway resistance) and the chosen level of assistance (0% to 100%) for the respiratory muscles. A recent advance is the development of PAV+, a mode that provides intermittent automated measurements of the patient's compliance and resistance, which are used by the ventilator to adjust the specific support for the patient. No studies have yet documented improved outcome using PAV.

Adaptive Support Ventilation (ASV): This mode can deliver both controlled (similar to pressure-control) and assisted (similar to pressure support) pressure cycles related to a minute ventilation target set by the clinician and based on automated measurements of the patient's respiratory mechanics.

Neurally Adjusted Ventilatory Assist (NAVA): Like PAV, with NAVA, the level of ventilator assistance is proportional to the patient's effort, but the signal is a diaphragmatic electromyogram signal from diaphragmatic contraction obtained from electrodes on an esophageal catheter. A significant benefit of NAVA is improvement in patient-ventilator synchrony and reduced work of breathing by ensuring the respiratory muscles are supported throughout inspiration when compared with other commonly used mechanical ventilation modes. NAVA is not yet in widespread use, and the patient groups most likely to benefit have not yet been defined.

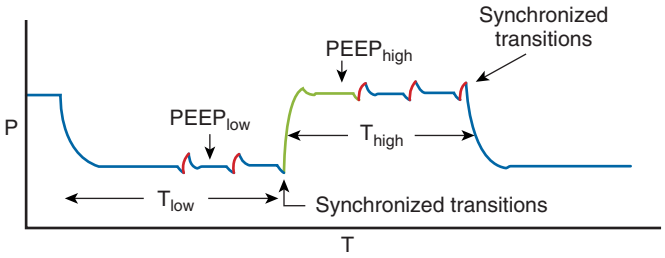

FIGURE 4 Bilevel ventilation uses two pressure levels (PEEP-low and PEEP-high) for two time periods (time-low and time-high), with spontaneous breathing at PEEP-low or PEEP-high. *PEEP,* Positive end-expiratory pressure.

SmartCare (Dräger Medical, Lübeck, Germany): This closed loop system provides automated adaptation of the level of PSV and initiates an automated weaning protocol to decrease the level of PSV and initiate SBTs when a low level of PSV is attained. The first multicenter study comparing automated weaning to standard of care ($n = 144$) documented that automated weaning reduced the total duration of mechanical ventilation and weaning duration, and the proportion of patients requiring NIV after extubation. Additional clinical trials are under way.

MECHANICAL VENTILATION STRATEGIES FOR ALI AND ARDS

Many recent advances have been made in developing protective mechanical ventilation strategies for patients with ARDS. These include low tidal volume ventilation, permissive hypercapnia, open lung strategy, and high-frequency oscillatory ventilation. The initial strategy for management of ALI/ARDS should include the use of low tidal volume ventilation (6 mL/kg) with adequate PEEP.

Low Tidal Volume Ventilation: Alveolar stretch from high tidal volumes can result in VILI through stimulation of an exaggerated alveolar and systemic inflammatory response. High tidal volumes are associated with high plateau pressures, which are associated with increased mortality. The ARDS-Network landmark ARMA multicenter, randomized controlled trial documented that low tidal volume (6 mL/kg) versus high tidal volume (12 mL/kg) ventilation in patients with ARDS was associated with a significantly lower mortality rate (31% vs 40%; $P = 0.007$) in the low tidal volume group. Ventilator-free days and number of days without non–pulmonary organ system failures were also decreased in the low tidal volume group. The incidence of barotrauma was similar: 10% versus 11%. The *Guidelines for Mechanical Ventilation of the Trauma Patient* from the participants of the Inflammation and Host Response to Injury, a large-scale collaborative research project, standardized clinical management in trauma patients to ensure that a low tidal volume, lung-protective strategy is used for patients with ALI or ARDS. This also provides guidelines for the PEEP and weaning of mechanical ventilation (Box 1).

Permissive Hypercapnia: Low tidal volume ventilation to reduce volutrauma can result in decreased minute ventilation leading to hypercapnia and acute respiratory acidosis. Permissive hypercapnia accepts deliberate hypoventilation in order to reduce alveolar overdistension and pressures in ARDS patients with severe hypoxemia. Resultant hypercarbia and respiratory acidosis are managed medically. Hypercapnia may worsen intracranial pressure and should be avoided in patients with traumatic brain injury. Tidal volume is gradually reduced to allow a slow increase in $PaCO_2$. Alkali therapy with sodium bicarbonate or tromethamine can be used to treat the acute respiratory acidosis.

Open Lung Strategy: Combining the use of low-volume tidal volume strategies, with the application of PEEP at levels above the lower inflection point, and permissive hypercapnia has been termed the "open-lung approach." Depletion of surfactant and low levels of PEEP lead to cyclic atelectasis with repeated collapsing and opening of the remaining function alveoli in patients with ARDS. Cyclic opening and closing of alveoli can lead to leukocyte activation, VILI, and loss of functional residual lung capacity. Increased levels of PEEP lead to recruitment of collapsed alveoli, reduced ventilation-perfusion mismatch, improved arterial oxygenation, and increased functional residual lung capacity. By maintaining end-expiratory pressure, alveoli that are unstable and prone to collapse will

BOX 1: Pocket card summary of mechanical ventilation of the trauma patient

Mechanical Ventilation Protocol: Inflammation and the Host Response to Injury

In patients with ALI or established ARDS ($PaO_2/FiO_2 \leq 300$ or $PaO_2/FiO_2 \leq 200$, respectively, with bilateral pulmonary infiltrates), aim for the following within 24 hours of meeting criteria.

1. Initial tidal volumes may be set at 8 mL/kg predicted body weight (PBW); tidal volumes should be reduced by 1 mL/kg at intervals of <2 hours until the tidal volume = 6 mL/kg. Tidal volume calculations are based on predicted body weight as follows:

 For Males: PBW (kg) = 50 + 2.3 {height (inches) − 60}
 For Females: PBW (kg)= 45.5 + 2.3 {height (inches) − 60}
2. PaO_2 55-80 mm Hg or SpO_2 88%-95%. FiO_2/PEEP ratio should be ≤ 5 and PEEP must be ≤ 35 cm H_2O.
3. Arterial pH 7.25-7.45 with RR <35 and $PaCO_2 \geq 25$. HCO_3 infusion may be given if necessary. If pH <7.15, then Vt may be increased by 1 mL/kg to pH ≥7.15 and target plateau pressures (see number 4) may be exceeded.
4. Plateau pressures (Pplat) ≤ 30 cm H_2O. Reduce Vt to no less than 4 mL/kg. If Vt <6 mL/kg and Pplat <25, then increase Vt until Pplat = 25-30 or Vt = 6 mL/kg.

Patients not meeting ALI/ARDS criteria can be ventilated using the mode, rate, and tidal volume chosen at the treating physician's discretion.

Patients should undergo a daily assessment of their readiness for a spontaneous breathing trial (SBT):

(a) resolution or stabilization of the underlying disease process; (b) no residual effects of neuromuscular blockade; (c) exhibiting respiratory efforts; (d) hemodynamically stable; (e) $FiO_2 \leq 0.5$ and PEEP ≤ 8 cm H_2O; (f) PaO_2 >70 mm Hg; (g) Ve <15 L/min; (h) Arterial pH between 7.30-7.50; (i) ICP <20 cm H_2O. If not ready for an SBT, then return to a comfortable, nonfatiguing mode of ventilator support and reassess daily.

If ready, then the patient should receive **a trial of spontaneous breathing (SBT) on CPAP for 30-90 minutes. Criteria for failure of a SBT:**

(a) RR >35 for ≥ 5 min; (b) SpO_2 <90% for ≥ 30 seconds; (c) HR >140 or increase or decrease of 20% from baseline; (d) SBP >180 mm Hg or <90 mm Hg; (e) sustained evidence of respiratory distress; (f) cardiac instability or dysrhythmias; (g) arterial pH ≤ 7.32; (h) ICP ≥ 20 cm H_2O. If any criteria are met, the CPAP trial is terminated and patient returned to a nonfatiguing mode of support and rested overnight. Repeat CPAP in the morning.

If patient completes CPAP trial, the following criteria should be assessed to determine readiness for extubation and patient should be extubated if possible:

(a) does not require suctioning more than every 4 hours; (b) good spontaneous cough; (c) endotracheal tube cuff leak; (d) no recent upper airway obstruction or stridor; (e) no recent reintubation for bronchial hygiene.

remain open. The optimal PEEP level is difficult to determine, but evidence suggests that maximal recruitment and lung volume maintenance occurs when the PEEP is set at a level just above the inflection point (Pflex) on the pressure-volume curve in patients with ARDS. A recent meta-analysis confirmed that higher versus lower levels of PEEP was associated with improved an survival rate among patients with ARDS. Despite the use of increased PEEP, it has been shown that decreasing plateau pressures (Pplat) results in a lower mortality rate in patients with ARDS (Figure 5). The study does not reveal a safe threshold for Pplat in ALI/ARDS patients. A bivariate analysis also showed that lower Pplat quartiles were associated with reduced mortality compared with higher Pplat quartiles ($P = 0.039$) suggesting that tidal volume reduction benefits patients even when Pplat is already less than 30 to 35 cm H_2O.

High-Frequency Oscillatory Ventilation (HFOV): HFOV delivers small tidal volumes at frequencies of 3 to 15 Hz to maintain adequate minute ventilation. Oxygenation is manipulated by adjusting mean airway pressure similar to the use of PEEP in conventional mechanical ventilation. Ventilation and carbon dioxide elimination are controlled by changing the tidal volume, by amplitude or power, or by adjusting the frequency. Increasing the amplitude or decreasing the frequency will cause an increase in carbon dioxide elimination. Amplitude or power is set to achieve appropriate chest wall movement and adequate CO_2 elimination. HFOV is used as a rescue strategy when other modes of mechanical ventilation fail. It is also used in patients with bronchopleural fistulae or tracheobronchial injuries to maintain low mean airway pressures in an effort to resolve air leaks within the tracheobronchial system.

Two randomized trials—the Oscillation for ARDS Treated Early (OSCILLATE) Trial by the Canadian Critical Care Trials Group and the High-Frequency Oscillation in ARDS (OSCAR) Trial in the United Kingdom—showed that in adults with moderate-to-severe ARDS, early application of HFOV, as compared with a ventilation strategy of low tidal volume and high PEEP, did not reduce in-hospital mortality rates.

Although the exact severity threshold at which to initiate a trial of HFOV remains unclear, an emerging approach includes the following severity criteria:

- $FiO_2 > 0.6$ and $SpO_2 < 88\%$ on CMV with PEEP > 15 cm H_2O, or
- Plateau pressures > 30 cm H_2O, or

- Mean airway pressure 24 cm H_2O, or APRV with high pressure 35 cm H_2O

Airway Pressure-Release Ventilation (APRV): APRV is a pressure-limited, time-cycled mode of mechanical ventilation that allows the patient unrestricted spontaneous breathing during application of continuous positive airway pressure (CPAP) with a very short release time, resulting in open lung mechanical ventilation. APRV has two settings of pressure. The high pressure setting allows spontaneous breathing and accounts for 80% to 95% of the cycle time creating an open lung. The remainder of the cycle allows for a periodic pressure release to the low pressure setting to allow for ventilation and carbon dioxide clearance while preventing alveolar collapse. APRV is used when patients are able to spontaneously breathe, yet high mean airway pressure is required for alveolar recruitment for severe hypoxemia.

ADJUNCTS TO MECHANICAL VENTILATION IN PATIENTS WITH ARDS AND SEVERE HYPOXEMIA

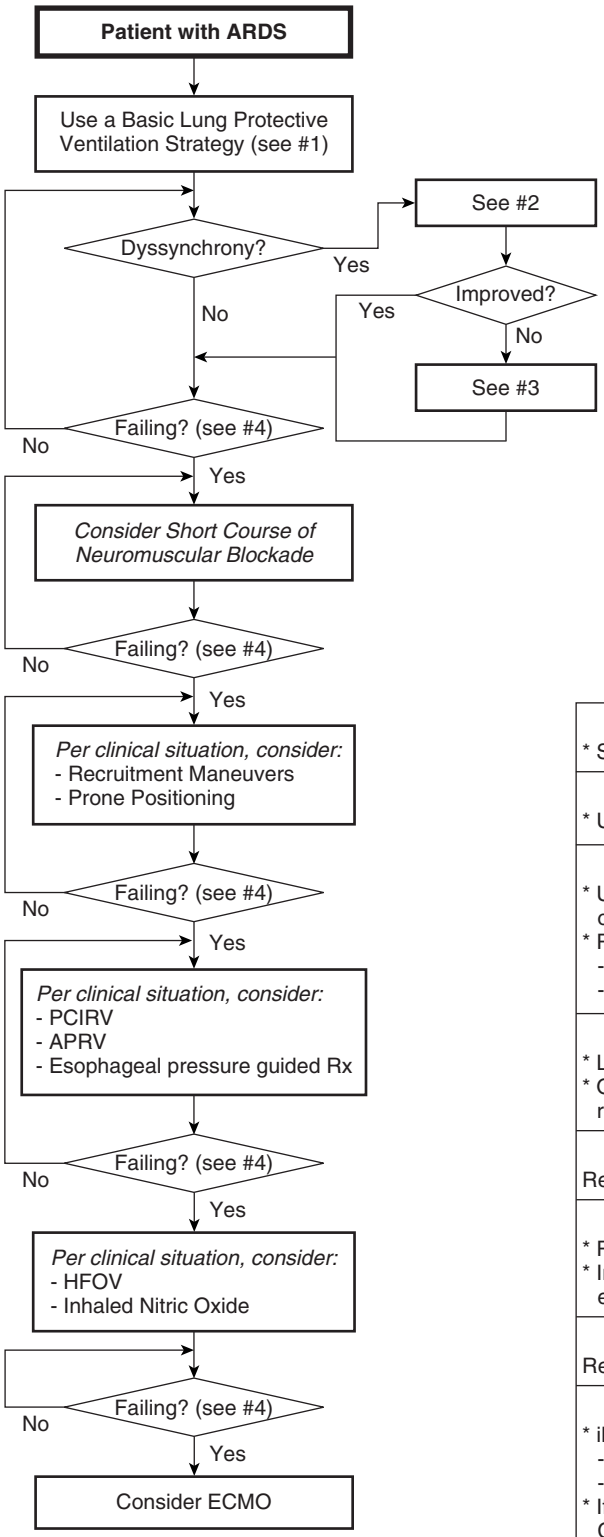
In patients with severe life-threatening hypoxemia, a number of strategies are used, including fluid management, recruitment maneuvers, neuromuscular blockade, prone position, inhaled nitric oxide, and extracorporeal membrane oxygenation.

Recruitment Maneuvers: Alveolar recruitment is aimed at improving pulmonary gas exchange and preventing VILI, atelectasis, and atelectrauma. Recruitment maneuvers (RMs) can increase alveolar functional residual lung capacity, and PEEP can then maintain the alveoli to prevent collapse. Recruitment refers to the dynamic process of reopening unstable airless alveoli through an intentional transient increase in transpulmonary pressure, accomplished via many methods. A common method for RMs is to provide sustained inflation with 30 cm H_2O PEEP for 30 seconds or 40 cm H_2O PEEP for 40 seconds; alternatively, the use of a pressure control RM with high PEEP 40, low PEEP 20, I : E 1 : 1 for 2 minutes is effective. The optimal methods of RMs (sustained inflation vs incremental PEEP) and optimal pressure, duration, and frequency of RMs have not been tested in large clinical trials. A recent systematic review concluded that RMs were associated with a significant increase in oxygenation with few serious adverse events. Transient hypotension and desaturation during RMs is common but is self-limited without sequelae. Given the uncertain benefit and lack of information regarding impact on clinical outcomes, RMs should be considered for use only in patients with life-threatening hypoxemia.

Fluid Management: A conservative fluid management strategy was superior to a liberal strategy in ALI/ARDS patients; outcomes included improved lung function and oxygenation and decreased duration of mechanical ventilation and ICU stay but no difference in 60-day mortality. Diuretic therapy should be considered in severe hypoxemia (PaO_2/FiO_2 ratio < 100). A careful assessment of adequacy of perfusion and cardiac performance should be completed before initiation of diuretic therapy. Reassessment should be continued while diuresis is ongoing.

Neuromuscular Blockade: A multicenter, double-blind trial of 340 patients with severe ARDS confirmed that early administration of a neuromuscular blocking agent (cisatracurium) improved 90-day survival and increased time off mechanical ventilation without increasing muscle weakness compared to placebo. Enthusiasm for this approach must be tempered with concern for critical illness polyneuropathy.

Inhaled Nitric Oxide: Nitric oxide is a selective pulmonary vasodilator leading to decreased pulmonary vascular resistance, pulmonary arterial pressure, and right ventricular afterload. Low-dose inhaled nitric oxide has shown improved short-term oxygenation in ALI and ARDS patients without affecting duration of mechanical ventilatory support or mortality rate. Inhaled nitric oxide may be considered a salvage therapy in patients who continue to have life-threatening hypoxemia despite optimization of all other treatment strategies.



Prone Positioning: Changes in patient positioning can have a dramatic effect on oxygenation and ventilation in patients with severe ARDS and severe hypoxemia. Prone position can improve the distribution of perfusion to ventilated lung regions, decreasing intrapulmonary shunt and improving oxygenation. The use of intermittent or extended prone positioning can significantly improve oxygenation in 60% to 70% of patients. Prone positioning can be performed safely by trained and dedicated nursing staff who are aware of its potential benefits in critically ill patients with severe hypoxemia. Prone positioning is a useful tool for treatment of severe hypoxemia. Recent meta-analyses in patients with ARDS documented a significantly decreased mortality rate with prone positioning, with an absolute mortality reduction rate of 10% in severely hypoxemic ARDS patients.

Extracorporeal Membrane Oxygenation (ECMO): ECMO is considered in patients with severe ARDS and hypoxemia with reversible lung disease who have failed other rescue strategies. ECMO provides oxygenation, provides ventilation with total extracorporeal CO_2 clearance, minimizes barotrauma with complete lung rest, and is accomplished via venovenous ECMO support, until the patient's endogenous lung function improves. Substantial progress in ECMO has been achieved. Potential complications resulting from the use of ECMO include bleeding (including intracranial hemorrhage), coagulopathy, thrombosis, and mechanical complications. Of 1473 adults with severe ARDS, ECMO was associated with a 50% survival to discharge. Patients with severe ARDS and hypoxemia should be referred to an ARDS center with ECMO experience to achieve the best outcomes possible. Adult patients are cannulated percutaneously with large 21F to 31F venous catheters for drainage of deoxygenated blood and infusion and oxygenated blood. Anticoagulation is necessary, and heparin continuous infusion is common, and monitored with ACT or PTT studies.

The CESAR trial (Conventional Ventilation or ECMO for Severe Adult Respiratory Failure) was a prospective randomized trial (n = 180) in the United Kingdom. Of the 90 patients assigned to ECMO treatment, only 68 received ECMO; others were managed with mechanical ventilation and rescue strategies. Sixty-three percent of patients transferred to an ECMO center survived to 6 months without disability versus 47% in the conventional management group (RR 0.69, CI 0.05-0.97, P = 0.03). A criticism of this study is that the conventional cohort was not managed with low tidal volume, low plateau pressure, open lung protective mechanical ventilation. Another multicenter ECMO clinical trial, ECMO to Rescue Lung Injury in Severe ARDS (EOLIA), is being initiated in France to address this issue.

INCREMENTAL APPROACH TO THE MANAGEMENT OF SEVERE ARDS

- Development of ICU protocols reduces undesirable variability, mandates best evidence practice, promotes action and timeliness, and facilitates multidisciplinary communication.
- At the University of Michigan, we have developed an algorithm (Figure 6) for management of critically ill patients with severe ARDS/severe hypoxemia to provide evidence-based care.

1: Basic LPVS

- ARDS Network ventilation strategy:
 a. Using VCV or PCV and targeting VT 4-6 mL/kg PBW
 b. Maintain Pplat ≤30 cm H_2O
 c. PEEP/FiO_2 per table

2: Pt-Vent Dyssynchrony, Step 1

- Initial strategy should be to:
 a. Assess potential to treat with pharmacologic agents (e.g., sedation, NMB agents), and
 b. Consider minor ventilator adjustments (e.g., flow rate & pattern, inspiratory pause)
- If above does not work, consider increasing VT 1 mL/kg (max 8 mL/kg), provided Pplat ≤28-30 cm H_2O

3: Pt-Vent Dyssynchrony, Step 2

- Consider a variable flow pressure breath mode of ventilation:
 a. Volume Control+
 b. Pressure Control Ventilation

4: Criteria for Failing LPVS

- PaO_2 <55 torr on FiO_2 =1.0 and Pplat >30 cm H_2O on VT =4 mL/kg PBW

Neuromuscular Blockade

* Short course (48 hrs) associated with mortality benefit in RCT

Recruitment Maneuvers

* Use: 35-45 cm H_2O x 20 sec, or PCV with 40/20 for 2 minutes

Prone Positioning

* Use unit specific rotation frequency, but evidence suggests majority of day (>17 hrs) in prone position, if tolerated
* Recommend a 48 hr trial, stop if no improvement, as evidenced by:
 - Reduced FiO_2 by 0.10
 - Increased PaO_2/FiO_2 by 30

Pressure Control Inversed Ratio (PCIRV) Ventilation

* Lengthen Ti to increase Pmean
* Observe exp flow graphic; stop when auto-PEEP present, regardless of I:E ratio

Airway Pressure Release Ventilation (APRV)

Refer to Respiratory Care policy

Esophageal Pressure (Pes) Guided Therapy

* Requires switch to AVEA ventilator & placement of Pes catheter
* Informs of transpulmonary end-inspiratory (Ptp-plat) and end-expiratory (Ptp-PEEP) pressures

High Frequency Oscillatory Ventilation (HFOV)

Refer to Respiratory Care policy (policy follows Oscillate protocol)

Inhaled Nitric Oxide (iNO)

* iNO Test
 - 20-60 minute test on 40 ppm
 - Positive response: increase in PaO_2/FiO_2 of >10
* If positive response, titrate and consider iloprost, per Respiratory Care Policy
* If no response, discuss with team to consider stopping

Note: *iNO is a very costly drug compared to alternatives*

Extracorporeal Membrane Oxygenation (ECMO)

* Absolute contraindications: irreversible pulmonary process and inability to anticoagulate
* Evaluate, but lower survival if on vent 7-10 days pre-ECMO

FIGURE 6 ARDS mechanical ventilation algorithm, including rescue strategies, used at the University of Michigan. (AVEA ventilator; CareFusion, San Diego, Calif.) *ARDS,* Acute respiratory distress syndrome; *FiO_2,* fraction of inspired oxygen; *LPVS,* lung protection ventilation strategy; *NMB,* neuromuscular-blocking; *PaO_2,* arterial partial pressure of oxygen; *PBW,* predicted body weight; *PCV,* pressure control ventilation; *PEEP,* positive end-expiratory pressure; *RCT,* randomized controlled trial; *VCV,* volume controlled ventilation; *Vt,* tidal volume.

- In patients with ARDS, initial low tidal volume ventilation should be initiated, set at 6 to 8 mL/kg of predicted body weight (PBW); tidal volumes should be reduced by 1 mL/kg at intervals of 2 hours until the tidal volume is set at 6 mL/kg. Goal: SpO_2 88% to 95%, PaO_2 55 to 80 mm Hg, plateau pressures < 30 cm H_2O while using lowest FiO_2 possible.
- If no improvement is made, recruitment maneuvers should be considered. If oxygenation improves during recruitment maneuvers, the PEEP should be increased until optimal PEEP is achieved.
- If no improvement, evaluation for a possible intracardiac shunt and/or pulmonary hypertension should be initiated. Diagnostic strategies include pulmonary artery catheter placement and/or transthoracic or transesophageal echocardiogram. Inhaled nitric oxide should be considered as a therapeutic strategy to improve oxygenation. If there is still no improvement in oxygenation, prone positioning should be considered.
- At this point, for a patient with persistent severe hypoxemia, transfer of the patient to an ARDS Referral Center with experience in other ARDS treatment modalities, including rescue strategies, APRV, HFOV, and ECMO should be considered (Figure 7).

WEANING AND LIBERATION FROM MECHANICAL VENTILATION

- Mechanical ventilation has significant potential risks such that efforts should be focused on liberation from mechanical ventilation once adequate lung recovery has occurred.
- Nearly half of the time spent with mechanical ventilation is spent weaning the patient.
- A daily SAT followed by an SBT should be performed in all patients on mechanical ventilation. A randomized multicenter trial that compared this "wake up and breathe" protocol (paired SAT/SBT) versus usual care plus a daily SBT in the control cohort confirmed that SAT/SBT resulted in improved outcomes with reduced mortality rate, increased number of ventilator-free days, and reduced ICU and hospital length of stay.
- Continuous protocols for weaning from mechanical ventilation directed by respiratory therapists are associated with shorter duration of ventilation and shorter ICU length of stay. Patients who fail an SAT/SBT trial are returned to their previous ventilator settings and rescreened for another SAT/SBT trial in 24 hours. The patient must be carefully evaluated to determine the cause of the SAT/SBT failure. The patient must be assessed for anxiety, pain, secretions, muscle weakness, atelectasis, hypoxemia, hypercarbia, and all other potential causes for lack of resolution of ARF.
- Patients who complete a paired SAT/SBT trial (CPAP with low pressure support [5 cm H_2O] or automatic tube compensation, or T piece) should be assessed to determine readiness for extubation. At the completion of the SAT/SBT trial, the rapid shallow breathing index (RSBI), the ratio of respiratory frequency to tidal volume (f/Vt, respiratory rate × tidal volumes in liters), is calculated and an arterial blood gas is obtained to evaluate for hypercarbia. For example, a patient who has a respiratory rate of 25 breaths/min and a tidal volume of 250 mL/breath has an RSBI of (25 breaths/min)/(0.25 L) = 100 breaths/min/L. RSBI less than 105 is associated with 80% wean success; RSBI that is 105 or higher is associated with 95% wean failure.
- Prior to considering extubation, additional assessment includes the following: (a) does not require tracheal suctioning more than every 4 hours; (b) good spontaneous cough; (c) endotracheal tube cuff leak; (d) no recent upper airway obstruction or stridor; (e) no recent reintubation for bronchial hygiene.
- If failure to wean and/or extubate persists despite maximal and repeated efforts to achieve these endpoints, other steps may be required prior to successfully liberating the patient from

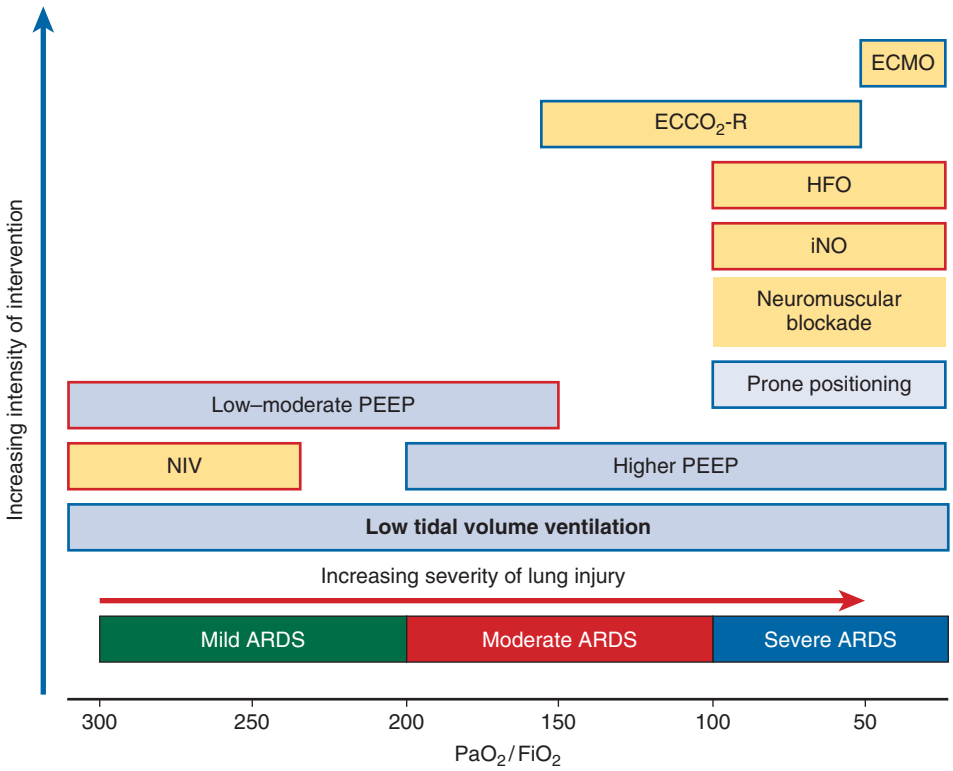


FIGURE 7 Increasing intensity of treatment intervention for increasing severity of ARDS, with all treatment strategies available at ARDS Referral Center, including ECMO. *ARDS,* Acute respiratory distress syndrome; *$ECCO_2$-R,* extracorporeal carbon dioxide removal; *ECMO,* extracorporeal membrane oxygenation; *FiO_2,* fraction of inspired oxygen; *HFO,* high-frequency oscillation; *iNO,* inhaled nitric oxide; *PaO_2,* arterial partial pressure of oxygen; *PEEP,* positive end-expiratory pressure. *(From Thompson BT: Problems with ARDS trials: Time for more splitting and less lumping?* Critical Care Canada Forum 2011. *Available at: http://www.criticalcarecanada.com/presentations/2011/ards_trials_time_for_more_splitting_and_less_lumping.pdf)*

mechanical ventilation. Some patients require prolonged and more gradual ventilator weaning, which may be best facilitated by tracheostomy placement. In addition, data from observational studies show that up to 60% of ventilator-dependent patients who are discharged from the ICU can be successfully weaned when they are transferred to specialized units dedicated to ventilator weaning.

TRACHEOSTOMY

- Some patients benefit from early tracheostomy, including those with traumatic brain injury and ARF for airway protection, and those who will require prolonged mechanical ventilation (i.e., patients with ARDS) for patient comfort.
- Previous studies suggested that tracheostomy was superior to prolonged intubation for VAP prevention. However, two recent, large, prospective, randomized clinical trials have found no difference in VAP or any other outcomes measures in comparing early (6-8 days) with late (13-15 days) tracheostomy in 419 patients or comparing early (4 days) with late (after 10 days) tracheostomy in 909 patients in the TracMan trial. Early tracheostomy should not be performed for VAP prevention but may be considered for other reasons, such as difficult airway and difficult-to-wean patients, particularly for patient comfort.

VENTILATOR-ASSOCIATED PNEUMONIA

Amy Rushing, MD

INTRODUCTION

Pneumonia, the most common nosocomial infection, remains a postoperative complication that prolongs hospital stay and increases mortality. Clinicians categorize pneumonia into multiple subtypes: community-acquired pneumonia (CAP), hospital-acquired pneumonia (HAP), and ventilator-associated pneumonia (VAP). Each condition has its own group of common bacterial pathogens; the latter two share multidrug-resistant organisms. This chapter focuses on ventilator-associated pneumonia, defined as pneumonia that develops 48 hours after endotracheal intubation. The incidence of VAP ranges from 9% to 27%, with the rate of occurrence at 1% to 3% per ventilator day. The mortality rate approaches 50% depending on an individual patient's clinical circumstances. In spite of the evolving sophistication of critical care medicine, VAP can be difficult to diagnose, leading to a delay in treatment of a potentially fatal infection. This, in addition to the ongoing antimicrobial resistance that pervades the intensive care unit (ICU), warrants a review of how to recognize and treat VAP, with special attention to selecting appropriate empiric antibiotic therapy and tailoring subsequent therapy to available culture data. The latter task is particularly important in prevention of further spread of multidrug-resistant bacteria, such as methicillin-resistant *Staphylococcus aureus* (MRSA) and the gram-negative organisms, *Pseudomonas aeruginosa* and *Acinetobacter baumannii*.

DIAGNOSIS

Diagnosis of VAP in the intensive care unit remains a challenge for clinicians because the classic signs and symptoms are nonspecific in nature. At present, the only modality that provides an absolute diagnosis is a lung biopsy that shows microbial invasion with inflammatory changes. Because this procedure is invasive and carries a high risk of potential complications, intensivists rely alternatively on a combination of findings and clinical acumen to obtain a diagnosis. Patients with development of new onset hypoxia, purulent sputum, and fever with leukocytosis or infiltrates on chest radiograph should

be evaluated for pneumonia. Some of these manifestations may occur with other conditions (acute lung injury, congestive heart failure, pulmonary embolus, and tracheobronchitis), so careful assessment of the patient with a high index of suspicion is important so as not to delay collecting cultures and starting empiric antibiotic therapy.

Culture collection remains a key element in the diagnosis and appropriate treatment of VAP. Some debate exists as to what method yields the most accurate microbiologic data that differentiate simple colonization from an actual infection. For some time, fiberoptic bronchoscopy with quantitative analysis of bronchoalveolar lavage (BAL) was thought to be one of the best techniques for diagnosis of pneumonia. Mueller and colleagues found that the preliminary culture results obtained from a BAL correlated well with final culture data when the quantitative threshold was defined as 10^5 cfu/mL or more. A separate study performed by Wood and colleagues compared this invasive technique with blind bronchial brushings and blind endotracheal aspirates and found no statistically significant differences in the reliability of culture data and each technique's ability to detect clinically relevant pathogens. The study's findings were substantiated by a Cochrane review that showed similar results where nonquantitative, transbronchial aspirates yielded similar results to quantitative, directed culture collection with similar clinical outcomes. With these data in mind, the clinician should consider patient tolerance for and patient comfort with a selected collection technique. The caveat to this concept is that directed quantitative cultures may be appropriate for patients who have already received antibiotic therapy during a prolonged ICU stay or who have immunosuppression.

With recognition of VAP as a diagnostic dilemma, Pugin and colleagues developed the Clinical Pulmonary Infection Score (CPIS) to aid clinicians in making a timely diagnosis. The score includes several clinical factors that can be determined at the bedside (Table 1). A CPIS of 6 or higher has been shown to predict significant pulmonary infection with a high sensitivity and specificity of 100% and 93%, respectively. The advantage of this system lies in the relative ease and rapidity of determining a score based on traditional signs and symptoms of VAP. CPIS has been endorsed by the American Thoracic Society and the Infectious Diseases Society of America as an aid to not only initiating empiric antibiotic therapy in patients with suspected VAP but also to determining initial clinical response to such therapy. Currently, a level I recommendation is that those patients who maintain a CPIS score of 6 or less after 72 hours of empiric antibiotic therapy should be evaluated for early discontinuation of such therapy. Although there is validity to this scheme, some have shown that it carries a much lower specificity and sensitivity and may not apply to certain patient populations. Parks and colleagues recently studied the value of the CPIS among a trauma population and found that it was inconsistent in determining resolution of VAP based on the threshold score of 6 or less. Specifically, they found the sensitivity and specificity of CPIS were 72% and 53%, respectively, among trauma patients who contracted hospital-acquired pneumonia. This work cautions clinicians that CPIS, although a potentially useful aid for bedside diagnosis, may not apply to patients who have sustained significant chest trauma or subsequent hypoxemia from transfusion-related acute lung injury (TRALI).

TABLE 1: Clinical pulmonary infection score

Diagnostic feature	0	1	2
Tracheal secretions	Rare	Abundant	Abundant and purulent
CXR infiltrate	None	Diffuse	Localized
Temperature (°C)	≥36.5 and ≤38.4	≥38.5 and ≤38.9	≥39.0 or ≤36.5
White blood cells ($\times 10^9$/L)	≥4.0 and ≤11.0	<4.0 or >11.0	<4.0 or >11.0 + bands ≥0.5
PaO_2/FiO_2 (mm Hg)	>240 or ARDS	—	<240 or no ARDS

ARDS, Adult respiratory distress syndrome; *CXR,* chest x-ray; *PaO_2/FiO_2,* partial pressure of oxygen in arterial blood/fractional concentration of oxygen in inspired gas.

TREATMENT

After the diagnosis of VAP is made, the next step lies in appropriate treatment of suspected organisms. Empiric antibiotic therapy is recommended to start as soon as VAP is clinically suspected, followed by rapid deescalation of therapy once the specific microorganism has been identified. Empiric therapy is determined based on the patient's ventilator length of stay (LOS). Patients who have had a ventilator LOS less than 4 days typically yield pathogens native to nasopharyngeal flora: methicillin-sensitive *S. aureus* (MSSA), *Haemophilus influenzae,* and *Streptococcus pneumoniae*. Late-onset VAP, defined as VAP that occurs in those with a ventilator LOS greater than 4 days, yields gram-negative and multidrug-resistant organisms: *P. aeruginosa, A. baumanii,* and *Stenotrophomonas maltophilia*. Representing approximately 25% of pathogens implicated in VAP, *S. aureus* remains the most common microorganism, with one half of the isolates expressing methicillin resistance. On the basis of these data, the American Thoracic Society published antibiotic recommendations for empiric treatment of VAP (Table 2). The initial treatment includes initiation of an antipseudomonal cephalosporin, carbapenem, or beta-lactam/beta-lactamase inhibitor in addition to an antipseudomonal fluoroquinolone or aminoglycoside and vancomycin or linezolid to cover MRSA. The combination of antibiotics should continue until a specific organism with its sensitivity has been identified or interval evaluation at 72 hours reveals a CPIS score of 6 or less.

Once the culpable pathogen has been identified, the duration of treatment can be determined. Historically, acceptable practice was treatment of VAP for 14 to 21 days. This concept, however, has changed with evidence that a shorter duration of antibiotic therapy provides ample treatment with less incidence of recurrent infection by multidrug-resistant organisms. A Cochrane review of studies

TABLE 2: Empiric antibiotic therapy for ventilator-associated pneumonia

Early onset VAP defined as ventilator LOS <4 d	Ceftriaxone, fluoroquinolone, ampicillin-sulbactam, or ertapenem ± macrolide
Late onset VAP defined as ventilator LOS >4 d	Antipseudomonal cephalosporin or antipseudomonal carbapenem or beta-lactam/beta-lactamase inhibitor + antipseudomonal fluoroquinolone or aminoglycoside + linezolid or vancomycin

LOS, Length of stay; *VAP,* ventilator-associated pneumonia.

looking at 1700 patients found that a limited 7-day to 8-day course of directed antibiotic therapy resulted in an increased number of antibiotic-free days and decreased the incidence of recurrent VAP by multidrug-resistant organisms when compared with a longer 10-day to 15-day course. The exception to these findings was noted among patients who were diagnosed with VAP resulting from nonfermenting gram-negative bacilli (NF-GNB). This particular subset of patients had a greater recurrence of VAP after a shorter antibiotic course. Thus, patients with development of VAP as a result of NF-GNB likely benefit from a longer course of therapy up to 2 weeks in duration. This conclusion was further validated by Magnotti and colleagues when looking at antibiotic duration based on interval quantitative BAL. Surveillance culture data collected during directed antibiotic therapy revealed that longer treatment courses were required for *P. aeruginosa* and MRSA and *A. baumannii*. Thus, clinicians should not only consider the patient's clinical progress but also the isolated microorganism when determining the duration of VAP treatment.

One NF-GNB that has emerged as one of the most challenging pathogens in VAP is *A. baumannii*. In the last decade, *A. baumannii* has developed multidrug-resistant isolates that have limited therapeutic options. In particular, carbapenem-resistant strains have led to the treatment of this pathogen with second-line agents that include polymyxin E (colistin) and tigecycline, an antimicrobial initially approved for complicated intraabdominal and soft tissue infections. Multiple studies have examined the efficacy of these two drugs, specifically aerosolized regimens of colistin that limit its known nephrotoxicity. Arnold and colleagues examined the use of adjunctive aerosolized colistin in the treatment of multidrug-resistant *A. baumannii* and found patients had a survival advantage despite a greater severity of illness. Further studies are needed to develop novel approaches to treat *A. baumannii* pneumonia given that current therapeutic interventions are limited and this robust organism carries a more significant mortality risk compared with other nosocomial pathogens.

One other pathogen that warrants discussion is MRSA. As previously mentioned, it is the most common isolate in VAP and carries a significant morbidity and mortality. Currently, two primary antibiotic options exist for the treatment of MRSA VAP: vancomycin and linezolid. Several trials have compared clinical efficacy of these drugs, and overall, the results vary. A meta-analysis of seven randomized trials performed by Kalil and colleagues showed no significant difference in clinical cure rates between the two antibiotics. Linezolid was associated with an increased risk of thrombocytopenia and adverse gastrointestinal effects. A more recent randomized double-blind trial performed by Wunderink and colleagues showed greater eradication of MRSA pneumonia with linezolid compared with vancomycin based on clinical and microbiologic endpoints. In spite of these findings, they found no difference in all-cause 60-day mortality between the two groups. At present, the recommendation endorsed by the American Thoracic Society is that either antibiotic may be prescribed to treat MRSA pneumonia and the choice is ultimately made at the clinician's discretion.

SUMMARY

Although VAP is quite common in the ICU setting, it still remains a clinical challenge to diagnose and treat. A high index of suspicion should lead to early culture collection and initiation of empiric antibiotic therapy because early treatment reduces mortality. Considering the patient's hospital LOS and one's own institutional antibiogram, empiric therapy should cover potential multidrug-resistant organisms with plans to stop certain antibiotics once culture data have been elucidated. Careful management of broad-spectrum antibiotics helps to slow the evolution of multidrug-resistant pathogens, as does limiting the duration of treatment to a 7-day to 8-day course for organisms other than NF-GNB. Although *A. baumannii* and MRSA continue to pose serious risks to patients in the ICU, clinicians can help limit further development of multidrug-resistant pathogens by following evidence-based guidelines in antibiotic administration.

Extracorporeal Membrane Oxygenation for Respiratory Failure in Adults

Robert J. Moraca, MD, and
George J. Magovern, MD

INTRODUCTION

Acute respiratory distress syndrome (ARDS), first described nearly in 1967, continues to be a major contributor to morbidity and mortality, as well as an important component of resource consumption, in the intensive care unit. The syndrome is the most serious manifestation of acute lung injury, which can develop from a wide range of direct pulmonary (aspiration, toxic inhalation, infection, near drowning) or extrapulmonary (disseminated sepsis, thoracic trauma, circulatory shock) sources. Ventilator management focuses on minimization of barotrauma and prevention of increasing levels of CO_2 retention. Standard ventilator strategies to limit development of pulmonary distention and promote recruitment of atelectatic alveoli include pressure-controlled ventilation, inverse-ratio ventilation, and low-frequency ventilation. Current mortality rates remain high and range between 40% and 100% in published reports, and the long-term pulmonary morbidity from ventilator-induced lung injury secondary to barotrauma is underreported. Veno-veno extracorporeal membrane oxygenation (VV ECMO) removes deoxygenated blood from the venous circulation, removes carbon dioxide, and oxygenates the blood and returns it to the right atrium and ventricle. Theoretically, VV ECMO is a logical approach to broker the competing problems of lung protection and effective gas exchange in ARDS because it separates these processes and allows control over the degree of native lung function. The use of VV ECMO has significantly increased since 2007 with the improvement in techniques and outcomes (Figure 1).

THE EXTRACORPOREAL MEMBRANE OXYGENATION SYSTEM

A typical ECMO system comprises a membrane oxygenator, heat exchanger, roller or centrifugal pump, circuit tubing, and catheters appropriate to the mode of access. A parallel circuit containing a second pump and oxygenator may be used to ensure efficient CO_2 removal at low-flow rates or to increase oxygenation at higher flow rates. In some systems a parallel circuit is included to minimize the effects of oxygenator complications and to facilitate oxygenator exchange. Heparin-bonded components are utilized where possible to decrease anticoagulation requirements and reduce the systemic inflammatory response to the circuit. Most systems maintain the circulating blood at normothermic temperatures, but slight hypothermia has been suggested to reduce oxygen consumption requirements with high metabolic demand or concern for cerebral injury.

Indications

VV ECMO should be considered in any adult patient suffering from acute onset and potentially reversible severe respiratory failure with significant hypoxia or hypercarbia despite maximal ventilator management. Although there are many causes of respiratory failure in adults, including pulmonary embolism, acute cardiogenic pulmonary edema, and hypercarbic respiratory failure, the most common etiology is ARDS. Although variations in the clinical definition of ARDS are common, the criteria established by the American-European Conference on ARDS are the accepted standard (Box 1). Several methods for grading the severity of ARDS have been developed, but the most commonly used is the Murray Score, which assesses four factors: extent of infiltration on chest film, degree of hypoxemia, level of positive end expiratory pressure (PEEP) required for oxygenation, and respiratory system compliance. A Murray Score of higher than 3 is generally accepted as an indication for consideration of VV ECMO in severe ARDS.

Contraindications

VV ECMO can be a life-saving tool for severe refractory respiratory failure when appropriate patients are selected. Absolute contraindications for VV ECMO include active intracranial hemorrhage, prolonged high pressure, FiO_2 ventilation greater than 10 days, metastatic malignancy with a short life expectancy, and severe baseline advanced respiratory failure without potential treatment options such as lung transplantation or lung volume reduction surgery. Premorbid conditions in patients considered for VV ECMO are very common, so each patient should be evaluated on a case-by-case basis, with attention to baseline function and comorbidities, duration of current illness, number of organ system failures, and overall prognosis. Young patients with few to no medical problems and isolated pulmonary system failure tend to have the best outcomes. In addition, daily multidisciplinary assessment for medical futility should be measured by the progression of illness, subsequent organ failure(s), and complications that may become a contraindication for continuing VV ECMO support.

Technique

The following are the well-accepted percutaneous approaches for the insertion of VV ECMO for respiratory failure:

1. Right femoral vein to the right internal jugular vein (Figure 2)
2. Right internal jugular vein and inferior vena cava (IVC) into right atrium with a three-port Avalon cannula (Maquet, Wayne, NJ) (Figure 3)

The goals of both of these approaches are to take deoxygenated blood from the IVC (see Figure 2) or IVC and superior vena cava (SVC) (see Figure 3), pass it through an oxygenator, and return it to the right atrium and right ventricle. Prior to placing VV ECMO, patients should have a central line in the left internal jugular or left subclavian vein as well as an arterial line. Telemetry monitoring during insertion is important, as multiple wires inserted into the right atrium in a hypoxic patient are prone to inducing arrhythmias. In the supine position, both groins to the knees bilaterally and the neck from the tragus to the sternal notch are prepped with an antiseptic. It is important to use sterile drapes that extend from the patient's feet to avoid contamination of the long wires used during insertion. It is our preference to access the right femoral vein, as the left femoral vein crosses behind the left common iliac artery, making insertion more difficult. Using ultrasound guidance, we identify and access both the right femoral vein and right internal jugular vein with a 0.038-inch × 210-cm guidewire and 0.038-inch × 100-cm guidewire, respectively. Once both wires, have been placed, a bolus 100 units/kg of heparin is given intravenously. The right internal jugular vein is serially dilated with 8F, 12F, and 16F dilators prior to insertion of 18F

BOX 1: Criteria for acute respiratory distress syndrome

1. Acute onset
2. PaO_2/FiO_2 of less than 200 mm Hg
3. Bilateral infiltrates on chest radiography
4. Pulmonary capillary wedge pressure less than 18 mm Hg and no clinical evidence of left ventricular dysfunction

Fem-Flex II femoral arterial cannula (Edwards, Irvine, Calif). Once inserted, the wire and dilators are removed, and the cannula is clamped. Either simultaneously or sequentially, the right femoral vein, accessed with a 0.038-inch × 210-cm guidewire, is serially dilated with 8F, 12F, and 16F dilators prior to inserting the 24F Fem Trak multiport femoral venous cannula (Edwards, Irvine, Calif). The wire and dilators are removed, and the cannula is clamped. The long venous cannula is premeasured to have the metal tip lie just below the right costal margin in the IVC. The VV ECMO lines are then brought onto the field and connected to the circuit. It is critical to ensure that no air bubbles are in the tubing during connection. Communication with the perfusionist is paramount to ensure that the *inflow* from the patient to the circuit is the femoral cannula and the *outflow* with oxygenated blood into the patient is through the right internal jugular vein into the right atrium (see Figure 2). Cannulas are secured in position with zero silk sutures at the insertion point and Foley catheter holders along the leg and behind the ear onto the chest. Transient desaturation after the institution of VV ECMO commonly occurs due to the transfer of pump prime into the circulation and should resolve within 1 to 2 minutes. Most patients will flow between 3.5 and 5 L/min with 2200 to 2800 revolutions per minute. The maximum inflow flow negative pressures should not exceed −100 mm Hg, and the maximum outflow pressures should not exceed −150 mm Hg. Initial ECMO settings are the oxygenator at 100%, and the sweep is set at 4 L/min. A chest and abdominal

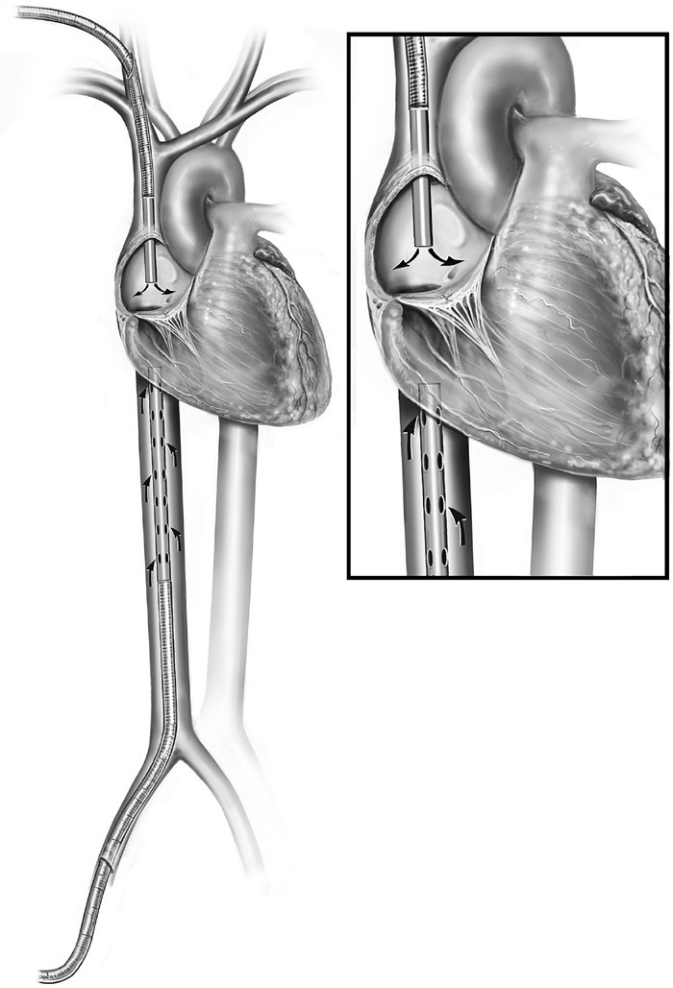

FIGURE 2 Right femoral venous to right internal jugular venous cannulation for veno-veno extracorporeal membrane oxygenation (ECMO). Inflow of deoxygenated blood through the inferior vena cava to the ECMO circuit, and the oxygenated blood is then returned into the right atrium.

radiograph are obtained to confirm cannula position, and a heparin infusion is begun to maintain partial thromboplastin time (PTT) between 40 and 50 seconds.

The Avalon cannula is a multiport single cannula placed in the right internal jugular vein with two ports: one for patient *inflow* from the IVC and SVC and the second for *outflow* from the right atrium (see Figure 3). Using ultrasound guidance, identify and access the right internal jugular artery with a 0.038-inch × 100-cm guidewire and serially dilated with 10F, 12F, and 16F dilators prior to inserting the cannula. It is imperative during insertion of the Avalon cannula that echocardiographic or fluoroscopic guidance is used to ensure that the introducer wire is in the IVC and not the right ventricle, as there have been several case reports of improper wire position and subsequent cannula insertion through the free wall of the right ventricle, with frequently fatal consequences. Once inserted, the wire and dilators are removed, and the cannula is clamped and connected to the VV ECMO circuit. The patient has *inflow* to the circuit from the IVC and SVC and *outflow* with oxygenated blood to the right atrium (see Figure 3). The cannula comes in multiple sizes ranging from 13F to 31F and should be selected based upon patient size and desired VV ECMO flow. The Avalon cannula has the advantage of an avoiding groin access with the rare potential for patient extubation and ambulation while on VV ECMO.

MANAGEMENT

A critical care nurse and an ECMO specialist (typically a perfusionist, respiratory therapist, or physician) should be assigned to provide 24-hour monitoring and care for the ECMO system and the patient on support. It is imperative that individual institutions develop their own protocols and certification of the team, including nurses, critical care physicians, and surgeons for ECMO circuit management.

Ventilator Management

The goal of VV ECMO is to minimize both barotrauma from hyperinflation and high airway pressure and to limit pulmonary oxygen toxicity. Following stabilization on VV ECMO, we typically set ventilators to assist control, tidal volume (TV) of 4 to 6 cc/kg, a maximum peak inspiratory pressure (PIP) of 30 cm H_2O, and a PEEP of 5 cm H_2O, oxygenation set at 100%, with a ventilator rate of 10. The ventilator FiO_2 is then weaned to maintain a PaO_2 greater than 60. In some circumstances, when the respiratory failure is severe, we will use pressure control ventilation. Baseline lung compliance is calculated (Compliance = TV/PIP-PEEP) and then measured daily to assess improvements in the respiratory system. VV ECMO flow rates are titrated to produce venous blood saturation of 80% to 85% and arterial saturation of greater than 90%. To optimize the oxygenation-carrying capacity in patients, we maintain hemoglobin greater than 10 to 12 g/dL. The sweep gas flow rate is adjusted to produce pCO_2 at 40 mm Hg. Patients with primary hypercarbic respiratory failure are maintained on low-flow ECMO (15-30 mL/kg/min) to effect carbon dioxide removal while providing maximum lung rest. It is our practice to wean the ventilator to normal settings and achieve a compliance of greater than 50 prior to VV ECMO weaning.

Systemic Anticoagulation

Systemic anticoagulation is maintained with continuous infusion of heparin to produce PTT of 40 to 50 seconds to reduce aggregation on the VV ECMO tubing and deposition on the membrane oxygenator. Aggressive correction of coagulopathy and prompt surgical response to bleeding sites can reduce bleeding complications to manageable levels in most patients. In patients with refractory bleeding and other contraindications for anticoagulation, we have successfully managed VV ECMO patients without anticoagulation.

Sedatives and Analgesia

The use of sedation and paralysis is based on patient requirements. In situations where agitation significantly elevates O_2 demand and movement impairs ventilation, reduces venous return, or risks accidental decannulation, both may be needed. Clinical assessments of sedation are made every 4 hours and documented, and sedation is adjusted as indicated. It has been our experience that significantly higher doses of sedation are needed due to reduced drug bioavailability from sequestration in the circuit, interaction with the PVC tubing, and loss of blood volume from the VV ECMO prime. Standard critical care protocols of daily sedation weaning are important to limit the prolonged use of high sedatives and especially paralytics in the ICU, which can have deleterious consequences.

Renal

An attempt should be made to aggressively diuresis the patient to dry weight or less to reduce and minimize the interstitial edema. In situations where renal function is compromised, the early use of continuous veno-veno hemofiltration (CVVH) is utilized to remove volume. This will help to reduce overall body edema and improve pulmonary compliance to facilitate lung recovery and VV ECMO weaning.

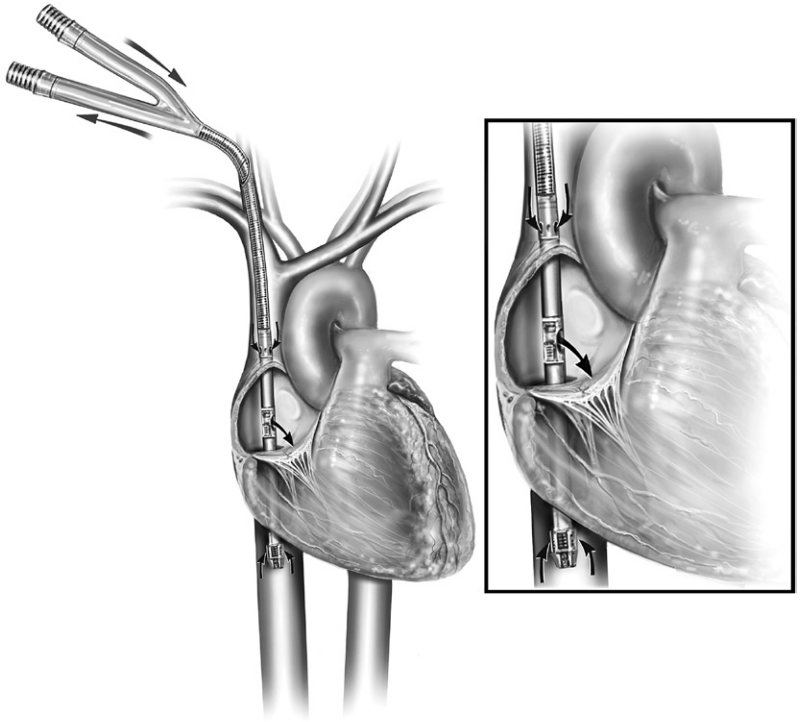

FIGURE 3 Avalon cannulation for veno-veno extracorporeal membrane oxygenation (ECMO). Inflow of deoxygenated blood through the inferior vena cava and the right internal jugular vein to the ECMO circuit, and the oxygenated blood is then returned into the right atrium.

Infection

Prophylactic antibiotics are given prior to insertion and discontinued within 24 hours, with further antibiotic or antifungal therapy directed to the underlying infectious illness. White blood cell count, C-reactive protein, and systemic vascular resistance are good predictors of ongoing infection. However, temperature may be unreliable while on VV ECMO because a significant amount of passive cooling occurs. Therefore, cultures are routinely performed while on VV ECMO. Activated protein C has a demonstrated survival benefit in severe sepsis, but its use with VV ECMO poses a serious bleeding risk.

TROUBLESHOOTING THE ECMO

Recirculation

Recirculation is a phenomenon that occurs when the inflow and outflow cannulas are too close together. Although not inherently dangerous, it reduces the efficiency of the VV ECMO circuit and may be a cause for persistent hypoxia. This can be assessed by visually examining the cannulas for appropriate color differential (the *inflow* to the circuit should be dark red and the *outflow* back to the patient should be bright red) and radiographic location of the cannulas (the metal tip of the femoral venous cannula on chest x-ray should be below the diaphragm). In addition, the PaO_2 of the *inflow* cannula should not be higher than the systemic PaO_2. When this does occur, repositioning the cannulas farther apart will solve the problem.

Superior Vena Cava Syndrome

SVC syndrome can occur in patients on VV ECMO due to mechanical obstruction of the SVC, typically with the right internal jugular VV ECMO cannula. It may occur rapidly after insertion or insidiously over the first several hours. Once it occurs, it is best managed by downsizing and exchanging the SVC cannula. Manipulation of the patient position to head-up is only a temporary measure. SVC syndrome is typically seen in smaller patients with a body surface area (BSA) less than 1.6 and in patients with significant hardware already lying in the SVC (pacemaker leads, indwelling dialysis catheters). It is important to obtain an echocardiogram and chest x-ray to ensure that cardiac misadventure with subsequent tamponade or pneumothorax is not the etiology.

Persistent Hypoxia

Some patients with severe respiratory failure may require maximal ventilator support in addition to maximal VV ECMO support for several days to weeks before any sign of recovery is seen. After ensuring proper ventilator and oxygenator function, strategies to address persistent hypoxia include systemic cooling to 33° F (to reduce metabolic demand), increasing hemoglobin to greater than 14 g/dL, and adding a second oxygenator in parallel.

Hemolysis

Heparin-bonded circuits and centrifugal pumps have greatly reduced the incidence of hemolysis to approximately 6% of patients, as reported in registry data. This complication is manifested by refractory anemia and elevated bilirubin and confirmed by elevated serum plasma free hemoglobin, lactate dehydrogenase, and decreased haptoglobin.

Thrombocytopenia

Thombocytopenia is a common problem with VV ECMO and is rarely caused by heparin-induced thrombocytopenia (HIT). Unless documented on serotonin release assay, direct thrombin inhibitors

are not routinely used. Patients with bleeding complications or persistent thrombocytopenia may be managed safely without heparin. Platelets are transfused as necessary to maintain the platelet count at higher than 25,000.

WEANING AND LUNG RECOVERY

The return of lung function is signaled by improving PaO_2 with the ability to wean the ventilator FiO_2, improving lung compliance, and reducing peak airway pressures. The ventilator is set to a TV of 7 to 8 cc/kg with PIP less than 35 mm Hg and a FiO_2 less than 60%. Then VV ECMO FiO_2 is weaned slowly over several days to maintain a systemic PaO_2 greater than 70. The FiO_2 of 21% is maintained for 24 hours with PaO_2 greater than 70, the heparin infusion is stopped, and the VV ECMO cannulas are clamped and removed at the bedside. Hemostasis is achieved with direct pressure for at least 30 to 45 minutes. In our experience, open surgical repair of the venous access site is rarely needed, even in cannulas that have been in for 4 to 6 weeks. The patient is maintained on the ventilator until a standard ventilator weaning process is instituted.

DISCUSSION

ECMO was first used successfully over 30 years ago and has become the standard of care for refractory respiratory failure in neonates and older children. Adult ARDS carries a mortality rate that can approach

100% in patients who are failing conventional treatment, and the care of these patients is expensive and resource intensive. Theoretically, VV ECMO support melds well with the needs of the ARDS patient: it provides excellent CO_2 removal, while reducing barotrauma and oxygenation demands on the potentially recoverable native lung. ECMO support is associated with significant comorbidity, particularly related to anticoagulation and bleeding, but these complications are usually manageable and occur at a rate that can be reconciled with the high mortality seen in untreated patients.

Etiologies for ARDS requiring VV ECMO are quite diverse (Figure 4). VV ECMO is rarely evaluated in a cohort consistent for diagnosis because these niche populations are usually too small for timely recruitment. Nevertheless, over the last decade, survival to discharge following VV ECMO appears to be stabilizing at around 50% for patients with respiratory failure without concomitant cardiac failure (see Figure 1). This appears to be related to the development of improved oxygenators and cannulas and the use of veno-veno rather than veno-arterial cannulation when cardiac support is not necessary. Use of heparin-bonded components in the ECMO circuit has not eliminated serious bleeding but has reduced the level of heparin infusion required to maintain an acceptable anticoagulation status.

Recognition of the role of ventilator-induced barotrauma in limiting the efficacy of mechanical ventilation has led to the development of less traumatic ventilator management approaches such as pressure-controlled and inverse-ratio ventilation. When used as a component of a standardized protocol, these methods can increase the number of patients who recover without transition to ECMO support and may also increase the recovery potential of the native lung in patients who progress to ECMO.

In summary, although the results of a robust randomized clinical trial in a well-defined patient population are awaited, there is evidence that VV ECMO can increase survival in patients with ARDS refractory to conventional therapy. Use of this technique, however, is appropriate only in conjunction with a well-constructed respiratory management protocol that is initiated at the time of ARDS diagnosis.

Tracheostomy

William D. Tobler, Jr., MD, and Suresh "Mitu" Agarwal, MD

INTRODUCTION

Tracheostomy is a commonly performed procedure by trauma/critical care surgeons, otolaryngologists, and pulmonologists. The term *tracheostomy* and *tracheotomy* are often used interchangeably. However, *tracheostomy* denotes the formation of a stoma, whereas *tracheotomy* defines the act of creating an opening in the trachea.

The first reports of open tracheostomies date back to Egypt circa 3600 BC, with the first elective procedures described by Asclepiades of Bithynia in 124 AD. Modern-day procedures were not specified until Chevalier Jackson provided a detailed description in 1909. In particular, he emphasized a long incision, good exposure, division of the thyroid isthmus, and avoidance of an incision near the first and second tracheal rings. Since that time, the advent of respiratory ventilators and further advances in the medical care of critically ill patients have increased the incidence of those undergoing tracheostomy.

In the 1980s, Pasquale Ciaglia popularized the percutaneous tracheostomy, which was first described in 1957. This technique is an alternative approach performed via sequential dilatation. This can be readily performed at the bedside, which prevents risks associated with transporting patients and concomitantly limits resources required to run an operating room.

INDICATIONS AND CONTRAINDICATIONS

The indications to perform a tracheostomy are many but include most commonly ventilator dependence, followed by airway obstruction, and to assist with pulmonary toilet (Table 1). The two absolute contraindications to performing a tracheostomy are a significant skin or soft tissue infection and conditions leading to distorted anatomy.

Timing

The appropriate timing to perform a tracheostomy remains an issue of debate. Some advocate performing a tracheostomy after 3 days of intubation, while others support waiting up to 3 weeks of ventilator dependence. When deciding to perform a tracheostomy, the most important, yet often most challenging, factor to determine is the expected length of time a patient will require ventilator support. The advantages of a stoma include improved patient comfort, decreased nursing care, lessened oropharyngeal ulceration, and better patient communication. Tracheostomy has also been shown to decrease the need for ventilator dependence in certain patient populations. In contrast, prolonged laryngeal intubation increases the risk of subglottic stenosis and should be avoided. At this current time there are no large prospective randomized trials that show improved long-term outcomes with early tracheostomy. The authors recommend performing tracheostomy within 7 days when the need for ventilator support is expected to be greater than 2 weeks.

TABLE 1: Indications for tracheostomy or cricothyroidotomy

Ventilator dependence	Facilitation of ventilation support Prolonged intubation
Airway obstruction	Anatomic abnormalities Angioedema Burns Failed intubation Infection leading to obstruction Laryngeal dysfunction Neck irradiation Neoplasm Neurologic dysfunction or injury Obstructive sleep apnea Postoperative Traumatic obstruction
Pulmonary toilet	Aspiration Excessive bronchopulmonary secretions

Open Tracheostomy

Elective open tracheostomies are usually performed under general anesthesia, but they can be completed with local anesthesia if a patient cannot be intubated. This is executed in the operating room under most circumstances but can also be performed safely at the bedside if adequate resources are available. When performed in the intensive care unit, the surgeon should make every effort to replicate the utilities of an operating room such as appropriate lighting, an open tracheostomy tray, and electrocautery.

The patient is placed in the supine position, and a shoulder roll is utilized for neck extension if cervical immobilization is not an issue. Next, the patient is prepped and draped from the nipple line to above the thyroid cartilage. Some advocate prepping inferiorly to below the xiphoid in preparation for the unlikely scenario of an emergent sternotomy. A 3-cm horizontal incision is made using a scalpel 2 cm above the sternal notch. A horizontal incision is recommended in elective cases because it follows Langer's lines and leaves a cosmetically appealing incision after decannulation. A vertical incision can also be performed, which transverses tension lines but also avoids injury to the anterior jugular veins. After incision, the subcutaneous tissue and platysma muscle are dissected bluntly with electrocautery. The sternohyoid and sternothyroid muscles are then encountered and retracted laterally with an incision made vertically through the linea alba. The next structure deep to the strap muscles is the thyroid isthmus. This can either be ligated using electrocautery or suture ligation. Once the thyroid isthmus is retracted, the pretracheal fascia should be cleared using sharp dissection. At this time, the important landmarks of the airway should be identified. Superiorly, the cricoid cartilage provides a marker for the first tracheal ring, which lies immediately caudad.

A cricoid hook is then employed to elevate the tracheal rings. Using a #11 blade, the surgeon makes a horizontal incision between the second and third tracheal rings. Placement superior to this increases the risk of subglottic stenosis, whereas inferior placement increases the risk for tracheoinominate fistula formation. Per surgeon preference, stay sutures can be placed on each ring above and below the incision. These allow identification of the tracheotomy in the event of an unanticipated decannulation. Similarly, a Bjork flap can be created by an H-type incision in the trachea and subsequently suturing the inferior tracheal mucosa to the skin. This flap is rarely created because it has been seen to result in delayed cutaneous closure of the stoma after decannulation.

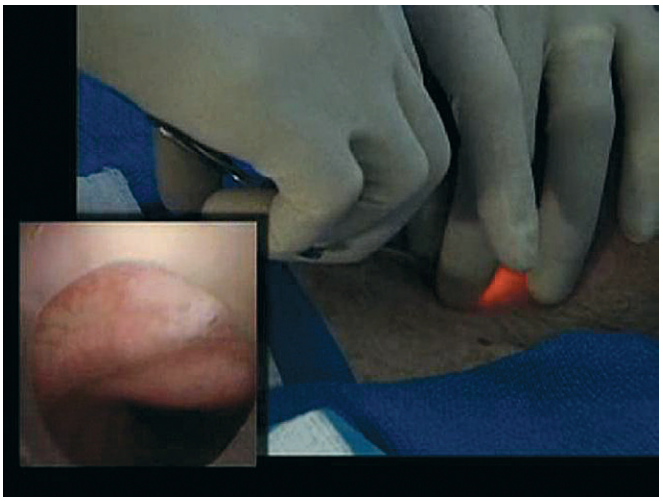

FIGURE 1 Palpation of the tracheal wall is visualized bronchoscopically to identify optimal placement.

At this point, the anesthesiologist retracts the endotracheal tube, and a Trousseau dilator is used to open the tracheal incision. The surgeon then places the tracheostomy into the airway under direct visualization. The cuff is inflated, and the ventilator is connected to the tracheostomy cannula. Similar to intubation, proper placement is verified by chest rise, bilateral breath sounds, and CO_2 confirmation. Lastly, the four corners of the tracheostomy neck plate are secured using 3-0 prolene sutures, and a tracheostomy tube tie is placed.

Percutaneous Dilatational Tracheostomy

Percutaneous dilatational tracheostomy utilizes the Seldinger technique to perform a minimally invasive approach that can be easily performed at the bedside. This requires two trained physicians: one who performs the tracheostomy and one who does a simultaneous bronchoscopy. The procedure is safe and successful, but an open tracheostomy kit should always be available at the bedside.

The patient is positioned, prepped, and draped as mentioned above for the open technique. The surgeon at the head of the bed performs a continuous bronchoscopy to visualize the airway and endotracheal (ET) tube placement (Figure 1). Occasionally, the ET tube needs to be retracted a few centimeters. A 1.5-cm incision is then made in the skin 2 cm above the sternal notch. Blunt dissection is performed through the subcutaneous tissue. The bronchoscope is then used for transcutaneous illumination to verify anticipated placement of the tracheostomy. At this point, a 14-gauge needle is inserted through anterior tracheal tissue into the tracheal lumen after the endotracheal tube has been pulled back to the level of the vocal cords (Figure 2). Once visualization of the needle is confirmed in the airway by bronchoscopy, a guidewire is placed through the catheter inferiorly toward the carina (Figure 3). The insertion needle is removed over the guidewire, and a series of well-lubricated dilators are passed to create a sufficient tracheotomy. There are several modifications of this system ranging from one tapered dilator to a series of multiple graduated dilatations (Figure 4). Recently a technique that allows for balloon dilatation of the trachea has been developed. Once adequate dilation is performed, the tracheostomy tube is threaded over the dilator and into the airway under direct visualization (Figure 5). Next, the bronchoscope is cannulated into the tracheostomy to confirm placement of the tracheostomy tip in the airway 3 to 5 cm above the carina. Once this is achieved,

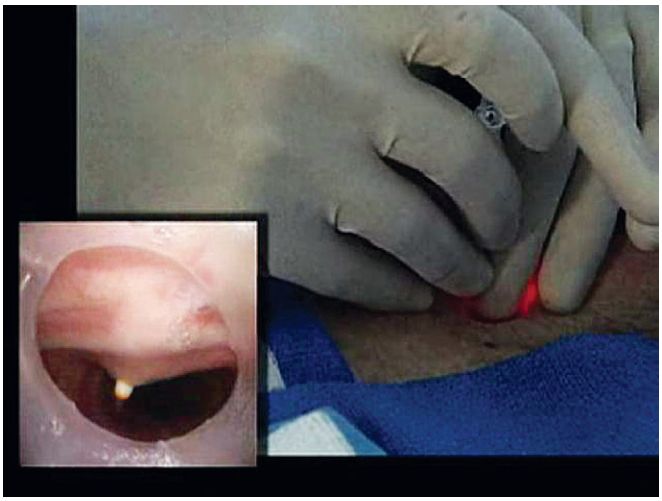

FIGURE 2 A 14-gauge angiocatheter is introduced into the tracheal lumen to place a guidewire.

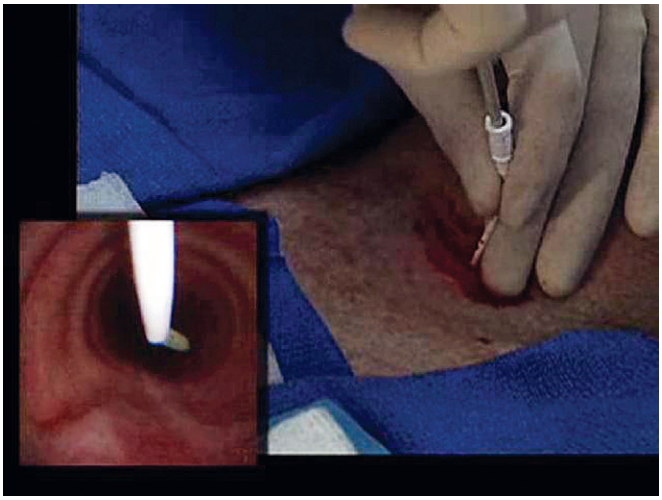

FIGURE 3 A guidewire is passed through the angiocatheter, and the angiocatheter is removed.

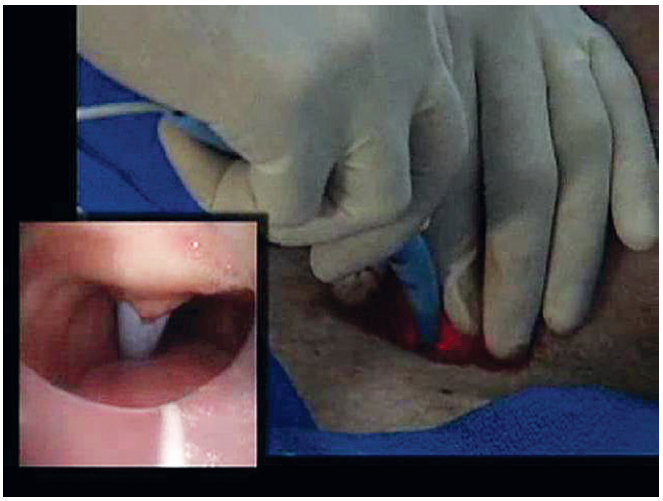

FIGURE 4 After a small punch is used to facilitate dilation, a single tapered dilator is introduced over the guidewire until the stoma is dilated to an aperture of 36 French.

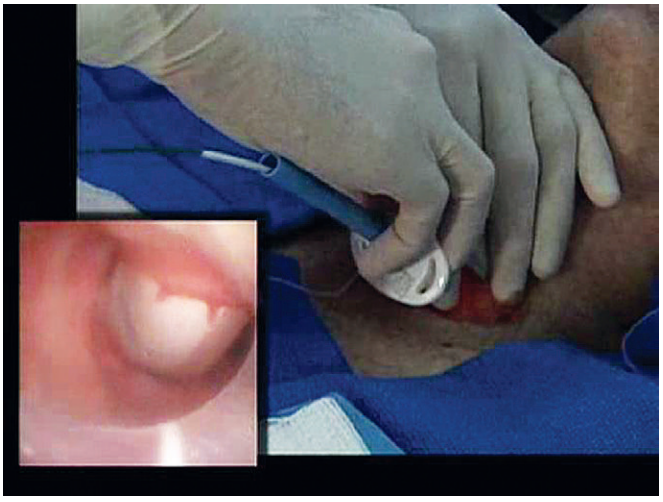

FIGURE 5 The tracheostomy tube is inserted over the guidewire.

the ventilator is connected and the ET tube is removed. A formal bronchoscopy may be necessary to remove blood, secretions, or debris. Tracheostomy placement is then confirmed and secured as described above.

Emergent Cricothyroidotomy

In the event that an airway must be obtained immediately and ET tube intubation has failed, an emergent cricothyroidotomy should be performed. In this situation, the cricothyroid membrane is identified between the thyroid and the cricoid cartilage. A scalpel is used to make a generous incision superficial to this area in a vertical fashion to avoid the anterior jugular veins. The soft tissue is then bluntly dissected. Once the cricothyroid membrane is identified, a horizontal incision is made through the membrane into the airway lumen. The back handle of the scalpel can assist to circumferentially dilate the opening. Once this is achieved, a tracheostomy tube or ET tube is placed directly into the airway. Confirmation is obtained by the measures stated above and the airway is secured with sutures. This is only a temporary measure if airway protection is still indicated. A formal conversion to tracheostomy should be performed once the patient has stabilized. Emergent tracheostomy is more difficult than cricothyroidotomy and should only be performed if the cricothyroidotomy will worsen the patient's condition (i.e., laryngeal fracture). See Figure 4 in the chapter on "Airway Management in the Trauma Patient."

Complications

Complications of tracheostomy are divided into early and late subsets. In the past, routine postoperative chest x-ray was recommended for surveillance, but this has largely been abandoned. Currently, chest x-ray is only indicated after technically difficult procedures or if the patient experiences clinical deterioration unresponsive to ventilator modification.

Early Complications

Early complications encompass intraoperative and postoperative complications that occur within 7 days. These include hemorrhage, pneumothorax, pneumomediastinum, subcutaneous emphysema, infection, airway fire, loss of airway (accidental decannulation), and

airway obstruction. Postoperative bleeding and pneumothorax are the most common early complications.

In order to avoid hemorrhage, all patients should have corrected coagulopathy before proceeding with tracheostomy. Minor bleeding occurs more frequently and is usually self-limited. If more substantial bleeding is encountered, then packing of the wound with hemostatic agents or suture ligation of superficial sources should be performed. The sources of this bleeding are most frequently from the skin incision, anterior jugular veins, thyroid isthmus, or thyroid ima artery. In the event that uncontrollable hemorrhage is encountered, the patient needs to be taken back to the operating room for a tracheostomy revision.

Pneumothorax can occur if the dome of the parietal pleura is penetrated. This can be managed by observation if the pneumothorax is small and the patient does not have respiratory failure. However, a chest tube thoracostomy will need to be inserted if the patient experiences acute respiratory failure or significant pneumothorax on chest x-ray. Pneumomediastinum and subcutaneous air usually resolve without intervention but should be monitored for improvement.

The remaining early complications occur infrequently. Avoiding electrocautery once the trachea is entered prevents airway fire. In the event of an airway fire, the procedure should be stopped and the ET tube replaced. Lastly, when the airway is compromised or obstructed, the source should be identified quickly. Airway obstruction often occurs from mucus plugging of the tracheostomy and malposition of the tube against the tracheal wall. Therefore, continued nursing care and caution when manipulating the tracheostomy are postoperative priorities. After accidental decannulation, the tracheostomy tube can be replaced through the stoma if the tract has epithelialized. However, if this proves difficult, then replacement through the stoma should be abandoned because of impending respiratory failure and the creation of false passages. The safest measure to take when dealing with airway compromise after decannulation or obstruction is to perform an oral-laryngeal reintubation.

Late Complications

Late complications occur after 7 days. These include laryngotracheal stenosis, fistula (tracheoinnominate and tracheoesophageal) formation, delayed stoma closure, tracheomalacia, and rarely vocal cord paralysis. Laryngotracheal stenosis results from infection and chondritis of the tracheal wall, leading to granulation tissue formation. This can be prevented by limiting incision size during the initial operation and postoperative tracheostomy care to prevent local infection and maintaining cuff pressures of less than 25 mm Hg. Stenosis can be treated with tracheal dilatation or surgical resection.

Fistula formation is a dreaded complication of tracheostomy placement. Tracheoinnominate fistula occurs by erosion of the tracheostomy tip through the tracheal wall and into the artery. Placing the tracheostomy above the fourth tracheal ring prevents this. If this complication is suspected, immediate pressure should be applied to the area, which can be achieved by hyperinflation of the cuff or by placing a finger directly through the skin incision inferiorly to compress the vessel against the sternum. Definitive repair needs to be performed in the operating room, but mortality remains extremely high. In addition, tracheoesophageal fistula occurs from direct injury to the posterior tracheal wall during the initial procedure or from erosion of the tracheostomy tube posteriorly. This can be stented but likely will require definitive operative repair.

The remaining complications are uncommon. Tracheomalacia and delayed stoma closure are the result of wound healing issues. Tracheomalacia occurs from ischemic insult to the tracheal wall and may require tracheoplasty if conservative measures fail. Delayed stoma closures occur when a patient has been decannulated after a prolonged period of time. If this is encountered, the tract can be surgically excised and closed primarily.

Tracheostomy Types, Postoperative Care, and Decannulation

In order to place a tracheostomy and take care of them in the postoperative period, it is important to know the various types of tracheostomy tubes because they come in various sizes and shapes. Today, most tracheostomies are made from synthetic plastic material, but in the past, they were made of metal. Initially, an 8-mm inner diameter tube with an 89-mm length should be inserted if patient anatomy permits. This allows for an open airway with minimal resistance and can be easily downsized when appropriate. Ideally the tip of the tube should be in the middle of the tracheal lumen 3 to 5 cm above the carina. Obese patients or patients with a longer neck may require an extended-length tube to prevent obstruction against the tracheal wall. Most tracheostomies are supplied with an inner cannula, which allows for easy removal in the event of mucus plugging or to block fenestrations before a patient is ready. Fenestrations are holes located on the tube of some tracheostomies. These allow air to pass around the tube in order to permit phonation. Because this affects air delivery to the lungs, patients should only have fenestrated tubes when stable and showing improvement in respiratory status. The last significant variable is the tracheostomy cuff. The cuff is an inflatable balloon that secures the tube within the airway, allows for positive pressure ventilation, and may prevent aspiration. Cuffs can cause necrosis of the surrounding tracheal wall, but this occurs less frequently when cuff pressure is less than 25 mm Hg. Once a patient is stable and respiratory status is improving, it is recommended to switch to an uncuffed tracheostomy tube.

In the postoperative period it is important to maintain a patent and clean tracheostomy with frequent nursing care. Suctioning can help decrease secretions, but there is a fine line between too much suctioning because this can cause trauma to the airway. Inner cannulas should be removed daily and cleaned, and the airway should be assessed for patency. The surrounding surgical site should also remain clean to prevent infection.

Patients can be considered ready for decannulation when safely off the ventilator for at least 48 hours and there are no future anticipated indications to be placed back on the ventilator. In addition, a patient must have few secretions before decannulation can proceed. Decannulation can occur at any time with any size tracheostomy. However, the usual course is to downsize the tracheostomy and trial a capped period of 24 to 48 hours. Downsizing and tracheostomy exchange can safely be performed after a stoma track is well formed—usually 7 to 10 days after the initial procedure.

SUMMARY

Tracheostomy is a common procedure, and the principles of placement and care should be in the armamentarium of any surgeon taking care of critically ill patients. Open and percutaneous tracheostomies have associated benefits and risks, so the performing surgeon should decide which to perform on a patient-by-patient basis. Tracheostomy is a safe procedure, but it has its own complications. Understanding the etiology of each complication will allow the surgeon to prevent their occurrences.

Acute Kidney Failure

Kenneth Waxman, MD, FACS

OVERVIEW

Alterations in renal function are common after surgical emergencies, trauma, and major operations. In these settings, successful recovery of renal function is dependent on prompt diagnosis and protective management strategies.

Acute kidney injury (AKI) is characterized by an acute decrease in glomerular filtration rate (GFR). The true incidence of AKI and acute renal failure (ARF) has been difficult to define, given the broad and various definitions used to quantify and study altered renal function. Relatively recent introduction of consensus definitions, such as RIFLE (risk, failure, loss, and end-stage renal failure) criteria and AKIN (Acute Kidney Injury Network) staging, have provided standard definitions to facilitate more uniform outcome reporting. With use of these definitions, recent studies suggest that AKI occurs in up to two thirds of patients in the intensive care unit (ICU). Moreover, increasing severity of AKI is associated with increasing mortality. AKI is also associated with increased morbidity, such as increased hospital length of stay and cost of care, and has been linked to other in-hospital complications, such as increased difficulty in weaning from mechanical ventilation. Preoperative risk factors for development of AKI include older age, emergent surgery, hepatic disease, obesity, high-risk surgery, vascular disease, and chronic obstructive pulmonary disease (COPD). Prompt recognition of AKI facilitates effective treatment. Although the incidence rate of AKI appears to be rising, overall outcomes from AKI are gradually improving.

DEFINITIONS

The RIFLE criteria (Table 1), defined in 2004 by the Acute Dialysis Quality Initiative (ADQI) Group, quantifies the severity of AKI. Studies by Hoste and colleagues and by Osterman and Chang found that mortality progressively increased with increasing RIFLE severity and that patients in all of the RIFLE classifications had higher mortality rates than those in the ICU without AKI.

In 2005, the AKIN also formulated consensus diagnostic criteria for AKI (Table 2). The AKIN definition of AKI is "an abrupt (within 48 hours) reduction in kidney function currently defined as an absolute increase in serum creatinine of either ≥0.3 mg/dL or a percentage increase of ≥50% (1.5-fold from baseline) or a reduction in urine output (documented oliguria of <0.5 mL/kg/hr for >6hrs)." These criteria can only be applied in the face of adequate fluid hydration. The AKIN staging system is arguably more inclusive than the RIFLE criteria. Chertow and associates found that an acute absolute change in creatinine of 0.3 or more was associated with increased mortality, length of stay, and cost of care. Barrantes and colleagues found that patients who met the AKIN definition of AKI were three times as likely to die during hospitalization.

In 2007, Coca and colleagues published a review and meta-analysis of eight studies that suggested that even smaller elevations in serum creatinine values than recommended in RIFLE and AKIN (on the order of 10% to 24%) were associated with a twofold risk of short-term death in several clinical settings; the Coca paper hypothesized that poor outcomes from AKI may in part result from delay in diagnosis caused by the lag time of serum creatinine testing.

DIAGNOSIS OF ACUTE KIDNEY INJURY

Comorbidities and potentially nephrotoxic medications should be identified. Identification of signs and symptoms suggestive of urinary tract obstruction is also important. Although physical examination in critically ill patients with AKI has been shown to be of limited accuracy, ascertaining clinical clues to patients' hemodynamic and volume statuses is essential.

Urinalysis with microscopy is useful in determination of the etiology of AKI. Presence of casts or other cells can suggest etiology. Red cell casts suggest glomerulonephritis or vasculitis, and white cell casts may raise the possibility of interstitial nephritis or pyelonephritis. "Muddy brown" casts and renal tubular epithelial cells are pathognomonic for acute tubular necrosis (ATN) and differentiate ATN from prerenal azotemia, which is characterized by normal sediment or occasional hyaline casts. Dark heme-positive urine without red blood cells (RBCs) on microscopy is diagnostic of rhabdomyolysis.

Distinguishing between prerenal azotemia and ATN, the two most common etiologies of AKI, is critical but not always simple. Aside from analysis of urine sediment, response to fluid repletion is frequently used in this distinction. Return to baseline of renal function in 24 to 72 hours after fluid repletion suggests prerenal etiology. Urine chemistries can also aid in the diagnosis. The fractional excretion of sodium (FeNa) measures the ratio of the sodium excreted to the sodium filtered by the formula:

$$\text{FeNa} = (\text{urine sodium} \times \text{serum creatinine}) / (\text{serum sodium} \times \text{urine creatinine}) \times 100$$

Prerenal azotemia is characterized by FeNa less than 1%, and FeNa more than 1% suggests ATN. However, FeNa may be spuriously low in patients with severe sepsis, heart failure, or cirrhosis, despite the presence of ATN. Conversely, FeNa may be falsely elevated in patients on diuretics, with glucosuria, or with preexisting renal insufficiency. In the case of diuretic use, the fractional excretion of urea (FEurea) has been shown to accurately distinguish between prerenal azotemia and ATN with the following formula:

$$\text{FEurea} = (\text{urine urea nitrogen} \times \text{serum creatinine}) / (\text{BUN} \times \text{urine creatinine}) \times 100$$

with *BUN* for blood urea nitrogen. Prerenal azotemia is indicated by FEurea less than 35% and ATN by FEurea more than 50%. Although of variable utility, other serum and urinary measures may also be used in aggregate to distinguish ATN from prerenal azotemia. These tests are summarized in Table 3, in order of general usefulness.

Serologic tests, such as antinuclear antibody, hepatitis B surface antigen, and antiglomerular basement membrane antibody, are useful for distinguishing the etiology of glomerular diseases. Elevated creatinine phosphokinase levels are seen with rhabdomyolysis.

BUN levels reflect the balance between urea production, metabolism, and excretion and frequently rise as renal function declines. Numerous nonrenal sources of BUN exist, including dietary protein intake, parenteral hyperalimentation therapy, catabolism of endogenous proteins, corticosteroid administration, and upper gastrointestinal bleeding. However, a recent study by Beier and colleagues suggests that elevation of BUN value is predictive of long-term mortality, independently of normal creatinine.

Most clinicians rely on changes in serum creatinine and BUN values as indicators of renal function because they are accessible and familiar. However, BUN and creatinine values can be misleading, as serum creatinine levels are influenced by nonrenal factors such as age, gender, race, body weight, muscle mass, protein intake, and drugs; accordingly, changes in creatinine values tend to lag behind actual alterations in GFR. BUN levels are influenced by nutritional intake and the degree of catabolism, independently of renal function. For

TABLE 1: RIFLE criteria

	S_{Cr} criteria	Urine output criteria
Risk	Increased 1.5×-2× baseline	<0.5 mL/kg/h for 6 h
Injury	Increased 2×-3× baseline	<0.5 mL/kg/h for 12 h
Failure	Increased >3× baseline *or* S_{Cr} >4.0 mg/dL with acute rise ≥0.5 mg/dL	<0.3 mL/kg/h for 24 h *or* Anuria for 12 h
Loss	Persistent renal failure for >4 wk	
ESRD	Persistent renal failure for >3 mo	

ESRD, End-stage renal failure; *RIFLE,* risk, injury, failure, loss, and end-stage renal disease; S_{Cr}, serum creatinine.

TABLE 2: Acute Kidney Injury Network staging system

Stage	S_{Cr} criteria	Urine output criteria
I	Absolute increase ≥0.3 mg/dL *or* Increased 1.5×-2× baseline	<0.5 mL/kg/h for 6 h
II	Increased 2×-3× baseline	<0.5 mL/kg/h for 12 h
III	Increased >3× baseline *or* S_{Cr} ≥4.0 mg/dL with absolute increase ≥0.5 mg/dL *or* Need for RRT	<0.3 mL/kg/h for 24 h *or* Anuria for 12 h

RRT, Renal replacement therapy; S_{Cr}, serum creatinine.

TABLE 3: Diagnostic indices that distinguish prerenal azotemia from acute tubular necrosis

Measurement	Prerenal azotemia	ATN
Urinalysis	Normal or hyaline casts	Muddy brown casts
Response to fluid repletion	Within 24-72 h	No response
FeNa	<1%	>1%
FEurea	<35%	>50%
BUN/creatinine ratio	20	10
Urine sodium (mEq/L)	<20	>30
Urine osmolality (mOsm/L)	>350	300

ATN, Acute tubular necrosis; *BUN,* blood urea nitrogen; *FeNa,* fractional excretion of sodium; *FEurea,* fractional excretion of urea.

these reasons, alternatives to serum creatinine and BUN values serve as more specific markers, earlier indicators, and better prognostic tools for kidney injury.

Belcher and associates reviewed one of the most promising of these markers, interleukin-18 (IL-18). A proinflammatory cytokine thought to be released by injured proximal renal tubules, IL-18 is both a mediator and biomarker of AKI and can be reliably measured in the urine. The authors cite research that identifies IL-18 as an early indicator of AKI, as a tool for distinguishing prerenal azotemia and hepatorenal syndrome (HRS) from ATN, and as a prognostic tool to predict mortality and viability of renal transplant.

Belcher and associates also discuss neutrophil gelatinase-associated lipocalin (NGAL), an acute-phase reactant indicative of inflammatory injury that is upregulated and released by proximal renal tubular cells within a few hours of tubular damage. Like IL-18, studies suggest that NGAL can be used as an early indicator, in the differential diagnosis, and as a prognostic tool for AKI.

Kidney injury molecule 1 (KIM-1) is a type 1 cell membrane glycoprotein only expressed by proximal tubular cells in response to injury. It is detectable in urine and has been shown to discriminate ATN from other causes of AKI and is also used as a prognostic tool, as it predicts outcomes.

Cystatin C is a cysteine protease inhibitor secreted by all nucleated cells and is freely filtered by the glomerulus. Although several studies suggest that serum cystatin C is superior to serum creatinine as a surrogate for GFR and thus better for the early detection of AKI, another study suggests urinary cystatin C may be better.

Liver-type fatty acid–binding protein (L-FABP) is an intracellular molecule found in the proximal renal tubules where it binds lipid peroxidation products. Although urinary levels of L-FABP may be affected by liver injury or systemic inflammation, they are largely determined by tubular injury.

RADIOLOGIC IMAGING

Renal ultrasound scan is an important test to differentiate the etiology of AKI. Use of ultrasound scan to determine kidney size and echogenicity, cortical thickness, and the presence or absence of hydronephrosis is convenient and noninvasive. The presence of a thin rim of decreased echogenicity ("renal sweat") may surround the kidneys in patients with kidney injury. The addition of color Doppler technology may also useful in the diagnosis of AKI. Measurement of the resistivity index (RI), an indicator of perfusion based on

measurement of flow at the level of the arcuate or interlobar arteries, may help differentiate between prerenal azotemia (normal RI), ATN (reduced RI), and postrenal obstruction (elevated RI). Another promising ultrasound technique for the diagnosis of AKI is contrast-enhanced ultrasound scan, which makes use of microbubble-based contrast agents to help quantify renal blood flow, which is often decreased early in the progression of AKI. Ultrasound scan is critical for the diagnosis of hydronephrosis, in which it is more than 95% accurate in detecting dilation of the collecting systems and renal pelvis. A postrenal obstructive cause of AKI is suggested when hydronephrosis is present bilaterally. Assessment of bladder volume with ultrasound scan is important in the case of bilateral hydronephrosis. A postvoid residual volume greater than 150 mL is suggestive of bladder-outlet obstruction, and if it is observed in the presence of a urinary catheter, catheter malfunction should be considered. If ultrasound scan results are negative, computed tomographic (CT) scan may be necessary to elucidate the etiology of obstruction, such as obstructing stones or pelvic mass.

MEDICATION REVIEW

Thorough investigation of medications and ingestions is essential in determining the etiology of AKI. Certain medications can elevate serum creatinine levels without affecting GFR, leading to misdiagnosis of AKI. The drugs cimetidine and trimethoprim do this by blocking tubular creatinine secretion, and several drugs and substances interfere with the creatinine assay. The drug tenofovir disoproxil fumarate, used in the treatment of HIV/AIDS, has been shown to elevate serum creatinine levels without affecting measured GFR by an undefined mechanism.

A number of medications and substances can induce AKI (Table 4). The use of nephrotoxic agents should be limited when possible, especially in the presence of shock and decreased renal blood flow. If AKI is already present, medication doses must be adjusted to avoid toxicity.

DIFFERENTIAL DIAGNOSIS

Prerenal Azotemia

Prerenal azotemia is caused by decreased renal perfusion. This can occur as a result of decreased cardiac output for any reason, an absolute decrease in extracellular fluid volume (i.e., hemorrhage, gastrointestinal losses, burns), a decrease in the effective circulating volume (i.e., heart failure, portal hypertension), or shifting volume out of the intravascular space (i.e., third spacing). Prerenal azotemia is reversible if treated early and aggressively with fluid resuscitation, improvement in cardiac output, or correction of the third-space defect. If untreated, however, hypoperfusion of the kidney leads to tissue ischemia and cell death, resulting in progression to renal injury.

Abdominal compartment syndrome has increasingly been recognized as an important cause of prerenal azotemia. High intraabdominal pressures (>20 mm Hg bladder pressure) result in renal venous hypertension, which can lead to renal hypoperfusion and oliguria. If the condition is detected early, medical management with fluid resuscitation may be effective. However, early decompressive laparotomy is usually necessary for definitive reversal of abdominal compartment syndrome; immediate reversal of prerenal azotemia often results.

TABLE 4: Medications associated with direct and indirect nephrotoxicity

Direct nephrotoxicity				Indirect nephrotoxicity		
ATN	*Osmotic Nephrosis*	*Interstitial Nephritis*	*Glomerular Injury*	*Decrease in Intrarenal Blood Flow*		*Volume Depletion*
Iodinated Contrast	Hypertonic Solutions	NSAIDs	NSAIDs	Crystal Deposition (Intrarenal Obstruction)	Retroperitoneal Fibrosis (Ureteral Obstruction)	Diuretics (Loop, Mannitol, Thiazide)
Aminoglycosides	IVIG	Beta-lactams	Zoledronate	Indinavir	Ergotamine	
Amphotericin B		Quinolones	Pamidronate	Sulfadiazine	Sotalol

Hetastarch						
Mannitol						

ATN, Acute tubular necrosis; *IVIG,* intravenous immunoglobulin; *NSAIDs,* nonsteriodal antiinflammatory drugs; *PPIs,* proton pump inhibitors.

Postrenal Azotemia

Postrenal azotemia occurs from obstruction of urinary flow at any point in the urinary tract from the renal collecting system to the level of the urethra. Increased backflow builds pressure and decreases filtration. This type of azotemia can be caused by prostatic disease, neurogenic bladder, obstruction of an in-dwelling urinary catheter, abdominal or pelvic tumors, adhesions from prior surgery or radiation, vesicoureteral reflux, ureteral or bladder stones, medications that cause crystals or fibrosis, or myeloma light chains (in multiple myeloma). The obstruction must be corrected to resolve the azotemia. Complications of postrenal azotemia include urinary tract infection from urinary stasis, hyperkalemia caused by impaired excretion, and rarely, postobstructive diuresis marked by significant diuresis that leads to hypotension.

Intrinsic Renal Disease

Intrinsic renal disease results from injury to the parenchyma of the kidney, including the glomeruli, the interstitium, and the renal tubules.

Glomerular Disease

Glomerular disease is classified as nephritic or nephrotic and can have an acute or insidious onset. Nephritic syndrome is characterized by hematuria, proteinuria, hypertension, and edema from pores in the glomeruli allowing leakage of red blood cells and protein into the urine. Etiologies include bacterial endocarditis, systemic lupus erythematosus (SLE), poststreptococcal glomerulonephritis, hepatitis B antigenemia, immunoglobulin A (IgA) nephropathy, and hepatorenal syndrome.

The hallmark of nephrotic syndrome is marked proteinuria with minimal hematuria and anasarca. Frequently, the diagnosis of nephrotic syndrome requires renal biopsy. Etiologies include minimal change disease (MCD), focal segmental glomerulosclerosis, and membranous nephropathy.

Interstitial Disease

Many conditions that affect the renal interstitium have been recognized, including allergic, drug-induced, infectious (bacterial, viral, fungal, parasitic), autoimmune (SLE, Sjögren's disease, Goodpasture syndrome), infiltrative (lymphoma, sarcoid), and idiopathic forms of disease. The most common etiology of acute interstitial nephritis (AIN) is a drug-induced disease; it is thought to underlie 60% to 70% of cases. Illicit drugs, penicillins, cephalosporins, sulfonamides, and nonsteroidal antiinflammatory drugs (NSAIDs) are some of the most common offenders. AIN can cause fever, rash, eosinophilia, and eosinophiluria; however, none of these are reliably diagnostic. Kidney biopsy is the gold standard of diagnosis but is rarely needed. Timely discontinuation of the offending agent is usually effective treatment. The use of steroids in drug-induced AIN is controversial, but a recent study suggests that early administration of steroids (within 2 weeks) may prevent long-term sequelae.

Hyperuricemia, hyperuricosuria, and hyperphosphatemia, seen in tumor lysis syndrome, can cause deposits of crystals in the renal interstitium and tubules, leading to AKI. Similarly, ingestion of oral sodium phosphate solutions in bowel preparations for colonoscopy has been recognized as a cause of AKI resulting from crystal deposition. Allopurinol and rasburicase have been used for the prevention and treatment of tumor lysis syndrome.

Tubular Disease

Acute tubular necrosis was originally thought to be caused by a period of ischemia followed by reperfusion causing extensive necrosis. More recently, investigators have clarified the role of endothelial dysfunction, systemic inflammatory mediators, and oxidative stress in causing AKI. With this in mind, the term ATN currently is more often used to describe a clinical situation with adequate renal perfusion to largely maintain tubular integrity but not enough to sustain glomerular filtration. This is particularly true in the case of sepsis and shock of any etiology.

ATN is also caused by toxins, most commonly the aminoglycoside antibiotics. Other toxins that cause ATN include platinum, antifungals, rhabdomyolysis, hemolysis, and radiographic contrast, to highlight a few (see Table 4). Risk factors for ATN include volume contraction, age, and concomitant use of other nephrotoxins. Prevention of ATN is focused on achieving euvolemia while maintaining renal perfusion and avoiding further renal insults.

Rhabdomyolysis is caused by massive breakdown of muscle, with release of myoglobin, which can result in ATN. Rhabdomyolysis can be precipitated by drugs (heroin, cocaine, statins, alcohol), multiple trauma, crush injuries, seizures, muscle compression, and extreme exertion.

Contrast-induced nephropathy (CIN) is an acute decline in renal function seen after administration of intravenous radiographic contrast, specifically, an increase in serum creatinine of 25% above baseline or absolute increase of 0.5 mg/dL within 48 hours after administration of parenteral contrast. Although not well understood, it is likely the result of several factors. Transient hypotension from osmotic diuresis, vasoconstriction of glomerular vessels, and direct cytotoxic effect have been hypothesized. CIN is the third most common cause of hospital-acquired renal injury and is most prevalent among those with underlying renal disease.

Nephrogenic systemic fibrosis (NSF) is a recently diagnosed disease that occurs in patients with preexisting stage IV and V chronic kidney disease or acute renal failure that has been linked to intravenous administration of gadolinium-based contrast media for magnetic resonance imaging (MRI). Shortly after exposure to gadolinium (2 to 12 weeks) patients have development of skin thickening and fibrosis, similar to scleroderma, and can have rapid progression to joint contractures and severe disability. Systemic involvement may occur, leading to cardiomyopathy, pulmonary fibrosis, pulmonary hypertension, diaphragmatic paralysis, and death. The pathophysiology of the disease still remains unclear, but recent studies have shown gadolinium deposits in tissues of patients diagnosed with nephrogenic systemic fibrosis. Currently, prevention of NSF entails avoidance of gadolinium administration in this population. Several treatment options (steroids, intravenous immunoglobulin [IVIG], ultraviolet light, renal transplant) have been studied and have some benefit, but the evidence is based on small case studies or case reports and further evaluation is needed.

RENAL PROTECTIVE STRATEGIES

Prevention of Contrast-Induced Nephropathy

Contrast-induced nephropathy has historically been a common cause of AKI. Low-volume nonionic low-osmolar or isoosmolar contrast media are now clearly associated with a significantly lower incidence of CIN than high-osmolar agents that were commonly used in the past. For this reason, older high-osmolar contrast agents should be avoided.

Volume expansion is the primary prevention of CIN. Patients who receive fluid administration before radiologic studies have a lower incidence of nephropathy. However, the optimal choice of fluid has been controversial. Several meta-analyses of isotonic sodium bicarbonate show benefit over isotonic saline solution; however, a recent randomized controlled trial (RCT) suggested no difference between the two fluids, both of which were beneficial in preventing CIN.

N-acetylcysteine (NAC) is a free radical scavenger that has been shown in some studies to decrease the incidence of CIN compared with both placebo and saline solution alone. However, more recent studies showed no benefit to NAC in the prevention of CIN. Despite an unproven benefit, because it is safe and inexpensive, NAC is often used as part of a preventive regimen, in addition to volume expansion.

Other Preventive Strategies

The most important priority in renal protection is to maintain renal perfusion. Fluid choice, specifically crystalloid or colloid, for this purpose has been controversial. The landmark SAFE (Saline versus Albumin Fluid Evaluation) study compared saline solution and albumin and found no differences in the need for dialysis or survival between the two groups.

The use of synthetic colloids for volume expansion has been questioned because of studies implicating an increased risk of renal dysfunction. An increased risk of AKI was shown by a recent systematic review of the use of hydroxyethyl starches in patients with sepsis.

When fluid resuscitation is administered in critically ill patients, the amount given is of paramount importance. In general, early and aggressive fluid resuscitation has been associated with a lower incidence of AKI and better survival, particularly after trauma and sepsis. However, an observational study in patients with AKI reported increased mortality associated with a positive fluid balance, and an RCT in patients with acute lung injury reported fewer ventilator days with conservative fluid management, which did not increase the need for renal replacement therapy (RRT). The likely explanation for these conflicting results is that the need for fluid therapy changes during the time course of shock, with aggressive fluid administration essential in early prevention and resuscitation and more measured fluid administration optimal later in the course of AKI.

Erythropoietin (EPO) has shown some promising nonerythropoietic properties, including tissue protection and antiapoptotic effect in animal models of brain, heart, and kidney. Despite preclinical data that show protective effects in AKI, the EARLYARF (early acute renal failure) RCT in humans did not show benefit in EPO administration. However, proponents of EPO cite the use of poorly validated biomarkers, among other flaws in study design that may have been responsible for the apparent failure.

The use of diuretics, such as mannitol and furosemide, in the prevention and treatment of AKI has not been found to shorten the duration of AKI, reduce the need for RRT, or improve overall outcomes. Mannitol has proven beneficial in preventing ATN in patients after renal transplant and after severe crush injury. In a recent study, high-dose furosemide showed a protective effect on mortality in patients with acute lung injury but no significant effect after adjustment for post-AKI fluid balance.

Atrial natriuretic peptide (ANP) dilates afferent glomerular arterioles and constricts efferent glomerular arterioles and may selectively increase GFR. It has also been reported to inhibit agents that reduce renal blood flow. Although a recent RCT shows promising results in reducing the need for dialysis in cardiac surgery patients, prior studies did not show any benefit of ANP. Further studies are needed before its use can be recommended.

Dopamine at low doses increases renal perfusion and GFR; for this reason, dopamine has been evaluated for its role in renal protective strategies. Despite numerous studies on this subject, none have yielded evidence to support the usefulness of dopamine in AKI.

Fenoldopam, a dopamine-1 receptor agonist used in hypertensive emergencies, has been shown at its lowest dose to increase renal blood flow. In a recent meta-analysis of 16 randomized trials in critically ill patients with AKI, fenoldopam appears to reduce both mortality and need for RRT.

A promising study by Heemskerk and associates reports a significant decrease in plasma creatinine after an infusion of alkaline phosphatase (AP) in patients in intensive care with severe sepsis or septic shock. The authors propose that exogenous AP attenuates production of nitric oxide (NO), a systemic vasodilator that causes compensatory renal vasoconstriction, by inhibiting inducible nitric oxide synthase (iNOS), an enzyme that catalyzes production of NO. Reduction in NO may protect renal function; however, larger trials are needed to determine the presence of morbidity or mortality benefit.

Other agents evaluated for potential use in prevention of CIN or ATN include theophylline and prostaglandin E1. Both have shown promising but conflicting results; further study is needed before their use is recommended.

TREATMENT

Both hyperglycemia and hypoglycemia during the perioperative period or during critical illness correlate with adverse renal outcomes. Several studies suggest that aggressive glucose control is associated with decreased incidence of AKI and reduced need for RRT and may be protective of renal function in critically ill surgical patients. However, the largest and most recent RCT that compared intensive insulin therapy with conventional glucose control found no difference in need for RRT. Lung protective ventilation has become a mainstay in the treatment of adult respiratory distress syndrome (ARDS) as a result of the ARDSnet trial, which also suggested that the low-volume ventilation may be beneficial for the kidney as well. High-volume and high-pressure ventilation have been reported to contribute to AKI.

Renal Replacement Therapy

RRT remains the mainstay for treatment of severe AKI. Approximately 4% of critically ill patients with development of AKI go on to need RRT. However, consensus on best practice in regards to initiation, dose, and modality of RRT has not been established.

Timing of Initiation of Renal Replacement Therapy

Accepted indications for initiation of dialysis include severe acidemia, severe hyperkalemia, ingestion of a dialyzable substance that causes renal injury, volume overload in the presence of oliguria, and clinically apparent signs of uremia. Evidence suggests that there is benefit to early initiation of RRT in AKI; however, the literature is confounded by variable definitions of early and late, and differing indications for initiation of RRT. Continued studies are needed to further define when RRT is best initiated.

Frequency and Rate of Renal Replacement Therapy

Currently, wide variations are found in clinical practice in the frequency of RRT. Current studies have conflicting conclusions. A multicenter trial that studied outcomes related to dose of renal support was the Acute Renal Failure Trial Network (ATN) Study. This study assigned patients with hemodynamically stable conditions to the intermittent hemodialysis (IHD) group and patients with hemodynamically unstable conditions to continuous renal replacement modalities. The intensive management strategy underwent IHD 6 times per week or continuous therapy at 35 mL/kg/h. The less intense management strategy underwent IHD 3 times per week or continuous therapy at 20 mL/kg/h. No significant differences were seen between treatment groups in 60-day survival or renal recovery. To date, studies have not defined best practice guidelines for the frequency of RRT.

Modalities for Renal Replacement Therapy

Peritoneal dialysis (PD) is a simple but limited method for clearance of solute and ultrafiltration. Patients must have intact peritoneal cavities for PD to be effective, which is often not the case in critically ill surgical patients. PD has the advantage of being well tolerated hemodynamically, but the dialysate fluid increases intraabdominal pressure and thus can compromise respiratory status. Nonetheless, PD remains a useful option for selected patients with AKI.

Ultrafiltration (UF) is a technique that allows rapid removal of volume without significant solute removal. The ability to regulate the rate of UF allows titration to maintain intravascular volume and therefore maintain hemodynamic stability. UF has the primary application of treating volume overload in the presence of oliguria.

IHD is the most frequently used method for RRT in the United States. This method uses a semipermeable biocompatible synthetic membrane and an electrochemical gradient maintained with continuous dialysate flow to remove solute. The major benefit of IHD is rapid removal of solute. However, intravascular volume removal is frequently limited by hypotension. Another frequent drawback is hypoxia during treatment.

Continuous renal replacement therapies (CRRTs) are the most common methods for RRT internationally but are used less frequently in the United States. Continuous therapies use hemofiltration, a technique that, like ultrafiltration, removes volume but also has equal removal of solute as a result of the high permeability of the membrane used. In this case, solute clearance is dependent on volume filtered, and because the volume filtered is substantial, replacement fluid is infused continuously to avoid hemodynamic instability. Hemodiafiltration adds a dialysate flow to supplement hemofiltration clearance. Whether this addition adds benefit to hemofiltration alone is unclear.

Continuous venovenous hemofiltration (CVVH) and continuous venovenous hemodiafiltration (CVVHDF) are two frequently used methods of CRRT that have been evaluated and compared with IHD. These continuous methods were initially thought to be safer for patients with hemodynamically unstable conditions and more physiologic and thus better for the critically ill. However, studies to determine the optimal method of RRT have yielded contradictory results. In a recent meta-analysis of nine randomized trials, Bagshaw and colleagues found no difference in mortality or renal recovery between continuous and intermittent modalities.

Hybrid therapies also exist but have not yet been evaluated by prospective randomized trials. The most common hybrid modality is slow low-efficiency dialysis (SLED). SLED is a technique that is based on the observation that slower flow and longer treatments of IHD improve hemodynamic stability. SLED is sometimes performed over 8 to 12 hours nightly, avoiding typical daytime interruptions (procedures, radiology, surgery) and allowing for daytime mobilization.

Currently, many questions regarding the optimal choices for RRT remain unanswered; there are no evidence-based best practice guidelines. However, RRT clearly plays an essential role in the support of patients with AKI. A variety of techniques are available, all of which appear to be effective. RRT therapy should currently be selected based on institutional experience and expertise, and individual patient tolerance.

PROGNOSIS

The reported mortality rate of AKI is 30% to 60%. If RRT is necessary, reported mortality rates are over 50%. The reason for such high mortality is that AKI now usually occurs as part of a spectrum of multiple organ failure, most often associated with severe sepsis or septic shock. The mortality in this setting is often determined by the underlying septic syndrome, rather than by complications of individual organ failure. Of surviving patients of AKI, a significant number have development of chronic renal insufficiency, which necessitates chronic dialysis. The precise rate of development of chronic renal failure varies greatly in the literature, depending on the patient populations. A recent review of AKI estimates that overall, the risk of necessary chronic dialysis is approximately 12%.

ELECTROLYTE DISORDERS

Randall S. Friese, MD

OVERVIEW

A thorough understanding of fluid and electrolyte homeostasis is essential for the practitioner managing the surgical patient. The human body consists mostly of water. Body water composition is influenced by multiple factors, including age, gender, lean body mass, and degree of metabolic stress (trauma, surgery, and critical illness). Additionally, specific fluid and electrolyte concentrations are required to support normal cellular function. Neuronal impulse transmission, transmembrane action potential generation, skeletal muscle contraction, oxidative phosphorylation, and hormone release are examples of essential cellular mechanisms dependent on electrochemical gradients.

Fluid and electrolyte hemostasis is important in maintaining these electrochemical gradients, and this homeostasis can be perturbed by infection and injury, as well as excessive fluid losses or fluid administration. Most important, it should be recognized that

abnormal fluid and electrolyte concentrations affect all organ systems simultaneously. Appropriate diagnosis and treatment of fluid and electrolyte imbalances are vital in the care of the surgical patient.

SODIUM

Homeostasis

The cell membrane plays an important role in determining the distribution of total body water (TBW) across the intracellular and extracellular compartments. Water within the cell constitutes the intracellular fluid (ICF) compartment. Water within the interstitial space and intravascular space (plasma) constitutes the extracellular fluid (ECF) compartment. Free water will distribute across these compartments based on its concentration gradient (osmosis), which in turn is dependent on the amount of solute in each compartment. In an adult, body water constitutes 50% to 70% of TBW; the remaining proportion is composed of lipid and other non–aqueous-based materials (Figure 1).

The sodium/potassium pump, a transmembrane protein, maintains a high extracellular sodium concentration (low intracellular sodium levels) and a high intracellular potassium concentration (low extracellular potassium levels; Table 1). Thus, by controlling solute distribution across these compartments, the sodium/potassium pump is essential in moderating the distribution of body water. Additionally, since sodium is the main solute in the extracellular compartment (interstitial space and plasma), it is the major determinant of tonicity and osmolality.

Measurements of osmolar concentration and osmotic activity are often expressed in osmolarity and osmolality. Osmolarity is a measure of the amount of solute per liter of solution. Since the volume of solution is altered by changes in temperature and pressure as well as by the amount of solute added, osmolarity is difficult to determine. Osmolality is a measure of the amount of solute per kilogram of solvent, commonly water. Since the amount of solvent will remain constant regardless of changes in temperature and pressure, osmolality is easier to evaluate and is more commonly used. Tonicity describes solutions' osmotic activity relative to each other. Based on the amount of dissolved solute, one solution is either hypotonic (less solute), isotonic (similar amount of solute), or hypertonic (more solute) relative to another.

Plasma osmolality, normally 275 to 290 milliosmole per kilogram of water (mOsm/kg H_2O), is regulated by tight control of water intake and output. Osmolality is measured by osmoreceptors located in the supraoptic and paraventricular nuclei of the hypothalamus. In an increased osmotic state (depleted ECF volume), free water leaves the cytosol and these cells shrink, stimulating the release of arginine vasopressin (antidiuretic hormone [ADH]) from the posterior pituitary. ADH results in an increased permeability of water in the renal collecting tubules, causing water retention and an increase in ECF volume. ADH will also stimulate thirst, thereby increasing water intake (and ECF volume) in the conscious patient. With this increase in ECF volume, the increased osmotic state is reversed. Conversely, in a decreased osmotic state (expanded ECF volume), ADH and thirst are suppressed; this results in decreased fluid intake and increased renal water loss.

Total body sodium levels are regulated by the kidney through the renin-angiotensin-aldosterone axis and circulating B-type natriuretic peptide. However, sodium concentration is determined by changes in TBW. Alterations in sodium levels occur to support and maintain plasma volume and tissue perfusion, not sodium concentration. Most disorders of sodium concentration are secondary to abnormal water balance; therefore, an assessment of circulating volume status is always one of the earliest steps in assessing serum sodium disorders.

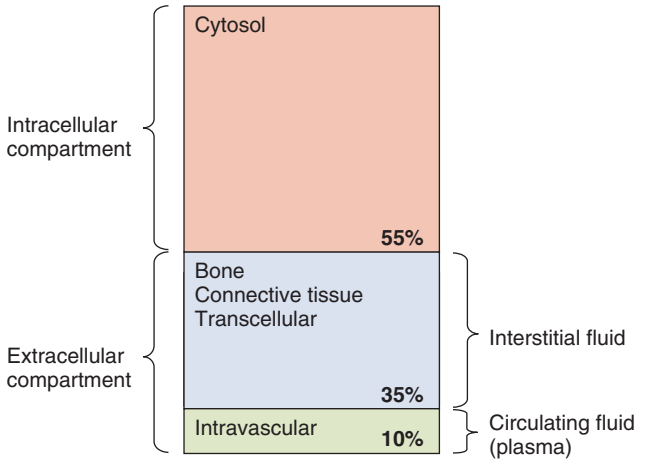

FIGURE 1 Distribution of total body water.

Hyponatremia

Defined as a serum sodium level lower than 135 mEq/L, hyponatremia is very common in hospitalized patients, particularly the elderly, the critically ill, and patients with neurologic disease and traumatic brain injury. Additionally, hyponatremia is associated with a significantly increased risk of mortality. In the simplest of terms, hyponatremia implies a greater amount of plasma water relative to sodium. Although it can occur with any osmotic state (hypotonic, isotonic, hypertonic), hyponatremia is most commonly associated with the hypotonic state (Figure 2).

Isotonic (isoosmolar) hyponatremia indicates a low measured serum sodium level in the presence of a normal serum osmolality (275–290 mOsm/kg H_2O). This low measured serum sodium level occurs when significant hyperlipidemia or hyperproteinemia is present. Proteins and lipids in plasma usually occur in micromolar concentrations having minimal effect on osmolality. However, when large concentrations of proteins and lipids are present in plasma, a bias occurs to the apparent concentrations of plasma constituents that exclusively occupy the aqueous fraction, such as sodium. TBW and total body sodium levels are unchanged. This

TABLE 1: Electrolyte composition of intracellular and extracellular compartments

	Intracellular compartment (mEq/L)	Extracellular compartment (mEq/L)	
		Plasma	Interstitial fluid
Sodium (Na^+)	10	140	145
Potassium (K^+)	150	4	4
Chloride (Cl^-)	0	103	114
Bicarbonate (HCO_3^-)	12	24	24
Magnesium (Mg^{2+})	40	3	2
Calcium (Ca^{2+})	0	5	3
Phosphorous (PO_4^{3-})	120	2	2

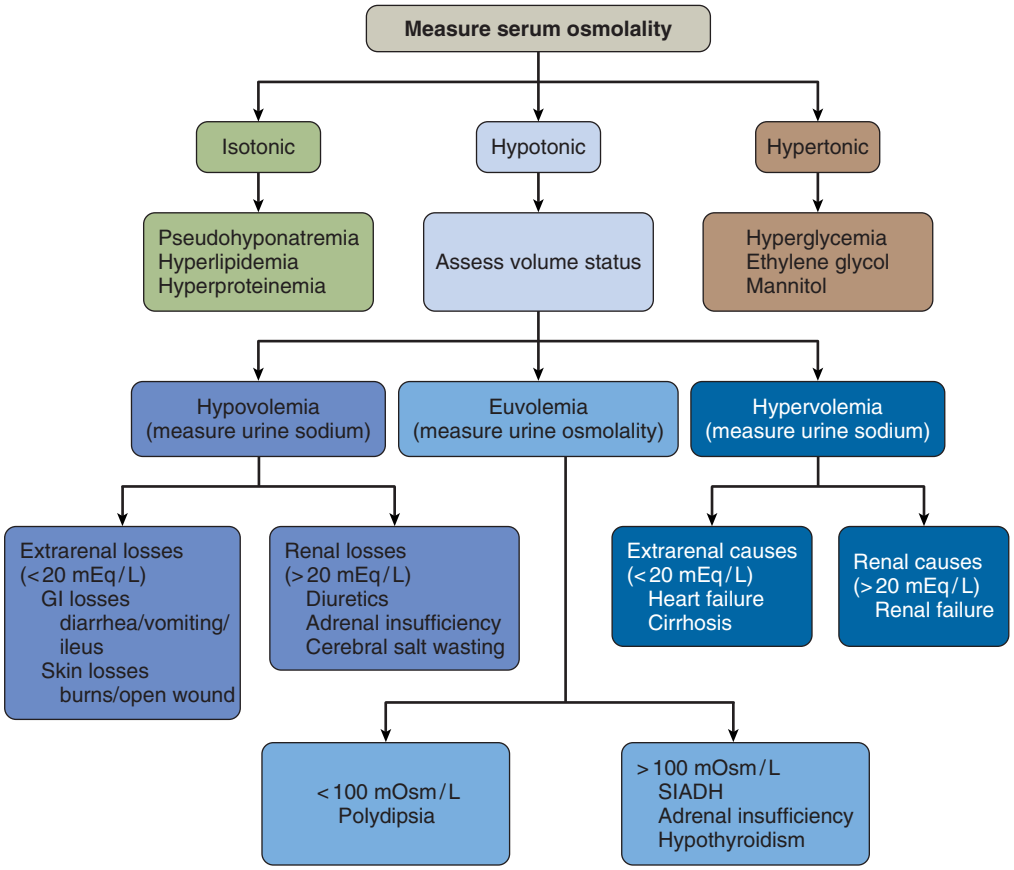

FIGURE 2 Hyponatremia algorithm. *GI,* Gastrointestinal; *SIADH,* syndrome of inappropriate antidiuretic hormone secretion.

type of hyponatremia is frequently referred to as pseudohyponatremia since it is secondary to a sampling error. By utilizing an analytic method that does not require a known volume of sample, such as a direct ion sensitive electrode, introducing bias into sodium measurements in the face of hyperlipidemia and hyperproteinemia can be avoided.

Hypertonic (hyperosmolar) hyponatremia indicates a low serum sodium level in the presence of high serum osmolality (>290 mOsm/kg H_2O). Because of the hyperosmolar state, a shift of water from the ICF compartment to the ECF compartment has occurred, resulting in a dilution of serum sodium. TBW and total body sodium levels are unchanged. Because this is a normal total body sodium state, something other than sodium is responsible for the increase in serum osmolality. Common causes include highly aqueous solutes, such as glucose, mannitol, glycerol, ethylene glycol, and glycine. Computation of an osmotic gap (OG), measured serum osmolality (MO) minus calculated osmolality (CO), can be helpful in identifying what compounds other than sodium are contributing to a hyperosmolar state.

$$CO = 2 \times (Na) + 1.15 \times (glucose/18) + BUN/2.8$$

$$OG = MO - CO \; (OG > 15 \text{ is indicative of unmeasured osmoles})$$

The relationship between hyperglycemia and measured sodium concentration is well described; for each 100 mg/dL increase in serum glucose, the measured sodium concentration will decrease by 1.6 mEq/L. For example, a patient with a serum glucose of 400 mg/dL should have 6.4 mEq/L (4×1.6 mEq/L) added to their measured serum sodium concentration in order to more correctly represent true sodium concentration. However, this relationship is nonlinear. For serum glucose measurements less than 400 mg/dL, a correction factor of 1.6 is used for each 100 mg/dL increase. For serum glucose measurements greater than 400 mg/dL, a correction factor of 2.4 is used for each 100 mg/dL increase. Treatment of hypertonic hyponatremia is directed toward eliminating the additional offending osmotically active agent. In the setting of hyperglycemia, serum glucose should be decreased with insulin injection. Hemodialysis may be required to eliminate other offending osmoles.

The most common type of hyponatremia, hypotonic (hypoosmolar) hyponatremia, indicates a low serum level in the presence of low serum osmolality (<275 mOsm/kg H_2O). It is important to recognize that this type of hyponatremia can occur with any volume state (hypovolemia, euvolemia, or hypervolemia). In fact, determining ECF volume status will aid in identifying the cause of the hyponatremia (see Figure 2). However, measuring ECF volume is difficult. Frequently, assessments of circulating (plasma) volume are used to estimate ECF volume. Unfortunately, these estimates are notoriously inaccurate.

Hypovolemic hypotonic hyponatremia results from renal or extrarenal losses of sodium. Renal sodium losses may be secondary to diuresis (diuretics) or adrenal insufficiency. Extrarenal losses are from the gastrointestinal tract (diarrhea/vomiting). Renal sodium losses can be distinguished from extrarenal losses through examination of urine sodium levels (renal losses: urine sodium > 20 mEq/L; extrarenal losses: urine sodium <20 mEq/L). The effects of these sodium losses on hyponatremia are exacerbated by fluid replacement with free water (drinking). In general, the treatment of hypovolemic hypotonic hyponatremia requires replacement of the sodium deficit with isotonic fluid; however, if the hyponatremia is severe and symptomatic (i.e., seizures), judicious administration of hypertonic saline is warranted. Sodium deficit is estimated by calculating the product

of TBW and the difference between the desired serum sodium concentration (140 mEq/L) and the current measured serum sodium concentration.

$$\text{TBW} = 0.6 \times \text{body weight in kg (TBW is roughly 60\% of body weight)}$$

$$\text{Na}^+ \text{ deficit (mEq)} = \text{TBW} \times (140 - \text{current } [\text{Na}^+])$$

For example, a 70-kg patient has current measured serum sodium of 115 mEq/L. The estimated sodium deficit would be:

$$\text{TBW} = 0.6 \times 70 = 42 \text{ liters (L)}$$

$$\text{Na}^+ \text{ deficit (mEq)} = 42 \text{ L} \times (140 - 115) \text{ mEq/L} = 1050 \text{ mEq}$$

The concentration of the sodium solution used will determine the total volume required to replace the desired amount of sodium. If normal saline, which has 154 mEq sodium/L, is chosen as the sodium replacement fluid, then 6.8 L would be required. If 3% hypertonic saline, which has 513 mEq sodium/L, is chosen as the sodium replacement fluid, then 2.0 L would be required.

$$\text{Normal Saline: } 1050 \text{ mEq sodium} \div 154 \text{ mEq sodium/L} = 6.8 \text{ L}$$

$$\text{3\% hypertonic saline: } 1050 \text{ mEq sodium} \div 513 \text{ mEq sodium/L} = 2.0 \text{ L}$$

Euvolemic hypotonic hyponatremia results from net increases in free water without clinical hypervolemia, most commonly resulting from inappropriate antidiuretic hormone secretion, glucocorticoid insufficiency, hypothyroidism, or psychogenic polydipsia. There are no associated sodium losses. Measurement of urine osmolality will help distinguish between water intoxication and an endocrine etiology. Since there are no sodium losses, the treatment is usually water restriction. However, there are now antagonists to vasopressin receptors (vaptans) that increase electrolyte-free water excretion and raise serum sodium concentration.

Hypervolemic hypotonic hyponatremia results from sodium and water gain (with free water gain exceeding sodium gain), most likely resulting from congestive heart failure, renal failure, or hepatic dysfunction (cirrhosis). Treatment requires sodium augmentation with isotonic fluid; however, if the hyponatremia is severe and symptomatic (i.e., seizures), judicious administration of hypertonic saline is warranted. Additionally, diuretics may be used to induce loss of free water.

Lastly, it should be noted that treatment of hypotonic (hypoosmolar) hyponatremia should also take into account the timing of the disease process. Acute hyponatremia is less common than chronic hyponatremia. Patients with acute hyponatremia, a decrease in serum sodium occurring over 48 hours or less, are at risk for brainstem herniation as sodium levels drop below 120 mEq/L. In patients with acute hyponatremia sodium levels should be corrected relatively quickly with sodium replacement (4 to 6 mEq/L over the first several hours) and free water restriction. Patients with chronic hyponatremia are at less risk of brain stem herniation, even with levels as low as 120 mEq/L. Sodium replacement in these patients should occur more slowly. Treatment in these patients with overly rapid sodium correction has been associated with osmotic demyelination syndrome (central pontine myelinolysis). In chronic hyponatremia, sodium should be replaced no faster than 0.5 mEq/L/h in order to avoid this demyelinating encephalopathy. For example, the previously referenced patient with a serum sodium of 115 mEq/L is down 25 mEq/L (140 − 115 = 25). To replace the sodium deficit of 1050 mEq no faster than 0.5 mEq/L/h, the sodium would need to be delivered over 50 hours.

$$25 \text{ mEq/L} \div 0.5 \text{ mEq/L/h} = 50 \text{ h}$$

Hypernatremia

Defined as a serum sodium level higher than 145 mEq/L, hypernatremia results from hypotonic fluid loss (most commonly) or hypertonic fluid gain and is frequently seen in extreme cases of dehydration. As ECF osmolality rises, ADH is released, the urine is concentrated, and thirst is stimulated. Hypernatremia is most commonly a disorder of free water imbalance, not sodium homeostasis. Thus, the high sodium concentration is usually secondary to a free water deficit. Unlike hyponatremia, where any osmotic state can be present (hypo, iso, or hyper), hypernatremia is always associated with a hyperosmotic state (serum osmolality > 290 mOsm/kg H_2O). Similar to hypotonic hyponatremia, hypernatremia can exist in conjunction with any volume state (hypovolemia, euvolemia, or hypervolemia). In fact, determining ECF volume status will aid in identifying the etiology of the hypernatremia (Figure 3). However, measuring ECF volume is difficult. Frequently, assessments of circulating (plasma) volume are used to estimate ECF volume. Unfortunately, these estimates are notoriously inaccurate.

Hypovolemic hypernatremia is secondary to a loss of hypotonic fluid, such as excessive diuresis, intractable vomiting, frequent diarrhea, or extreme sweating. Treatment focuses on correction of the free water deficit. However, in the presence of hypovolemia, circulating volume should be corrected with infusion of isotonic fluids prior to the correction of the free water deficit. Euvolemic hypernatremia results from a net loss of free water with normal circulating volume. Free water loss occurs commonly via the kidneys or as an increase in insensible fluid losses with poor water intake. A common cause of euvolemic hypernatremia is diabetes insipidus, either nephrogenic or central. Another common cause in hospitalized patients is excessive diuresis replaced by isotonic fluids. Treatment is focused on correction of the free water deficit. Hypervolemic hypernatremia is uncommon and usually secondary to iatrogenic sodium loading. This iatrogenic gain of hypertonic fluid is frequently secondary to hypertonic saline infusions or aggressive intravenous bicarbonate loading. Treatment for this uncommon type of hypernatremia focuses on free water replacement as well as diuretic use to enhance sodium excretion. Free water deficit is estimated by calculating the difference between normal TBW and current TBW. Current TBW is estimated based on normal TBW, desired serum sodium concentration (140 mEq/L), and the current measured serum sodium concentration.

$$\text{Current TBW} = \text{Normal TBW} \times (140/\text{current } [\text{Na}^+])$$

$$\text{Normal TBW} = 0.6 \times \text{body weight in kg (TBW is roughly 60\% of body weight)}$$

$$\text{Free Water Deficit} = \text{Normal TBW} - \text{Current TBW}$$

For example, a 70-kg patient has current measured serum sodium of 160 mEq/L. The estimated free water deficit would be:

$$\text{Normal TBW} = 0.6 \times 70 = 42 \text{ L}$$

$$\text{Current TBW} = 42 \times (140/160) = 36.75 \text{ L}$$

$$\text{Free Water Deficit} = 42 - 36.75 = 5.25 \text{ L}$$

Similar to treatment for hyponatremia, treatment for hypernatremia should take into account the timing of the disease process. Acute hypernatremia, an increase in serum sodium occurring over 48 hours or less, may be corrected more rapidly (1-2 mEq/L/h) than chronic hypernatremia (0.5 mEq/L/h). In the presence of chronic hypernatremia, a slower correction, over 48 to 72 hours, is warranted because of the development of idiopathic osmoles, cytoplasmic proteins within neurons, during the period of hypernatremia. These cytoplasmic proteins limit neuronal dehydration during prolonged hypernatremia and must be allowed to degrade prior to free water repletion in order to prevent cerebral edema.

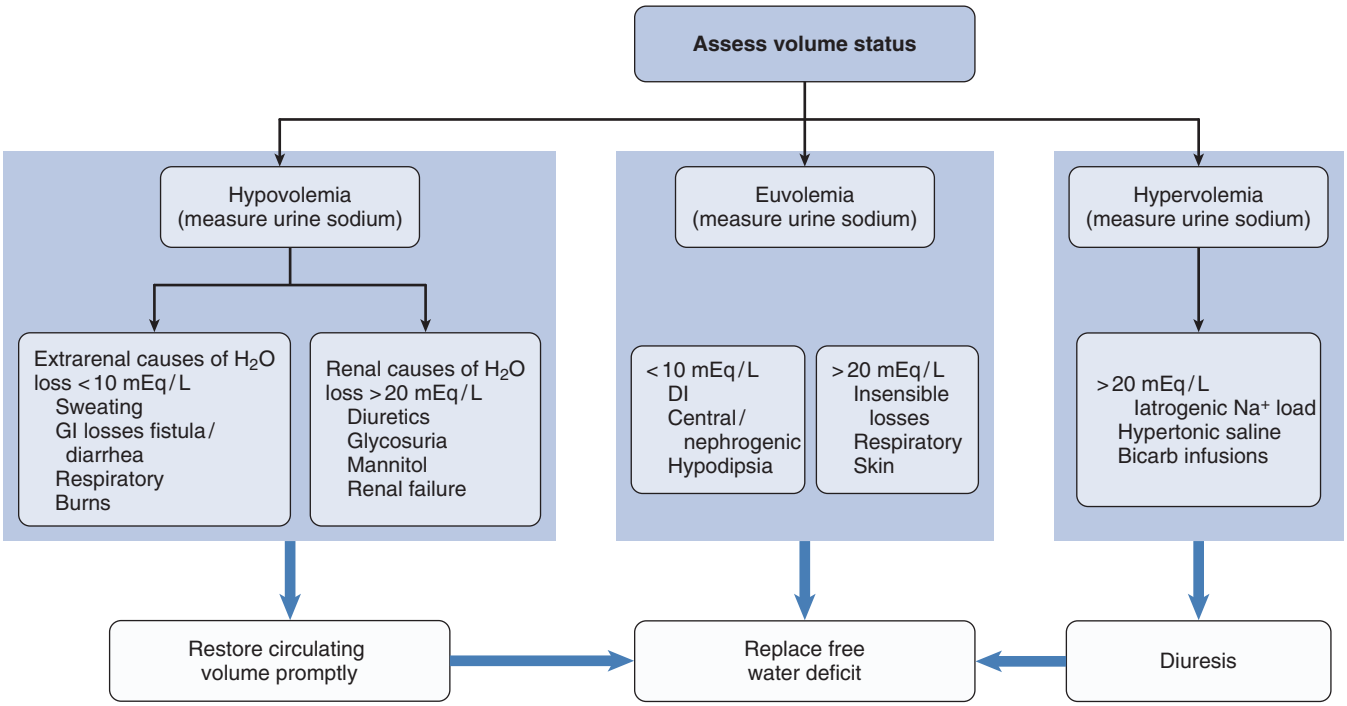

FIGURE 3 Hypernatremia algorithm.

POTASSIUM

Homeostasis

Potassium is the principle intracellular cation, with 98% of the body's potassium stores located within cells. The sodium/potassium pump, a transmembrane protein, actively maintains the concentration gradients of sodium and potassium across the cell membrane. The sodium and potassium electrochemical gradients across the cell membrane establish a resting membrane potential. An established resting membrane potential is essential for the normal function of nerve conduction, cardiac function and automaticity, and skeletal muscle contraction.

Homeostatic control of plasma and interstitial potassium concentration is critical. Within the ECF compartment, potassium concentration is maintained at a very narrow range (3.5-4.5 mEq/L). Potassium, as compared to other electrolytes, has the highest ratio of daily turnover and presents a significant homeostatic challenge. Potassium is efficiently cleared from the ECF compartment after intake; conversely, ECF potassium concentration is held constant even during times of poor potassium intake and fasting. The essential components of potassium homeostasis include sensing potassium intake through the gastrointestinal tract (normal dietary intake is 80 mEq/day), regulating potassium distribution between the ECF and ICF compartments, and regulating potassium excretion (stool 5 mEq/day; urine 75 mEq/day).

Hypokalemia

Hypokalemia, defined as a serum potassium level less than 3.5 mEq/L, is much more common than hyperkalemia in hospitalized patients; it occurs in up to 20% of that patient population. Because potassium homeostasis is essential to maintaining resting membrane potential, hypokalemia commonly presents as weakness, myalgias, and fatigability progressing to cramps, paresthesias, and tetany at levels below 2.5 mEq/L. Additionally, myocardial dysfunction, including premature ventricular contractions, sinus bradycardia, and ventricular tachycardia/fibrillation, can occur. Severe hypokalemia can result in rhabdomyolysis, myoglobinuria, and ascending paralysis leading to respiratory arrest. Other pathologic sequelae include renal free water losses secondary to diminished urinary concentrating ability as well as metabolic alkalosis from enhanced renal production of NH_3 and NH_4^+ as hydrogen ion is excreted in exchanged for renal potassium perseveration.

In patients with normal renal function, hypokalemia is commonly related to decreased potassium intake or loop diuretic use. However, several other less common etiologies should be considered (Table 2). It is important to note that a measured plasma potassium deficit is not linearly related to the amount of potassium required to replenish ECF levels, particularly when the measured ECF potassium concentration is less than 3.0 mEq/L. Because of the large intracellular stores of potassium, extracellular deficits draw on this source to maintain homeostasis. Thus, a total body potassium deficit exists when plasma levels are less than 3.0 mEq/L, and patients generally require large amounts of potassium replacement to correct deficits of this magnitude.

Treatment of hypokalemia focuses primarily on potassium replacement. However, a search for, and correction of, potential ongoing potassium losses should be undertaken. In the presence of dysrhythmias, electrocardiogram changes, severe myopathy, or paralysis, rapid intravenous administration of potassium chloride is warranted and should precede diagnostic testing. Continuous cardiac monitoring is essential during rapid potassium replacement. In addition, serum potassium concentrations should be intermittently checked since the total body potassium deficit is likely profound. It is difficult to determine total body potassium deficit, and a precipitous rise in plasma potassium concentration can occur once intracellular stores have been reestablished.

Hyperkalemia

Defined as a serum potassium level higher than 5.0 mEq/L, hyperkalemia is frequently secondary to either impaired potassium excretion

TABLE 2: Potential etiologies for potassium disorders

Hypokalemia	Hyperkalemia
Inadequate K^+ intake	Hemolysis
Increased K^+ excretion	Impaired excretion
Diarrhea	Renal failure
Metabolic alkalosis	Acidosis
Mineralocorticoid excess	Succinylcholine
Magnesium depletion	Massive tissue destruction
Insulin administration	
Delirium tremens	

or an impaired ability to redistribute ECF potassium into the ICF compartment. Since the kidney is extremely capable of maintaining ECF potassium levels by adaptive excretion, the development of hyperkalemia suggests renal dysfunction (see Table 2). The degree of hyperkalemia will also be influenced by the administration of potassium supplementation, a common medical therapy. Although renal dysfunction is the most common cause of hyperkalemia in the hospitalized patient, life-threatening increases in potassium concentration are also associated with a sudden shift of intracellular potassium into the ECF space (plasma and interstitium). These large shifts occur with acute severe metabolic acidosis or massive tissue destruction secondary to ischemia or significant soft tissue crush injury.

Although classically asymptomatic, hyperkalemia can be fatal secondary to an alteration in the cellular transmembrane potential of the cells responsible for cardiac automaticity as well as the conducting system. Initial electrocardiogram changes include peaked T waves with a shortened QT interval. At higher levels of hyperkalemia, progressive lengthening of the PR interval and QRS duration occur. Ultimately, the QRS interval widens and ventricular tachycardia occurs. Ventricular tachycardia further progresses into ventricular fibrillation, and the electrocardiogram will eventually flatline as electrical activity ceases.

Therapy for hyperkalemia is multifaceted and focuses on three main goals: (1) reduction of plasma potassium concentration, (2) preservation of myocardial conduction and membrane stability, and (3) reduction of total body potassium levels. These goals are prioritized based on the degree of renal dysfunction present, the patient's ability to tolerate plasma volume expansion, and the severity of the hyperkalemia. Reduction in plasma potassium concentration is achieved by saline loading, given the patient can tolerate plasma volume expansion. In conjunction with volume expansion with normal saline or other isotonic crystalloid solutions, concomitant administration of a kaliuretic diuretic will aid in decreasing total body potassium levels. The amount of renal dysfunction present will influence the degree of kaliuresis induced by the diuretic. Preservation of myocardial conduction and membrane stability is attained by administration of supplemental magnesium and calcium as well as by the relocation of potassium from the ECF compartment (plasma and interstitium) into the ICF compartment (cytosol). Magnesium sulfate and calcium chloride are administered intravenously and have immediate bioactive availability. Insulin and glucose are given to drive plasma potassium into the cell, shifting the potassium load to the ICF compartment. Finally, reduction of total body potassium is attained by kaliuresis, the use of a cation-exchange resin (Kayexalate), and/or hemodialysis.

MAGNESIUM

Homeostasis

Magnesium is the second most abundant intracellular cation (after potassium) and the most abundant intracellular divalent cation. The majority of total body magnesium is complexed to bone, and less than 1% of total body magnesium is present in the plasma. Magnesium is similar to calcium in that the biologically active portion is in the ionized form. However, unlike calcium, ionized magnesium is difficult to measure and serum levels are used to assess magnesium concentration. Although most circulating magnesium is ionized, about 33% is protein bound. Magnesium serves many important functions. It is required for protein synthesis, nucleic acid stability, and neuromuscular excitability. Similar to potassium, serum magnesium levels are maintained in a very narrow range (1.5-2.5 mEq/L). Magnesium is absorbed from the gastrointestinal tract through both active and passive transport mechanisms. In the kidney, 80% of serum magnesium is filtered in the glomeruli, with 95% being reabsorbed along the nephron.

Hypomagnesemia

Hypomagnesemia, defined as less than 1.5 mEq/L, is ubiquitous in critical illness because of the use of magnesium-poor maintenance intravenous fluids and is commonly secondary to insufficient intake or enhanced gastrointestinal or renal losses. Symptoms of low magnesium levels are anorexia, nausea, vomiting, lethargy, weakness, paresthesias, confusion, tetany, seizures, and cardiac arrhythmias (including ventricular fibrillation, torsades de pointes, and cardiac arrest). Hypomagnesemia occurs commonly in conjunction with hypokalemia, and concomitant replacement therapy is the rule rather than the exception. Similar to treatment of hypokalemia, treatment of hypomagnesemia often requires large amounts of magnesium to restore normal serum magnesium levels.

Hypermagnesemia

Defined as serum levels higher than 2.5 mEq/L, hypermagnesemia is uncommon and occurs almost exclusively in patients with renal failure. Other causes of hypermagnesemia include rhabdomyolysis, adrenal insufficiency, and benign familial hypocalciuric hypercalcemia. Symptoms that do not occur until levels exceed 5.0 mEq/L and are primarily neuromuscular and cardiovascular. Early symptoms, such as nausea and facial paresthesias, progress to sedation, hypoventilation, decreased deep tendon reflexes, and muscle weakness. Severe symptoms and sequelae of hypotension, bradycardia, and coma are not observed until magnesium levels exceed 15 mEq/L. Magnesium toxicity is exacerbated by concomitant hyperkalemia, hypocalcemia, and uremia. The mainstay of therapy for hypermagnesemia is magnesium administration cessation, plasma volume expansion, and intravenous calcium administration. Similar to treatment of hyperkalemia, plasma magnesium levels will be diluted with saline hydration. The addition of loop diuretics will increase magnesium renal excretion, thereby decreasing total body magnesium levels.

CALCIUM AND PHOSPHATE

Homeostasis

Calcium and phosphate homeostases are mediated through coordinated efforts of the gastrointestinal tract, bone, and kidney, which are all influenced by circulating parathyroid hormone levels. Calcium is

essential for neuromuscular function, coagulation, bone metabolism, as well as endocrine and exocrine secretion. Phosphorous is essential for bone metabolism, glucose utilization, and energy storage and utilization (adenosine triphosphate synthesis). Ninety-eight percent of total body calcium and phosphate are stored in bone. Plasma calcium occurs in three states: ionized (50%), protein bound (40%), and complexed (10%). The metabolically active form of plasma calcium is the ionized form. Total calcium concentration can be affected by serum albumin levels. Corrected serum calcium levels can be calculated based on circulating serum albumin levels using the following equation:

$$\text{Corrected}\,[Ca^{2+}] = \text{Measured}\,[Ca^{2+}] + 0.8(4 - [\text{Albumin}])$$

Due to its stabilizing effect on voltage-gated ion channels, plasma calcium concentration is tightly controlled. When calcium concentration is too low in the ECF space (hypocalcemia), voltage-gated channels start opening spontaneously, causing nerve and muscle cells to become hyperactive. This hyperactivity results in involuntary muscle spasms (hypocalcemic tetany). Conversely, when calcium concentration is too high in the ECF space (hypercalcemia), voltage-gated ion channels do not open as readily; this results in depressed nervous system function.

There are two important hormones for maintaining calcium and phosphate homeostasis; these are parathyroid hormone and 1,25-dihydroxycholecalciferol (calcitriol). Parathyroid hormone, part of a negative feedback loop, secretion is stimulated by hypocalcemia and counteracts this low calcium state by three modalities. First, parathyroid hormone secretion stimulates release of calcium from bone by inducing the generation of osteoclasts, which increase bone reabsorption. Second, urinary calcium losses are decreased by stimulation of renal tubular reabsorption of calcium. Third, parathyroid hormone indirectly increases calcium absorption by the small intestine by stimulating synthesis of calcitriol in the kidney (Figure 4). The synthesis of calcitriol involves several steps, including conversion of 7-dehydrocholesterol into vitamin D in the skin, the hydroxylation of vitamin D into 25-(OH)D in the liver and the final hydroxylation into 1,25-$(OH)_2$D, which occurs in the kidney.

Hypocalcemia

Hypocalcemia (calcium levels <8.4 mg/dL) is less common than hypercalcemia and is generally secondary to disorders of parathyroid hormone (decreased levels after surgical parathyroidectomy) or vitamin D (decreased synthesis in renal failure). Hypocalcemia is also commonly seen in critically ill patients with sepsis and burns. Clinical manifestations of hypocalcemia include perioral numbness, Trousseau sign (induction of carpopedal spasm with blood pressure cuff inflation), Chvostek sign (facial muscle spasm after facial nerve stimulation), muscle cramps, laryngeal spasm, and seizures. As hypocalcemia progresses, prolongation of the QT interval occurs and progression to malignant arrhythmias such as torsades de pointes or heart block may follow. Treatment of acute symptomatic

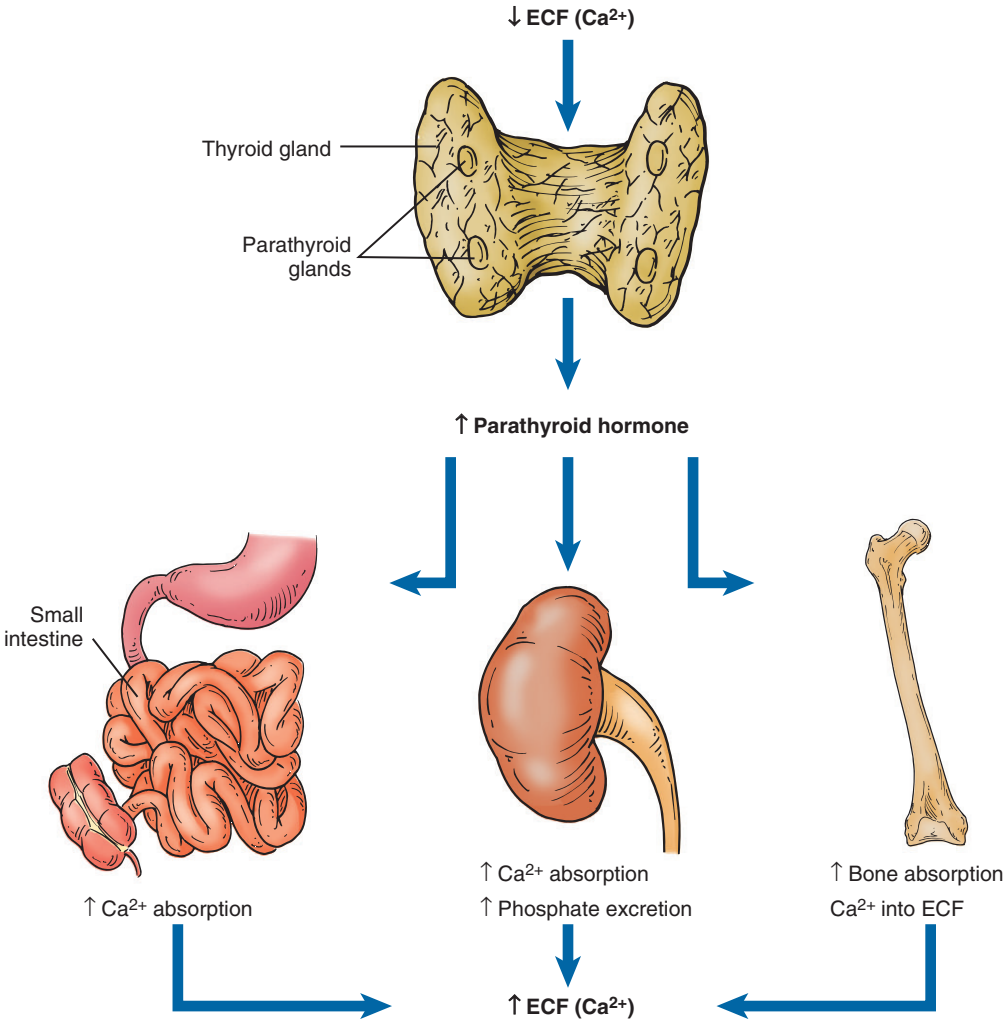

FIGURE 4 Calcium homeostasis. *ECF,* Extracellular fluid.

hypocalcemia should include administration of parenteral supplementation of calcium gluconate or calcium chloride. Cardiac monitoring and frequent reassessments of serum calcium levels should be carried out during calcium replacement.

Hypercalcemia

Hypercalcemia (calcium levels >10.4 mg/dL) is frequently due to either increased bone reabsorption or excessive calcium intake. Frequent symptoms are associated with renal (nephrolithiasis, nephrocalcinosis), musculoskeletal (weakness), intestinal (nausea, vomiting, constipation), neurologic (fatigue, depression, mental confusion), and cardiovascular (short QT interval, arrhythmias) manifestations. The most common etiology of clinically significant hypercalcemia is hyperparathyroidism. Non–parathyroid-mediated hypercalcemia can be due to malignancy, vitamin D intoxication, or granulomatous disease. Patients with asymptomatic hypercalcemia should be screened for hyperparathyroidism; urgent treatment is not required. Treatment of symptomatic or acute hypercalcemia is directed at increasing calcium excretion while minimizing bone reabsorption. These goals are attained with intravenous hydration and diuretic administration. The use of bisphosphonates can be added in the case of malignancy, but they work slowly. Glucocorticoids have been used as adjunctive agents for managing hypercalcemia associated with vitamin D intoxication, malignancy, and granulomatous disease. Hypercalcemic crisis (calcium levels >13 mg/dL) may require acute hemodialysis, especially in cases of renal dysfunction.

Hypophosphatemia

Hypophosphatemia (PO_4^{3-} levels <2.4 mg/dL) usually results from decreased gastrointestinal absorption, increased renal excretion, or may be secondary to a shift of serum phosphate into the ICF compartment. A significant intracellular shift of serum phosphate from plasma can occur after glucose loading in cases of malnutrition (refeeding syndrome), causing extreme hypophosphatemia. Most hypophosphatemia is asymptomatic; however, severe low levels can result in impaired cellular energy production resulting in rhabdomyolysis, cardiomyopathy, erythrocyte dysfunction, skeletal demineralization, muscle weakness, and respiratory dysfunction. Treatment is focused on replacement. Parenteral replacement should be used in cases of severe deficiency.

Hyperphosphatemia

Hyperphosphatemia (PO_4^{3-} levels >5 mg/dL) is most likely secondary to decreased renal excretion. Although often asymptomatic, there is potential for metastatic calcification, particularly with a calcium-phosphorus product in excess of 70 mg/dL. Assessing urinary phosphorus excretion will aid in determining the cause of hyperphosphatemia. In the absence of renal dysfunction, elevated levels of urinary phosphorous (>1500 mg/dL) indicate either exogenous phosphate ingestion or cellular release of phosphates secondary to tumor lysis of rhabdomyolysis. When renal function is preserved, hydration is the mainstay of therapy because it increases renal excretion of phosphates. In patients with renal failure, all exogenous phosphate sources should be discontinued. Calcium carbonate, aluminum, and magnesium can be used to bind phosphorous in the gastrointestinal tract. Finally, hemodialysis may be required for adequate phosphate clearance in patients with symptomatic hyperphosphatemia.

SUMMARY

Electrolyte disorders can be complex in etiology and require a thoughtful and therapeutic plan of correction. Serial electrolyte measurements are imperative to assess response to therapy. These disorders are potentially life-threatening conditions that require rapid assessment coupled with diligent follow-up.

Acid-Base Problems

Glen Whitman, MD

A certain mystique exists in medicine today regarding the subject of acid-base balance. Research conducted among several test group physicians at teaching hospitals revealed that arterial blood gas (ABG) interpretations are correct only 40% of the time. More distressingly, management error occurred 33% of the time because of incorrect interpretation. As many as 90% of intensive care patients have an acid-base disorder; thus, understanding acid-base balance is an essential component in the clinical management of critically ill patients.

NORMAL ACID-BASE METABOLISM

In general, the body attempts to maintain the pH of its fluids between 7.35 and 7.45, a pH that is associated with a H^+ ion concentration of 40 nmol/L. To put this concentration in perspective, the Na or K concentration in the body, which is expressed in mmol/L, is one million times more concentrated than the simple hydrogen ion H^+. Despite this minute concentration, H^+ is carefully regulated, as it has far-reaching effects and reacts readily with proteins and enzymes,

which significantly alters the rates of reactions for which they are responsible.

Most of the daily acid production comes from the metabolism of fats and carbohydrates. This produces carbon dioxide that, when combined with water, produces carbonic acid, which is in equilibrium with hydrogen and bicarbonate:

1. $CO_2 + H_2O = H_2CO_3$
2. $H_2CO_3 = H^+$ and HCO_3

In addition, proteins and phosphates that are eaten contribute a small amount to this acid load.

The body maintains acid-base homeostasis in a variety of ways, but an important mechanism is the direct buffering of H^+ via intracellular and extracellular proteins, bone, and serum HCO_3. The kidneys also play a major role, specifically compensating for acidosis through the absorption of HCO_3^- in the proximal tubule and through H^+ excretion in the distal tubule.

By far, however, the most effective manner of maintenance of appropriate pH is through ventilation, with modulation of the elimination of CO_2 production. This is immediately apparent on viewing the Henderson-Hasselbalch equation, which points out the importance of partial pressure of CO_2 (pCO_2) and HCO_3^- as they relate to pH:

$$pH = 6.10 + \log(HCO_3)/0.03\ pCO_2$$

One can see that pH is inversely related to pCO_2 and, of course, directly related to serum HCO_3^-.

Although normally minute ventilation is between 5 and 7 L, this can be increased by a factor of 10, thereby eliminating even a significantly abnormal quantity of CO_2 production through the lungs.

Arterial Blood Gas Interpretation

Most commonly, blood pH is measured with an arterial blood gas. In this type of analysis, the pH, pCO_2, and partial pressure of oxygen (pO_2) are directly measured. For the purposes of this chapter, a normal arterial blood gas has a pH of 7.40, a pCO_2 of 40, and a pO_2 of 100. For fluency in the discussion of acid-base issues, acidemia is the term used by convention when the pH is less than 7.4, and alkalemia is used when the pH is greater than 7.4 (e.g., the patient's condition is acidemic in the former case and alkalemic in the latter). But the measured pH, whether normal, acidemic, or alkalemic, is invariably the result of two or more processes that raise or lower the H ion concentration (e.g., hyperventilation, which lowers the H concentration, and uremia, which raises it). These individual processes are referred to as alkaloses and acidoses; depending on which is dominant, the patient experiences alkalemia or acidemia.

An unknown wag wrote that "human survival is a constant battle against the hydrogen ion," which emphasizes the point that death is invariably preceded by an acidosis. But to the extent that the process is caught early, intervention and reversal of the acidosis may be possible, and thus, a life may be saved. The key lies in early recognition.

What follows is a useful way to interpret a blood gas at the bedside, with the intent that the caregiver will have ample warning of an impending problem. To this end, the only two important values in a blood gas are the pH and the pCO_2. One needs to know both to determine the acid-base status of a patient. pO_2 has no relevance in this analysis. Hypoxia may be a cause of a metabolic acidosis, but knowledge of the patient's pO_2 does not help with determination of the presence or the degree of the acidosis (Figure 1).

On the basis of the Henderson-Hasselbalch equation, if the pCO_2 acutely drops 10 mm Hg, the pH rises 0.08 units, and vice versa. This assumes that there is no metabolic component to the patient's acid-base disorder. The serum bicarbonate concentration does change when the pCO_2 changes, because a change in dissolved CO_2 changes the HCO_3 concentration, but the change is only minimal. (To be perfectly accurate, if the pCO_2 changes 10 mm Hg, the HCO_3 concentration changes 2 mEq/L, in the same direction.) Thus, if one assumes no metabolic component to the acid-base disturbance, when faced with the results of an ABG, immediately on looking at the pCO_2, one can predict what the pH should be. The rule of thumb is that when the pCO_2 drops 10 mm Hg, the pH rises 0.08 units. However, if the measured pH is higher than that which was predicted based on the pCO_2 alone, the patient has a metabolic alkalosis on top of the respiratory disturbance. If the pH is lower than what would have been predicted based on the pCO_2 alone, the patient has a metabolic acidosis.

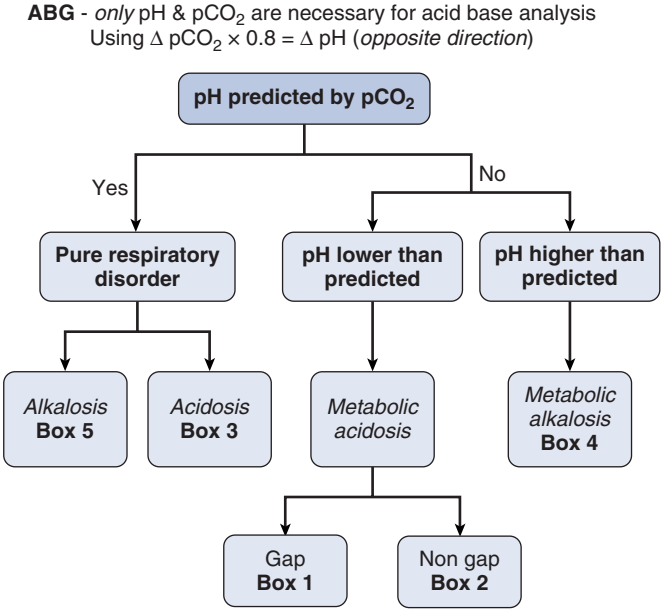

FIGURE 1 Algorithm for arterial blood gas *(ABG)* interpretation. One needs to know only the pH and the partial pressure of CO_2 *(pCO_2)* to determine the acid-base status of a patient; partial pressure of oxygen *(pO_2)* has no relevance in this analysis.

One can take this analysis a step further and become more quantitative regarding the degree of the metabolic disturbance. The difference between the predicted pH, based on the pCO_2 alone, and the measured pH (multiply the predicted and actual pH by 100 to work with a whole number) gives one a measure of the degree of the metabolic acidosis or alkalosis present. Furthermore, multiplication of that difference by 2/3 yields a variable called the base excess (if the pH was higher than predicted) or the base deficit (if the pH was lower than predicted). In reality, the base deficit quantifies the absolute deficit (or excess) of total body bicarbonate, expressed in mEq/L. In general, the bicarbonate space can be assumed to be roughly 1/3 the body weight. Consequently, a 90-kg person has a bicarbonate space of 30 L. A base deficit of 6 in such a person represents a total body bicarbonate deficit of 180 mEq (30 L bicarbonate space × base deficit of 6). By following the base deficit, one can determine the effectiveness of one's treatment of a metabolic disturbance (e.g., a lactic acidosis from cardiogenic shock). Successful therapy with improved cardiac output and oxygen delivery is associated with a decrease in anaerobic metabolism and a progressive amelioration of the base deficit.

METABOLIC ACIDOSIS

Metabolic acidosis is the most common acid-base disorder in medicine, a state characterized by excessive acid production (e.g., lactic acid), reduced acid excretion (e.g., renal failure), or the loss of whole

body alkali (e.g., diarrhea). Many life-threatening conditions are associated with metabolic acidosis, thus raising the importance of its prompt diagnosis and treatment. A metabolic acidosis is diagnosed when the serum HCO_3 concentration is less than 22 mEq/L, which roughly corresponds to a base deficit of more than 2.

To determine the cause of metabolic acidosis, first determine the presence or absence of an anion gap, which is the calculated difference between the serum cations and anions obtained at the same time that the arterial blood gas was drawn. In serum, the sum of the commonly measured cations (e.g., sodium) outnumber the anions (e.g., HCO_3 and chloride), which is the "gap." The normal anion gap is between 8 and 12 mEq/L and is made up of unmeasured and therefore "hidden" anions. When these unmeasured gap anions are added to the Cl^- and HCO_3^-, the sum equals the Na^+ concentration, in keeping with the fact that the body maintains electrical neutrality. In normal conditions, these unmeasured anions consist mainly of albumin, phosphate, and sulfate. In the intensive care unit (ICU), where albumin concentrations are frequently low, an appropriate correction should be taken into account. Albumin is negatively charged, and when its concentration diminishes, CL^- and HCO_3^- concentration increases to compensate, thus lowering the acceptable gap. Roughly, for every 1.0 g/dL decrease in serum albumin below 4.4 g/dL, the measured anion gap should decrease by 3 mmol/L.

Gap Acidosis

A large anion gap indicates the loss of HCO_3 ions without a concurrent increase in chloride. Electroneutrality is maintained by elevated levels of unmeasured anions, such as lactate, beta-hydroxybutyrate, acetoacetate, or abnormal quantities of PO_4, and SO_4, anions that do not normally make up the gap. A search for conditions that lead to these excess hidden anions and a widened gap should be undertaken (Box 1).

Methanol or Ethylene Glycol Toxicity

Both alcohols are toxic but are sweet and therefore are often ingested. Methanol is metabolized to formic acid, which inhibits oxidative phosphorylation-producing lactate, and ethylene glycol is converted to oxalic acid. In both cases, there is a widened osmolar gap (different from the anion gap) and an anion gap.

Diabetic Ketoacidosis

In uncontrolled diabetes, the increase in ketoacids is buffered by bicarbonate, diminishing its concentration, with a resultant gap acidosis. Once effective treatment with insulin has begun, the production of ketoacids ceases and the bicarbonate concentration rapidly normalizes.

Propylene Glycol

This substance is an additive for antifreeze, a solvent, and a moisturizer, among other uses. When ingested, it is converted to pyruvic acid, acetic acid, and then lactic acid, all of which cause an increased anion gap.

BOX 1: Anion gap metabolic acidosis

M	Methanol (osmol gap, >10)
U	Uremia
D	Diabetic ketoacidosis
P	Propylene glycol (radiator fluid and preservative in diazepam and lorazepam)
I	Isoniazid
L	Lactic acid (sepsis, ischemia, propofol, short gut)
E	Ethylene glycol (osmol gap, >10)
R	Rhabdomyolysis
S	Salicylates

Isoniazid

Isoniazid (INH) is an antibiotic that is used in the treatment of *Mycobacterium tuberculosis*. In some cases, it can cause a significant diminution in gamma-aminobutyric acid, leading to seizures, and a lactic acidosis on that basis.

Lactic Acidosis

Although most commonly seen in hypoperfusion syndromes in which cells undergo anaerobic metabolism producing significant lactate, a lactic acidosis may also arise from defects in lactate clearance, pyruvate dehydrogenase, or thiamine deficiency.

Renal Failure

A drastic decrease in glomerular filtration leads to a decrease in the excretion of sulfates, phosphates, urate, and hippurate (all unmeasured anions), along with a decrease in HCO_3 reabsorption.

Ethylene Glycol

As stated previously, this sweet alcohol, prone to abuse, leads to formation of the unmeasured anions, glycolate and oxalate, which cause a gap acidosis. Both are primary renal toxins.

Rhabdomyolysis

Crush injuries or other causes of myocyte cell death release organic acids into the blood stream, leading to an increase in unmeasured anions.

Salicylate

Aspirin overingestion initially causes a respiratory alkalosis with a compensatory metabolic acidosis. However, at high concentrations, salicylates inhibit key enzymes in the Kreb's cycle, uncoupling oxidative phosphorylation and causing a lactic acidosis. A useful mnemonic used to recall the causes of a gap metabolic acidosis is MUDPILERS (see Box 1).

In all acidoses, when a net retention of hydrogen ion occurs, the body activates three compensatory responses, namely: (1) buffering; (2) increased ventilation; and (3) increased renal absorption and regeneration of HCO_3.

In the face of a metabolic acidosis, the drop in pH immediately stimulates the ventilatory drive, enhancing CO_2 elimination with a concomitant rise in the pH toward normal.

Treatment of a Gap Acidosis

Immediate recognition and treatment of a metabolic acidosis can be lifesaving. In all cases, the underlying cause must be addressed with simultaneous support of the patient. In the ICU, severe metabolic acidoses is frequently treated with bicarbonate. However, its use does not come without a price: fluid overload, hypernatremia, hypocalcemia, impairment of hemoglobin/oxygen dissociation, and an acute lowering of cerebrospinal fluid (CSF) pH, which can cause mental status changes. Nevertheless, although the etiology for the acidosis is being addressed, maintenance of pH above 7.3 with hyperventilation and bicarbonate administration provides a margin of safety.

Interestingly, a low pH itself does not independently lead to the hemodynamic collapse seen in the acidemic, critically ill patient. In fact, there is a striking discordance between the clinical course and the outcome of acidemias caused by respiratory failure as opposed to those that are metabolic in origin. As an example, lactate may play

a key role in circulatory collapse, apart from the associated increase in H^+ concentration. Thus, although hemodynamic improvements are commonly observed after bicarbonate administration, given to buffer the acidosis, the truly pathologic molecule may not be addressed.

Nongap Acidosis

The causes of anion gap acidoses differ significantly from those of nongapped acidoses, most particularly in that none of the latter is primarily lethal. A nongap acidosis occurs when loss of HCO_3 is completely compensated for by an increase in Cl^- concentration and is perhaps better described as a hyperchloremic nongap acidosis. The two organs capable of contributing to this process are the gut and the kidney. A useful pneumonic for remembering its causes is FUSEDCARS (Box 2).

Gastrointestinal loss of HCO_3, as occurs in diarrhea, and renal losses, as seen in renal tubular acidoses, often part of longstanding diabetes, are typically seen in the ICU setting. When faced with a nongap hyperchloremic acidosis, the first step, therefore, is to determine whether the intestine or the kidney is the culprit. Urine pH is high or alkaline if the kidney is responsible but low if the intestine is the cause of bicarbonate loss. Physiologically, the normal kidney compensates for an acidosis both by reabsorbing bicarbonate in the proximal tubule and thick ascending limb, increasing proton secretion in the distal tubule, and by collecting duct and excreting protons as ammonium chloride (NH_4Cl). This process causes the urine pH to be low (<5) and implicates the intestine as the cause.

When the etiology is renal, the differential diagnosis can be narrowed down to a renal tubular acidosis, use of carbonic anhydrous inhibitors, spironolactone, early renal failure, or ureteral diversions. The loss of HCO_3 and impairment of H^+ secretion from the kidneys constitutes the renal tubular acidoses (RTA). With a proximal renal tubular acidosis, there is also a loss of HCO_3 absorption proximally, as opposed to a distal renal tubular acidosis in which there is dysfunction of the distal tubule and an inability to secrete protons.

Although the kidney and the intestine should be viewed as the primary causes, hyperchloremic acidosis is iatrogenically seen with the rapid administration of 0.9% NaCl resuscitation solution, a process that results in the loss of HCO_3, fully replaced by Cl^-.

RESPIRATORY ACIDOSIS

Respiratory acidosis (Box 3) occurs when ventilation fails to remove all of the CO_2 produced by the body's metabolism, with a resultant rise in pCO_2 above 40. Causes include loss of pulmonary elasticity as seen in idiopathic pulmonary fibrosis or sarcoid and long-standing chronic obstructive pulmonary disease (COPD) with gradual inability to eliminate CO_2. Both lead to a slow increase in CO_2 compensated for by the kidneys, which increase bicarbonate reabsorption.

However, an exacerbation of COPD and bronchiolar spasm as seen in an allergic reaction or asthma are acute causes of a respiratory acidosis frequently encountered in the surgical setting. But the most common cause is central nervous system (CNS) depression from narcotics; benzodiazepines; stroke, which can cause either hypoventilation or hyperventilation; and chest wall muscle weakness from residual muscular paralysis after surgery.

BOX 2: Nongapped acidoses

F	Fistula, pancreatic
U	Ureteroenterostomy
S	Saline administration
E	Endocrine (hyperparathyroidism)
D	Diarrhea
C	Carbonic anhydrase inhibitors
A	Ammonium chloride
R	Renal tubular acidosis
S	Spironolactone

Treatment

In all situations, the aim of the provider is to facilitate ventilation. In the case of bronchospasm, bronchodilators with beta agonists, anticholinergics, or steroids may be appropriate. For muscular weakness or even CNS depression, noninvasive pressure ventilation with pressure support and continuous positive airway pressure may obviate the need for intubation. It is important to address the adequate reversal of residual effects of neuromuscular blockade, with the administration of neostigmine, or the effects of narcotics or benzodiazepines, which can be neutralized with naloxone or flumazinal. However, if the rise in pCO_2 is poorly tolerated and associated with a change in mental status or hypoxia, then intubation and mechanical support are necessary. To a large degree, whenever a question exists regarding the effectiveness of noninvasive support, intubation is always appropriate. Hypoventilation is effectively treated with mechanical support, and given the ability to intubate atraumatically, allowing a patient to become hemodynamically compromised from hypoventilation, hypoxemia, and severe respiratory acidemia should almost never occur in the monitored setting.

METABOLIC ALKALOSES

In the ICU setting, a metabolic alkalosis (Box 4) is almost always the result of upper gastrointestinal losses or diuretic therapy. To occur, however, the alkalosis must be to some degree associated with intravascular volume depletion or hypokalemia; if not, the kidney simply excretes the excess bicarbonate.

Gastrointestinal Hydrogen Loss

As pointed out in the section on metabolic acidosis, loss of lower gastrointestinal secretions, as in diarrhea, causes an acidosis because these fluids are high in bicarbonate concentration. However, gastric secretions are high in hydrogen concentration, and gastric suctioning or vomiting leads to its loss and a concomitant alkalosis. In general, gastric acid, on entering the duodenum, causes pancreatic bicarbonate secretion, and the event is pH neutral. However, gastric suctioning prevents the secreted H^+ from reaching the duodenum,

BOX 3: Respiratory acidosis

CNS depressants (sedatives, CNS disease, obesity hypoventilation syndrome)
Lung disease (COPD, bronchospasm)
Kyphoscoliosis
Guillain-Barré syndrome
Myasthenia gravis

CNS, Central nervous system; *COPD,* chronic obstructive pulmonary disease.

BOX 4: Metabolic alkalosis

Volume contraction (vomiting, overdiuresis, ascites)
Hypokalemia
Mechanical ventilation in a hypercapneic condition
Alkali ingestion (bicarbonate)
Excess glucocorticoids or mineralocorticoids

and consequently, no stimulation to pancreatic bicarbonate secretion occurs.

Diuretic Therapy

In the surgical setting, postoperative patients experience hyperaldosteronism, the result of stress-induced stimulation of the renin-angiotensin system. In this setting, when loop diuretics are used, increased Na^+ delivery to the distal tubule occurs. This increased Na delivery in the face of aldosterone leads to increased Na absorption in exchange for K^+ and H^+. The H^+ loss is exacerbated by hypokalemia which invariably occurs in this situation. To a degree, a shift of intracellular K^+ to the extracellular space to compensate, but to maintain electrical neutrality, H+ ion enters the cell. This increased H^+ concentration in the distal tubular cell leads to its preferential secretion in exchange for Na^+, exacerbating the resulting alkalosis. Similarly, any cause in an increased circulating mineralocorticoid can lead to an alkalosis, and it always is associated with hypokalemia, for the reasons stated previously.

Contraction Alkalosis

Significant losses of predominantly bicarbonate-free fluid cause a contraction alkalosis. This is most commonly seen in the edematous patient treated with diuretics who has a significant, rapid fluid loss. In this situation, loss of free water around a fixed quantity of bicarbonate leads to its increased concentration. Similarly, significant dehydration or sweating with free water and NaCl loss leads to a rise in bicarbonate concentration. But by far, in the hospital, diuretic therapy is the most common cause of this metabolic derangement.

Hypercapneic Alkalosis

Chronic hypercapnea and its associated respiratory acidosis lead to increased H^+ secretion by the kidney. The ensuing rise in bicarbonate concentration can compensate to a large degree for the primary respiratory acidosis. However, if in this setting, the pCO_2 is rapidly lowered, as might be the case with overzealous mechanical ventilation, the respiratory acidosis vanishes in the face of the ongoing metabolic alkalosis. This can be dangerous if the rise in pH is significant and sudden, as acute intracerebral alkalosis can lead to delirium, seizures, and even death.

Therapy

Most metabolic alkaloses are volume responsive. Adequate volume expansion inhibits the production of renin and decreases any hyperaldosterone effect that may be contributing. Furthermore, NaCl administration replenishes the Cl^- ion, which is necessary for the adequate excretion of HCO_3^- in the collecting duct of the kidney. Finally, as mentioned previously, K^+ repletion is essential, or the kidney continue to excrete H^+ in exchange for Na^+ absorption, maintaining the alkalosis. Occasionally, acetazolamide is helpful to inhibit the carbonic anhydrase in the proximal tubular cells, preventing the absorption of bicarbonate in that portion of the kidney and allowing it to be excreted. However, this increases Na delivery to the distal tubule, which in the face of aldosterone activity leads to its resorption in exchange for K^+. Profound hypokalemia can result if this ion is not aggressively supplemented. Finally, if hypokalemia is allowed to continue in the face of acetazolamide therapy, Na reabsorption in exchange for hydrogen maintains the alkalosis, despite the prevention of bicarbonate resorption proximally.

BOX 5: Respiratory alkalosis

Catastrophic CNS event (CNS hemorrhage)
Drugs (salicylates, progesterone)
Pregnancy (especially the third trimester)
Decreased lung compliance (interstitial lung disease)
Liver cirrhosis
Anxiety

CNS, Central nervous system.

RESPIRATORY ALKALOSIS

As discussed in the beginning of this chapter, a fall in CO_2 leads to a rise in pH. Clinically, this is the result of hyperventilation. Although frequently the result of anxiety or pain, the most important causes are primary CNS stimulation, hypoxemia, sepsis, and pulmonary embolus. In the critically ill, CNS stimulation can be the result of a stroke or an acute rise in intracranial pressure, hypoxemia from heart failure or an acute lung injury, or sepsis from a gram-negative organism. Pulmonary embolus causes hyperventilation from primary stimulation of lung receptors. An acute respiratory alkalosis, of course, can be the result of hyperventilation from overaggressive mechanical ventilation. Hyperventilation with its resultant alkalemia causes cerebral vasoconstriction, with a decrease in cerebral blood flow. Neurologic symptoms, such as dizziness, confusion, and paresthesias, classically numbness around the mouth, can result. This is in distinct contrast to a metabolic alkalosis, which rarely causes CNS changes, as the increase in serum bicarbonate concentration is reflected in the brain much more slowly because of the blood–brain barrier, and the pH change associated with a decrease in pCO_2 occurs immediately (Box 5).

Treatment

Apart from overzealous ventilation, which is easily and immediately correctable, the clinical settings associated with respiratory alkalosis can be life threatening. Considering that stroke, brain tumor, sepsis, and pulmonary embolism are diagnoses that must be entertained, this acid-base disturbance should create a sense of urgency on the part of the provider to make a diagnosis and provide treatment. Attributing hyperventilation to anxiety, stress, or pain should be a diagnosis by default.

Central Line–Associated Bloodstream Infections

Anthony J. Baldea, Jr., MD, and
Christine S. Cocanour, MD, FACS, FCCM

INTRODUCTION

Central venous catheters (CVCs) are indispensible to the care of surgical patients. Fluid and blood product administration, hemodynamic monitoring, and dispensation of high-tonicity solutions such as antibiotics, vasopressors, and total parenteral nutrition are common indications for the approximately 7 million CVCs placed annually in the United States alone. One potential drawback associated with CVCs is that these indwelling devices provide a route for microorganisms to gain access to a patient's bloodstream. Bacteremia from colonization and subsequent infection from CVCs is termed catheter-related bloodstream infection (CRBSI). This diagnosis is problematic because whether the bloodstream infection (BSI) is from the central line or from another source can be difficult to establish; therefore, simpler definitions are used for surveillance. Central line–associated bloodstream infection (CLABSI) is the term used by the Centers for Disease Control's (CDC's) National Healthcare Safety Network and is defined as a BSI in a patient who had a central line within 48 hours before the development of the BSI and in whom no other source of infection is found. CLABSI is the most prevalent nosocomial infection, with an estimated 41,000 infections occurring in U.S. hospitals each year.

CLABSI is a significant burden on our healthcare system; it is associated with increased intensive care unit (ICU) and hospital length of stay (LOS) and higher mortality. A significant associated economic burden also exists, as each CLABSI is estimated to add an attributable cost of $5734 to $36,441 to the patient's hospitalization. Beginning October 1, 2008, the Center for Medicare and Medicaid Services (CMS) considers CLABSI to be a "never" event and refuses to pay for any associated additional healthcare costs. This has led to a heightened national focus on decreasing CLABSI, with significant progress being made. From 2001 to 2009, the incidence rate of CLABSI in ICU cases dropped 58%. With the continued emphasis on eliminating the adverse clinical sequelae and decreasing the financial burden that accrues from the development of nosocomial infections, the importance of understanding how to prevent, properly diagnose, and adequately treat CLABSI becomes paramount to surgical practice. This chapter focuses on the prevention and clinical management of CLABSI in short-term, nontunneled CVCs.

PREVENTION

Sixty-five percent to 70% of CLABSI cases are estimated to be preventable with the application of current evidence-based strategies. Many institutions have implemented "central line insertion and maintenance" bundles in an attempt to decrease CLABSI rates. The implementation of these catheter-care bundles has led to promising results, with a more than 50% reduction in CLABSI rates. These evidence-based bundles focus on basic concepts: maintenance of sterile conditions during insertion of CVCs, recommendations for site of insertion and catheter selection, optimization of postinsertion catheter care, appropriate catheter surveillance, and comprehensive education of the entire healthcare team. The following prevention guidelines are specifically of interest to the surgeon. For a complete set of recommendations, please see the CDC's 2011 Guidelines for the Prevention of Intravascular Catheter-Related Infections.

Hand Hygiene

Perhaps the most overlooked method of preventing CLABSI is also the simplest: hand washing with conventional soap and water or with alcohol-based foams or gels before the procedure. Despite the repeated emphasis in the literature and constant reminders from hospital administration, physicians consistently show poor compliance with basic hand hygiene, with an estimated 32% rate of appropriate hand-washing technique and frequency among physicians.

Skin Preparation

Minimization of CVC contamination at the time of catheter placement is critical. A key component of this process is skin preparation. Multiple studies have shown that the preferred agent for skin antisepsis is a greater than 0.5% chlorhexidine preparation with alcohol, which has an approximate 50% reduction in CLABSI rates when compared with the use of alcohol-based povidone-iodine solutions. The site should be scrubbed and allowed to dry for at least 30 seconds or according to the manufacturer's recommendation before proceeding with venipuncture.

Full Barrier Precautions

The placement of a CVC should entail the same sterile precautions that are followed in the operating room. The use of full barrier precautions (consisting of a mask, cap, sterile gloves, sterile gown, and a sterile full body drape) lowers CLABSI rates dramatically. The cost effectiveness of this strategy has been proven because the costs associated with purchasing these barrier supplies are more than offset by the savings accrued from CLABSI prevention.

Choice of Insertion Site

The subclavian, the internal jugular, and the femoral veins are the primary sites of CVC placement. In choice of a site, the benefits of use of that site must be weighed against the risk of infectious complications and the risk for mechanical complications such as pneumothorax, subclavian artery puncture, subclavian vein laceration, subclavian vein stenosis, hemothorax, thrombosis, air embolism, and catheter misplacement. CLABSI rates are lowest for short-term, nontunneled CVCs, when the chosen insertion site is the subclavian vein. Because the density of skin flora is a major risk factor for CRBSI, the femoral vein should be avoided in adults as it has a high colonization rate when compared with the internal jugular or subclavian vein. In addition, catheters placed in the femoral vein are associated with a higher risk of deep venous thrombosis.

The use of ultrasound scan guidance for the placement of CVCs is now recommended; its use substantially decreases mechanical complications and the number of attempts required for cannulation.

Catheter Selection

The choice of CVC has several potentially important implications on CLABSI rates. In general, one should select the CVC with the

minimal number of lumens essential for patient management because infection rates increase with an increased number of catheter lumens. A chlorhexidine/silver sulfadiazine or minocycline/rifampin-impregnated catheter is recommended whenever the catheter is expected to be in place for more than 5 days; both have been shown to decrease CLABSI rates.

Catheter Care

Sterile gauze or a sterile, transparent, semipermeable dressing can be used to cover the CVC site to minimize colonization. If the dressing becomes damp, loosened, or soiled, it should be changed. Routine dressing changes for short-term CVCs should be performed every 2 days for gauze dressings or at least every 7 days for transparent dressings. The use of a chlorhexidine-impregnated sponge placed at the skin insertion site can further decrease the risk for CRBSI.

Topical and systemic antibiotics should not be used for the sole purpose of CLABSI prophylaxis because the former is associated with fungal overgrowth and both are associated with promoting antimicrobial resistance.

Daily skin cleansing with 2% chlorhexidine rather than bathing with soap and water significantly decreases CLABSI rates.

Daily Assessment of Central Venous Catheter Necessity

Because the risk of CLABSI rises the longer that the catheter is in place, CVCs that are no longer essential to patient care should be removed as soon as possible. To accomplish this goal, daily assessment of the necessity of the CVC should be made by the surgical team. Catheter tip cultures do not need to be routinely obtained on removal.

Replacement of Central Venous Catheters

The routine replacement of CVCs that are functioning and have no local or systemic signs of infection is not necessary. Although this practice has been advocated to decrease CLABSI rates in the very high-risk population of adult burn patients, the same results have not been replicated in other critically ill patients; in fact, routine replacement increases CLABSI rates.

Catheter insertion over a guidewire should only be performed in replacement of a malfunctioning catheter, in exchange of a pulmonary artery catheter for a CVC, or in someone with difficult access in which the risk of complications from a new puncture is greater than the risk of infection. This technique is associated with a significantly lower rate of mechanical complications. Guidewire exchange should not be performed in those patients with CRBSI because the source of infection is often colonization of the insertion tract.

DIAGNOSIS AND TREATMENT

The most sensitive clinical finding of CRBSI is fever; this, however, has very poor specificity. Purulence and inflammation around the catheter insertion site is more specific but has poor sensitivity. A definitive diagnosis of CRBSI requires that peripheral blood cultures grow the same organism as that grown from a catheter tip or from quantitative catheter and peripherally obtained cultures of differential time to positivity criteria. Given the lack of reliable clinical indicators, a high index of suspicion of CRBSI in the proper clinical scenario is mandatory to initiate the workup, confirm the diagnosis, and implement an appropriate treatment strategy.

Diagnostic Workup

The suspicion of CRBSI should prompt the collection of peripheral blood cultures before antimicrobial therapy is started. If sufficient suspicion exists that the CVC is the source of infection, it should be removed and the distal 5 cm of the catheter tip sent for culture. The preferred method of microbiologic analysis of short-term CVCs is the roll plate technique with semiquantitative culture. Growth of greater than 15 colony-forming units (CFUs) from this segment of catheter is indicative of catheter colonization. A CRBSI is present when the same organism grows from both the peripheral blood and the catheter tip. Clinical improvement within 24 hours of catheter removal suggests that the catheter was the source of infection, but without positive cultures, it is not proven.

When it is unclear whether the CVC is the source of infection, and its removal is not desirable, quantitative blood cultures should be obtained, one from a peripheral vein and one from the CVC. CRBSI is diagnosed if the bacterial count from the catheter-drawn blood is threefold greater than that from the peripheral blood. If the laboratory has the ability to perform differential time to positivity (DTP), a CRBSI is defined when the growth of microbes from the CVC-drawn blood occurs at least 2 hours before the growth of microbes from the peripherally drawn blood. The suspicion of CLABSI should be heightened in a patient with no other obvious source of infection and multiple positive blood cultures.

The organisms that most commonly cause CLABSI are: *Staphylococcus aureus*, coagulase-negative *Staphylococcus* species, *Candida* species, and enteric gram-negative bacilli. The presence of common skin flora on only one blood culture typically represents a contaminated specimen and does not necessarily mandate immediate treatment.

Catheter Removal

A dilemma arises when a patient with a CVC has clinical signs of infection but whether the CVC is the cause is not clear. The decision to remove the catheter is made based on the clinical status of the patient and the appearance of the catheter insertion site. If a patient with a CVC has development of severe hemodynamic decompensation or signs of end organ failure in the setting of no other identified source of infection, the most prudent strategy is to obtain blood cultures, remove the CVC, culture the catheter tip, and start empiric antibiotics. In patients with severe immunocompromise, the catheter should likewise be removed if a CRBSI is suspected. If the insertion site has purulent drainage or is severely inflamed, the catheter should be removed. If the patient does not have the aforementioned clinical signs and also has no identified source of infection, the catheter may be left in place while awaiting the results of the blood cultures as described previously. In a study by Rijnders and colleagues in 2004, this "watchful waiting" strategy led to a 62% reduction in unnecessary catheter removal, without any significant changes in hospital length of stay or mortality.

Empiric Antimicrobial Selection

In the setting of a patient with a septic or neutropenic condition with suspected CRBSI, prompt initiation of appropriate empiric antimicrobials and removal of the CVC are essential to improving outcomes. In most healthcare settings, vancomycin is the preferred empiric antibiotic because of the high incidence of methicillin-resistant *S. aureus* (MRSA). In institutions that have a high percentage of MRSA isolates with a vancomycin minimum inhibitory concentration (MIC) value of more than 2 μg/mL or when the use of vancomycin is contraindicated, an alternative antibiotic, such as daptomycin, should be selected. Empiric antibiotic coverage for multidrug-resistant gram-negative bacilli (such as *Pseudomonas*

aeruginosa) should be added for patients with profound neutropenia, severely ill patients with sepsis, patients with femoral CVCs, and patients known to have colonization with these pathogens. To increase the likelihood of appropriate empiric antimicrobial therapy, the broad-spectrum antibiotic of choice in this setting should be selected based on the institution's unit-specific antibiogram and the susceptibility patterns of the organisms colonizing each individual patient. In addition, empiric therapy for suspected CRBSI from candidemia should be added if the patient has any of the following risk factors: prolonged use of broad-spectrum antibiotics, use of total parenteral nutrition, history of solid-organ or bone marrow transplant, presence of a femoral CVC, or use of total parenteral nutrition. To minimize the development of multidrug-resistant organisms, the cornerstone of treatment is to initiate broad-spectrum empiric antimicrobial coverage and promptly deescalate this therapy as soon as culture speciation and susceptibilities are known.

Therapy of Specific Pathogens

The diagnostic workup and management of a patient with a CRBSI depends on which specific pathogen is identified. The recommended duration of antimicrobial therapy varies depending on the pathogen, patient factors, and any associated complications from the bacteremia.

Coagulase-Negative Staphylococcus Species

Coagulase-negative *Staphylococcus* species commonly colonize the skin and represent the most common cause of CRBSI. Because the ubiquitous skin colonization with *Staphylococcus* species leads to high rates of contaminated blood cultures, whether a positive blood culture indicates a true CRBSI or contamination is difficult to tell. A high proportion of positive blood cultures drawn from multiple sites is indicative of a true coagulase-negative staphylococci CRBSI. Treatment for patients with an uncomplicated coagulase-negative staphylococci CRBSI consists of catheter removal and antibiotics given for 5 to 7 days. Vancomycin is the preferred antibiotic because most coagulase-negative staphylococci are methicillin resistant. Alternatively, in patients without intravascular or orthopedic hardware, the catheter is removed and the patient is observed without antibiotics. Additional blood cultures are obtained after catheter removal to confirm that bacteremia has resolved.

The presence of persistent bacteremia despite CVC removal should prompt further diagnostic investigation for other sources (such as endocarditis and septic thrombophlebitis). In the setting in which it is deemed clinically mandatory to keep the CVC in place and the patient has a suspected coagulase-negative *Staphylococcus* CLABSI, antibiotic catheter lock therapy is an option. This approach involves instillation of an antibiotic-heparin solution into the catheter lumen without removal of the CVC. This method, in conjunction with a longer course (10 to 14 days) of systemic antibiotic therapy, clears approximately 80% of coagulase-negative *Staphylococcus* infections without removal of the CVC. Failure of this approach to appropriately resolve the bacteremia should lead to CVC removal.

Staphylococcus Aureus

S. aureus bacteremia has a 25% to 30% risk of hematogenous complications, including infective endocarditis and other deep tissue infections. Failure to remove the CVC in the setting of *S. aureus* bacteremia and suspected CLABSI leads to delayed response to therapy, a higher relapse rate, and increased risk of complications. The treatment of uncomplicated *S. aureus* CRBSI is to remove the CVC and treat with systemic targeted antibiotic therapy for a course of at least 14 days. The strongest predictor of development of a complication from *S. aureus* CLABSI is failure of the bacteremia or fevers to resolve within 72 hours of instituting these measures. In this scenario, endocarditis should be suspected, and a transesophageal echocardiogram should be performed. Other diagnoses that should likewise be entertained are suppurative thrombophlebitis and osteomyelitis. In the situation of complicated *S. aureus* CLABSI, the duration of antibiotic therapy should be expanded to 4 to 6 weeks.

Gram-Negative Bacilli and Other Bacterial Species

Although the usual sources of gram-negative bacillary bacteremia are noncatheter sources (i.e., urinary tract infection, intraabdominal infection, pneumonia), the rate of gram-negative bacillus-related CLABSI appears to be increasing, representing a prevalence rate of up to 40% of all CLABSI in some series. This trend is thought to result from increased rates of solid organ transplants, improved care of chronically ill patients with immunocompromise, and changes in antibiotic utilization patterns. Catheter retention correlates with increased rates of treatment failure and risk of recurrent bacteremia, and CVC removal leads to a 1% risk of relapse. Thus, the current Infectious Disease Society of America (IDSA) recommendation in the setting of a gram-negative bacillus-related CLABSI is to remove the CVC and treat with systemic antibiotics for at least 7 days.

The treatment recommendations are similar for *Enterococcus* CLABSI, with ampicillin as the antibiotic of choice. Vancomycin may be used for *Enterococcus* species resistant to ampicillin, with an agent like daptomycin reserved for vancomycin-resistant *Enterococcus* species. For less-virulent bacterial species that are difficult to eradicate (i.e., *Bacillus*, Propionibacteria, *Corynebacterium*, *Micrococcus* species), the general recommendation (after contamination is ruled out with multiple positive blood cultures) is to likewise remove the CVC and treat with targeted systemic antibiotics for at least 7 days.

Candida Species

For patients with CLABSI and candidemia, prompt CVC removal has consistently been shown to decrease CLABSI-related mortality. The choice of antifungal agent depends on the species of *Candida*. Fluconazole is the agent of choice for most *Candida* species. It is preferred over amphotericin B because of an enhanced safety profile and equivalent treatment rates. In institutions with increased prevalence of fluconazole-resistant Candidal species, such as *Candida glabrata* and *Candida krusei*, the most efficacious and safest antifungal agent is an echinocandin (i.e., caspofungin). The current IDSA-approved treatment recommendation of uncomplicated catheter-related candidemia is to remove the CVC and initiate systemic antifungal therapy for at least 14 days after the first negative blood culture. In the setting of complicated candidemia, such as association with endocarditis or septic thrombophlebitis, the duration of antifungal treatment is extended to 4 to 6 weeks.

SUMMARY

Central venous catheters are commonly used instruments for complex, critically ill surgical patients. To minimize the negative sequelae associated with central line–associated bloodstream infections, strict adherence of all healthcare workers to simple, preventative measures is essential as is daily assessment of catheter necessity. A high index of suspicion regarding the identification of a central line–associated bloodstream infection is paramount because the signs and symptoms are generally nonspecific. Diagnosis is confirmed with the same organism harvested from multiple blood cultures and the catheter tip culture. The cornerstone of treatment of central line–associated bloodstream infection is timely diagnosis, catheter removal, prompt initiation of appropriate antimicrobial therapy, and deescalation of therapy once the susceptibility pattern of the offending organism is known.

The Septic Response

William G. Cioffi, Jr., MD, and Michael D. Connolly, MD

Sepsis is the dysregulated inflammatory response caused by infection. It is one of the most common causes of admission to an intensive care unit (ICU) and is a leading cause of death in patients in ICUs around the world. The incidence of sepsis continues to increase, and despite a significant amount of both clinical and basic science research, treatment of severe sepsis and septic shock remains a challenge for practitioners.

DEFINITION

Sepsis and the continuum of severe sepsis and septic shock were defined during a consensus conference in 1991, and the definitions were further revised during the International Sepsis Definitions Conference in 2001, sponsored by multiple international critical care and infection societies. These definitions were created to assist clinicians in recognizing sepsis at a patient's bedside and to more clearly define sepsis for future research:

- Systemic inflammatory response syndrome (SIRS) is the dysregulated inflammatory response to a variety of noninfectious stimuli, such as trauma, burns, pancreatitis, surgery, and autoimmune disorders. SIRS is considered present when two or more of the following conditions exist:
 1. Temperature greater than 38°C or less than 36°C
 2. Heart rate greater than 90 beats/minute
 3. Hyperventilation, demonstrated by respiratory rate of more than 20 breaths/min or partial pressure of carbon dioxide ($Paco_2$) lower than 32 mm Hg
 4. White blood cell count greater than 12,000 cells/mm^3, fewer than 4,000 cells/mm^3, or consisting of more than 10% immature (bands) forms
- Sepsis: the presence of systemic inflammation resulting from infection
- Severe sepsis: sepsis resulting in tissue hypoperfusion or organ dysfunction
- Septic shock: sepsis with persistent hypotension despite adequate fluid resuscitation

EPIDEMIOLOGY

The incidence of sepsis has increased dramatically over the last thirty years; the most recent data show that 1.66 million cases of sepsis are diagnosed annually in the United States. This increase is the result of improved diagnosis, but it also reflects an increasingly older population, multidrug-resistant organisms, and increased use of immunosuppressive drugs. Despite an aggressive campaign to diagnose and treat sepsis, the mortality rate still ranges from 20% to 50%; thus, sepsis is the eleventh leading cause of death in the United States.

Several risk factors for sepsis have been identified, including age of 65 years or older, belonging to certain racial and ethnic groups, and the presence of comorbid conditions. Heart disease, diabetes, renal failure, chronic obstructive pulmonary disease, malignancy, and chronic substance abuse also increase the risk for sepsis.

PATHOPHYSIOLOGY

The septic response occurs when the inflammatory process caused by an infection exceeds the body's ability to maintain a local response. The inflammatory process, usually triggered by the innate immune system, responds to the invasion of tissue by bacteria by initiating a cascade of proinflammatory and antiinflammatory mediators. Numerous proinflammatory cytokines have been described (tumor necrosis factor α, interleukin [IL]–1, IL-2, IL-6, IL-8, IL-10) and have been targeted as potential sites of therapy in the treatment of sepsis, unfortunately without much success at this time.

The inflammatory response is mediated by macrophages, monocytes, and neutrophils that secrete more cytokines, including leukotrienes, prostaglandins, and platelet-activating factor. When the proinflammatory cytokines exceed the homeostatic mechanisms of the inflammatory cytokines, the local environment is no longer able to contain the inflammatory process, and the inflammatory response becomes systemic. This systemic response leads to alterations in the microcirculation, tissue ischemia, apoptosis, and other destructive processes that result in organ dysfunction and failure.

DIAGNOSIS

The diagnosis of sepsis requires a high index of suspicion, thorough documentation of the history, and a careful physical examination to identify possible sites of infection. Laboratory and imaging studies are then ordered as appropriate to assess for evidence of infection or organ dysfunction. Laboratory testing should include complete blood cell count, serum electrolyte measurements, liver panel, lactate measurement, arterial blood gas measurements, blood cultures, urinalysis and urine culture, and culture of potential sites of infection when indicated. Radiographic imaging is often valuable in localizing the site of infection and usually includes plain radiography, ultrasonography, or computed tomographic scan.

Despite myriad potential indicators of sepsis, no single test guarantees a diagnosis of sepsis; therefore, clinician judgment and

clinical evidence of systemic inflammation (Tables 1 and 2) are necessary to identify patients with sepsis. The use of biomarkers is being intensely investigated and may eventually improve this diagnostic accuracy.

TREATMENT

Early and aggressive treatment of patients is crucial to improving outcomes in patients with sepsis. Rivers and colleagues demonstrated that early goal-directed therapy (EGDT) could dramatically improve outcomes for patients presenting to the emergency department with evidence of sepsis. Patients should be quickly assessed for adequacy of the airway and breathing; appropriate intravenous access should be obtained; and fluids should be administered. Patients should be triaged to the appropriate level of care, which is frequently the ICU, but initial therapy should be started immediately and not reserved until the patient reaches the ICU (Tables 3 and 4).

Initial Resuscitation

Immediate resuscitation with isotonic fluid boluses should be started. In patients with evidence of hypoperfusion and hypovolemia, an initial fluid challenge of up to 30 mL/kg is recommended. After the initial fluid bolus, the patient's response to the fluid challenge is determined, and if the response is inadequate, further fluid boluses should be administered as needed. Adequacy of response is determined by both clinical factors and measured endpoints of resuscitation, if necessary. Initial goals should be for a mean arterial blood pressure of 65 mm Hg or higher or a urine output of 0.5 mL/kg/hr or higher. If the patient does not respond to the second fluid bolus, then the clinician should consider placing a central venous catheter to measure central venous pressure (CVP) and either superior vena cava oxygen saturation ($ScvO_2$) or mixed venous oxygen saturation (SvO_2). Resuscitation should then continue to achieve a CVP of 8 to 12 mm Hg and either $ScvO_2$ of 70% or SvO_2 of 65%. In patients in whom lactate levels are elevated as a result of tissue hypoperfusion, resuscitation to a normal lactate level may also be used as an adequate endpoint of resuscitation.

The fluid of choice during initial resuscitation should be an isotonic crystalloid. Hydroxyethyl starches should not be used because they have not been shown to improve mortality rates and have been shown to increase risk for acute kidney injury. In patients who require a large volume of resuscitative measures, albumin supplementation may be considered. Although the initial description of EGDT recommended transfusing to a hemoglobin level of 10 g/dL or higher, current recommendations support restricting blood transfusion to patients with a hemoglobin level lower than 7 g/dL.

TABLE 2: Signs of organ dysfunction and failure

Central nervous system	Encephalopathy Polyneuropathy/myopathy
Cardiac function	Tachycardia Tachyarrhythmias Myocardial depression
Pulmonary system	Acute respiratory failure Acute lung injury Acute respiratory distress syndrome
Renal function	Acute renal failure
Gastrointestinal system	Ileus/pseudo-obstruction Gastritis Acalculous cholecystitis Pancreatitis Gut ischemia
Liver	Cholestasis Ischemic hepatitis
Metabolic function	Hyperglycemia Hyperlipidemia
Hematologic function	Disseminated intravascular coagulation Thrombocytopenia
Immunologic function	Immune dysfunction
Endocrine system	Pituitary, adrenal, and thyroid dysfunction

Antimicrobial Therapy

Antimicrobial therapy targeting all likely pathogens should be administered as soon as possible, ideally within 1 hour, after the diagnosis of severe sepsis or septic shock. If possible, cultures of blood, urine, and other fluids, if necessary, should be obtained before administration of antibiotics, but the need for these specimens should not delay antibiotic therapy. Multiple studies have shown increased rates of mortality when antibiotic therapy is delayed in septic shock.

When selecting an appropriate antimicrobial regimen, practitioners must be aware of the antimicrobial resistance patterns at their

TABLE 3: Summary of recommendations and goals for care of the septic patient

Initial resuscitation diagnostics	MAP: >65 mm Hg CVP: 8-12 mm Hg UOP: >0.5 mL/kg/hr Hemoglobin: >10 g/dL History and physical examination, cultures, radiographic studies
Antibiotics	Broad-spectrum antibiotics against likely pathogens; adjust therapy when culture results are available
Source control	Surgical repair, resection or drainage of source of contamination, evacuation of infectious material
Vasopressors	MAP: >65; fluid resuscitation and arterial catheter required
Inotropes	Physiologic cardiac output; fluid resuscitation and PAC/echocardiography required
Steroids	For septic shock unresponsive to fluid resuscitation and vasopressors; may be beneficial in relative adrenal insufficiency
Blood transfusion	Hemoglobin of 10 g/dL for initial resuscitation for lactic acidosis, hemorrhage, and coronary ischemia; otherwise goal of 7–9 g/dL may be considered
Ventilation	Tidal volume of 6 mL/kg and plateau pressure <30 cm H_2O for ARDS
Glucose control	Serum glucose: 140-180 mg/dL; insulin infusion and frequent blood glucose monitoring may be required
Renal replacement	Intermittent hemodialysis for hemodynamically stable patients; consider continuous hemodialysis for hemodynamically unstable patients;
Prophylaxis	VTE: Mechanical compression devices and heparin or low-molecular-weight heparin; use cautiously in patients at risk for bleeding; consider inferior vena cava filter when heparin cannot be used Stress ulcer: histamine blocker or proton pump inhibitor VAP: Maintain head of bed >30 degrees in intubated patients

ARDS, Acute respiratory distress syndrome; *CVP,* central venous pressure; *MAP,* mean arterial blood pressure; *PAC,* pulmonary artery catheter; *UOP,* urine output; *VAP,* ventilator-associated pneumonia; *VTE,* venous thromboembolism.

institutions and the most likely causative organisms. Patients with prior exposure to antibiotics, prolonged history of hospitalization, or history of colononization or infection with resistant organisms are at the greatest risk for sepsis from resistant organisms. Empiric antifungal therapy should be started in immunocompromised patients, including those receiving chemotherapy, chronic steroids, or immunomodulators and those who have received organ transplants.

The antimicrobial regimen should be assessed daily to determine whether deescalation of therapy can safely be achieved. Deescalation limits organism resistance, reduces toxicity, and decreases the cost of therapy.

Hemodynamic Support

Vasopressor support should be instituted when patients continue to demonstrate hypotension or tissue hypoperfusion despite fluid resuscitation. The initial goal for mean arterial blood pressure should be at least 65 mm Hg because this pressure has been shown to preserve tissue perfusion. However, the optimal mean arterial blood pressure may then be individualized to the patient on the basis of response to resuscitation. Norepinephrine is the initial vasopressor of choice. In comparison with dopamine, norepinephrine causes fewer complications of tachycardia and may improve outcomes.

Vasopressin should be added as the second vasopressor when patients fail to respond adequately to norepinephrine. Patients with septic shock have been shown to have relatively low vasopressin levels, and the addition of vasopressin has been shown to improve blood pressure and decrease norepinephrine requirements. However, vasopressin should not be used as a single agent and should be used only at low doses (up to 0.03 U/min). Although vasopressin appears effective at supporting blood pressure in septic shock, studies have failed to show any survival benefit.

In patients with continued hypoperfusion despite adequate fluid resuscitation and blood pressure, the addition of an inotrope should be considered. Both dobutamine and milrinone can increase the cardiac output but have a high incidence of causing hypotension. Historically, inotropes were also used in an attempt to increase cardiac function to supranormal levels; however, this approach is no longer recommended.

Monitoring

In patients with severe sepsis and septic shock, vital signs and other markers of resuscitation must be monitored frequently. All patients should be monitored with simple noninvasive measures such as telemetry, pulse oximetry, and blood pressure cuff measurements. Depending on the patient's condition, a number of invasive monitors may be indicated and added in a stepwise manner as the patient's condition warrants.

A Foley catheter should be placed in all septic patients, except those who are anuric. Arterial catheterization should be performed in patients who require prolonged vasopressor therapy, in order to more accurately measure blood pressure. Although these two interventions carry risk for serious complications, their benefit outweighs their risk in the short term.

TABLE 4: Timeline of implementation of recommended diagnostic and therapeutic goals

Time	Resuscitation	Antimicrobials	Vasopressors/ inotropes	Monitoring	Specific therapy	Supportive therapy
1 hr	Initiate crystalloid fluid resuscitation (500 mL every 10-15 min)	Empiric, broad-spectrum, high-dose antimicrobials		Continuous ECG, arterial saturation, blood pressure and UOP		O_2; consider intubation and mechanical ventilation before overt respiratory distress
1–8 hr	Titrate fluid resuscitation to elimination of base deficit and normalization of serum lactate	Radiographic investigation for localization and delineation of infection source Source control if necessary	Norepinephrine if circulatory shock persists after adequate fluid resuscitation Inotropes if chloride level or SvO_2 is persistently decreased	ICU transfer with full monitoring support Arterial catheter assessment If shock persists with >2 L resuscitation, central venous line (goal: CVP ≥8 mm Hg)		Consider low-dose steroid therapy ± ACTH stimulation test
8–24 hr	Dynamic evaluation of resuscitative goals (on basis of clinical and invasive monitoring endpoints)		Consider vasopressin if shock is refractory to norepinephrine	If pressor dependence persists after 3-5 L crystalloid infusion and CVP ≥8 mm Hg is achieved, suspect intravascular volume depletion or limited cardiovascular reserves, echocardiography, or PAC placement (initial goal: PCWP, 12-15 mm Hg)	Consider initiation of drotrecogin alfa if single organ fails and APACHE II score ≥25, or two or more organ failures in absence of APACHE score	Initiate enteral feeding Consider intensive insulin therapy
>24 hr		Narrow antimicrobial regimen, depending on isolation of pathogenic organisms or clinical improvement Reassess necessity for or efficacy of source control		Consider PAC in vasopressor-dependent patients with progressive respiratory, renal, or multiple-organ dysfunction		Intensive hemodialysis therapy for renal failure Low-pressure, volume-limited ventilation for ARDS

EGDT and the guidelines for surviving sepsis advocate for placement of a central venous catheter as a protocol for resuscitation in patients with evidence of tissue hypoperfusion. This catheter is used to reach a target CVP of 8 to 12 mm Hg and a target $ScvO_2$ of 70% or higher. Unfortunately, the value of CVP measurements in determining a patient's intravascular volume status remains controversial. A low CVP is probably indicative of a favorable response to volume resuscitation; however, in patients with normal to high CVP and in patients with abnormal cardiac function or pulmonary hypertension, CVP is likely to be an unreliable indicator of volume status. A pulmonary artery catheter is an even more invasive monitor that can provide more information about cardiac function than a central

venous catheter. The use of a pulmonary artery catheter has not been shown to improve outcome in septic patients and, in fact, may worsen outcomes.

The use of more dynamic indices of resuscitation is becoming more common. Arterial waveform analysis can be useful in intubated patients in sinus rhythm. Ultrasonography has become ubiquitous in the ICU, and it can be useful in determining a patient's volume status and cardiac function. Ultrasonography has the advantage of being noninvasive, but it is a static measure, therefore necessitating serial imaging Interpreting images is prone to variability in user skill.

Source Control

Rapid diagnosis and treatment of septic patients is crucial for a good outcome, but early resuscitation and supportive therapy must be accompanied by early identification of the source of infection. Failure to quickly identify a surgically correctable source of sepsis frequently leads to worsening sepsis and death. Implanted devices that are the potential source of sepsis should be removed if this is feasible. Patients with surgically correctable sources of infection (e.g., necrotizing soft tissue infections, peritonitis) should be taken to the operating room as soon as possible for eradication of the infectious source. Other infections may be amenable to percutaneous or endoscopic therapies (abdominal abscess, cholangitis).

SUPPORTIVE CARE

Ventilatory Support

Patients with sepsis frequently require mechanical ventilation because the sepsis increases the work of breathing or because mental status changes caused by infection can compromise the airway. Septic patients are at risk for developing acute respiratory distress syndrome (ARDS); therefore, ventilation of septic patients should follow the volume- and pressure-limited strategies used in patients with ARDS. Patients should be ventilated with a low tidal volume (6 mL/kg) and peak plateau pressures of 30 cm H_2O or lower. Positive end-expiratory pressure should be maintained to minimize alveolar damage from alveolar collapse at the end of expiration. Sepsis frequently progresses to severe ARDS, which may necessitate additional strategies such as recruitment maneuvers, prone positioning, advanced ventilatory modes, and extracorporeal membrane oxygenation.

Blood Products

Red blood cell transfusions during active resuscitation for sepsis-induced hypoperfusion are still a consideration during EGDT, but a more restrictive approach to transfusion is required once hypoperfusion has been corrected. Transfusion should be reserved for patients with hemoglobin levels lower than 7.0 g/dL, with active cardiac ischemia, or with poor oxygen delivery. Large studies have demonstrated that with more restrictive transfusion practices, outcomes have been similar or improved, even in patients with a history of cardiac disease. The reasons for improved outcomes probably depend on the multiple complications associated with transfusions, such as immunosuppression, acute lung injury, and transfusion reactions.

Corticosteroids

The adrenal glands and cortisol production are vital to the patient's response to stress and critical illness. Multiple investigators have evaluated the use of glucocorticoid supplementation during sepsis with mixed results; however, patients who remain in shock despite adequate fluid resuscitation and vasopressors appear to be the best candidates for hydrocortisone therapy. The cosyntropin stimulation test is no longer recommended, and hydrocortisone therapy should be started in patients with septic shock refractory to fluids and vasopressors. The hydrocortisone dosage should be 200 mg/day. Corticosteroids are not recommended in septic patients who are not in shock.

Glycemic Control

Hyperglycemia is associated with poor outcomes in critically ill patients; however, tight glucose control does not improve mortality rates and results in increased episodes of hypoglycemia. Blood glucose levels of 140 to 180 mg/dL should be the current target of therapy, with insulin therapy started for blood glucose levels higher than 180 mg/dL.

Renal Replacement Therapy

The incidence of acute kidney injury and renal failure in patients with sepsis remains high. The timing and intensity of renal replacement therapy have not been consistently shown to affect patient outcome, but early, intensive renal replacement may be helpful. In addition, no clear benefit of continuous renal replacement over intermittent hemodialysis has been shown. Therefore, recommendations for acute renal replacement therapy in septic patients should be similar to the indications in nonseptic patients.

Nutrition

In patients without contraindications to enteral nutrition (bowel obstruction, ileus, peritonitis), feedings should be started within 48 hours of diagnosis. Enteral delivery is preferred to parenteral nutrition when possible to decrease the risk of infection. In adequately nourished patients, deliberate low-calorie delivery in the first week, with titration to full goal only as tolerated, decreases diarrhea and infectious complications.

Chemical Prophylaxis

Patients with sepsis are at high risk for thrombotic events as a result of the inflammatory response and immobility. Chemoprophylaxis should be administered with daily subcutaneous low-molecular-weight heparin and intermittent pneumatic compression devices. Patients with decreased creatinine clearance should receive unfractionated heparin in place of low-molecular-weight heparin.

Prophylaxis of stress ulcers in vulnerable patients in the ICU has been shown to decrease gastrointestinal bleeding; therefore, septic patients with coagulopathy-related need for mechanical ventilation longer than 48 hours, with traumatic brain or spinal cord injury, with burns, or with recent upper gastrointestinal bleeding should receive prophylaxis with a proton pump inhibitor.

Activated Protein C

Recombinant human activated protein C (rhAPC) was introduced in 2001 after a large trial showed decreased rates of mortality among septic patients. Previous guidelines had recommended rhAPC in patients with severe sepsis and organ failure. However, more recent trials have failed to show a mortality benefit, and the drug has been withdrawn from the market.

Goals of Care

Despite improvements in care for septic patients, the mortality rate remains high, especially among patients in septic shock. An early discussion with the patient and family is imperative for clarifying appropriate expectations and goals of care. Family care conferences improve communication, improve family satisfaction, and, when necessary, facilitate end-of-life decision making.

SUMMARY

Sepsis is a common problem in surgical patients, and its incidence continues to increase. An early, aggressive treatment plan is vital to limiting organ dysfunction and improving patient outcomes.

Multiple Organ Dysfunction and Failure

Anne C. Mosenthal, MD, FACS

Multiple organ dysfunction syndrome (MODS) has paralleled the advances of critical care. A disease that is the direct result of a major physiologic insult and its resuscitation, it remains the most common cause of death in surgical intensive care units (ICUs). It is characterized by organ injury and/or failure that is distant from the primary cause of illness or insult, with clinical features of inflammation and immune dysfunction. Essentially the sine qua non of surgical critical illness, the syndrome is an artifact of the invention of the ICU and artificial life support systems. As our ability to reverse previously lethal insults and support failing organs continues to advance, the sequelae of extending life as well as the treatments themselves inevitably precipitate organ dysfunction. Despite many advances in critical care since the first description of MODS, few treatments for multiple organ failure have been identified, and therapy remains primarily supportive. Research in the risk factors for MODS has yielded more promise in identifying *prevention* strategies that are clinically applicable; strong evidence exists that advances in resuscitation, nutrition, transfusion, and ventilatory support can prevent MODS, ameliorate MODS, or shorten its duration. In the last decade these have clearly changed the epidemiology, outcome, and prognosis of MODS should it occur, but none can be identified as direct therapy. Survival to hospital discharge is increasingly possible, even with severe multiple organ failure, but the long-term sequelae from the syndrome are now being recognized as significant, with major disability, functional impairments, and up to 50% delayed mortality at 1 year.

HISTORY AND PATHOPHYSIOLOGY

A syndrome of organ failure was first described in the 1960s, shortly after the creation of ICUs helped patients to survive serious physiologic injury or sepsis. Baue coined the term "multiple organ system failure" in a landmark editorial in 1975, when he described the phenomenon of death in the ICU as a failure of multiple organ systems, often with uncontrolled infection. It was soon realized that multiple organ system failure was the final pathway to death after sepsis, systemic inflammatory response syndrome, or trauma, even if no infection could be identified, suggesting that a derangement of inflammation and immunity was the driving force with the syndrome. The clinical syndrome was generally defined as failure of two or more organ systems—pulmonary, renal, hepatic, cardiovascular, neurologic, or hematologic—with failure of more than three organs carrying a high risk of mortality. For the next 25 years, many studied this vexing syndrome, which was responsible for the majority of deaths in surgical ICUs, particularly after trauma, sepsis, and seemingly life-saving surgery. Attempts to identify the mechanisms and pathophysiology of MODS seemed to parallel the advances of surgical critical care. Studies identified microvascular thrombosis and ischemia of end organs as the histopathologic features of MODS. This, coupled with advances in hemodynamic monitoring that provided evidence of diminished oxygen delivery, suggested that global and regional hypoperfusion in shock and sepsis could be the final common pathway to MODS.

Although the oxygen delivery hypothesis was based on pathophysiologic evidence, an intense focus on measuring and maximizing oxygen delivery to supranormal levels to prevent multiple organ dysfunction did not ultimately translate into the hoped-for clinical benefit. The "gut-origin hypothesis" as described by Deitch and others suggested that MODS was the result of regional mesenteric hypoperfusion, mucosal ischemia, and loss of gut barrier function, leading to systemic immune dysfunction and inflammation. This led to the development of gut-targeted therapies that might preserve gut barrier function, including early enteral nutrition, nutritional supplements, glutamine, and selective decontamination of the digestive tract, to prevent multiple organ dysfunction. The two-hit hypothesis suggested that ongoing or secondary cellular hypoxia following an episode of shock or sepsis might be responsible for the derangements in inflammation and immune regulation. Mechanistic studies found that cellular hypoxia leading to targeted cell death or apoptosis, dysregulated immune and inflammatory cells, cytokine derangements at the cellular and tissue level, and endothelial cell damage in organ beds might be the mediators of MODS. While these mechanisms have been well characterized, their translation into clinical therapies has proved disappointing; chemotherapeutics targeting cytokines, protein C, and other mediators of MODS have never translated into significant improvements in mortality or patient outcomes in critical illness. More recently, it has been recognized that ICU interventions

themselves, while supporting organ function, can also precipitate MODS through barotrauma, endothelial injury, and predisposition to nosocomial infection. Currently, the mitochondrial dysfunction theory suggests that cellular hypoxia in shock or sepsis injures the mitochondrial cellular respiration process directly, leading to further derangements in oxidative metabolism, inflammation, and immunity.

CLINICAL PRESENTATION AND ORGAN SYSTEM MANAGEMENT

The clinical syndrome, while first described as multiple organ failure, has been redefined to multiple organ dysfunction, as the clinical presentation is now recognized to be a spectrum of organ derangements, from mild dysfunction to complete failure, the former of which can be reversible. Multiple scoring systems have been proposed in an effort to stratify the clinical severity, progression of disease, and prognosis. The most commonly used are the Marshall Multiple Organ Dysfunction Score (Table 1) and the Sequential Organ Failure Assessment (SOFA) score (Table 2). Each describes the clinical criteria across the spectrum for dysfunction to failure for six organ systems: pulmonary, renal, hepatic, central neurologic, cardiovascular, and hematologic. In addition, current understanding of each organ system dysfunction can be defined by organ-specific scoring systems, as exemplified by acute lung injury or acute kidney injury (Table 3). MODS also includes derangements of the endocrine system, metabolic system, immunologic system, and gastrointestinal system, which were not originally included in the description of the syndrome. These may present in a variety of ways that are clinically relevant, but they have not been systematically classified.

The clinical presentation of MODS begins at the time of physiologic insult and has an onset of organ dysfunction within 24 to 48 hours. The classic sequence of organ dysfunction typically begins with pulmonary dysfunction, followed by hepatic/gastrointestinal and then renal dysfunction, in that order. While it has long been held that once multiple organ failure has set in, high mortality is

TABLE 1: Multiple organ dysfunction (MOD) score

	Score

*Adrenergic agents are administered for at least 1 hour (doses given are in μg/kg/min).

†Renal SOFA was modified to exclude urine output.

TABLE 3: Risk, injury, failure, loss, and end-stage kidney disease (RIFLE) classification

Class	Glomerular filtration rate criteria	Urine output criteria
Risk	Serum creatinine ×1.5 over baseline	<0.5 mL/kg/hr × 6 hr
Injury	Serum creatinine ×2 over baseline	<0.5 mL/kg/hr × 12 hr
Failure	Serum creatinine ×3, or serum creatinine ≥4 mg/dL with an acute rise >0.5 mg/dL	<0.3 mL/kg/hr × 24 hr, or anuria × 12 hr
Loss	Persistent acute renal failure = complete loss of kidney function for >4 weeks	
End-stage kidney disease	End-stage kidney disease for >3 months	

For conversion of creatinine expressed in conventional units to SI units, multiply by 88.4. RIFLE class is determined based on the worst of either glomerular filtration criteria or urine output criteria. Glomerular filtration criteria are calculated as an increase of serum creatinine above the baseline serum creatinine level. Acute kidney injury should be both abrupt (within 1 to 7 days) and sustained (more than 24 hours). When the baseline serum creatinine is not known and patients are without a history of chronic kidney insufficiency, it is recommend to calculate a baseline serum creatinine using the Modification of Diet in Renal Disease equation for assessment of kidney function, assuming a glomerular filtration rate of 75 mL/min/1.73 m^2. When the baseline serum creatinine is elevated, an abrupt rise of at least 0.5 mg/dL to more than 4 mg/dL is all that is required to achieve the Failure class.

inevitable, in the current decade the epidemiology has changed; judicious management of early organ dysfunction can prevent its progression, and some of the process is reversible. Mortality from severe acute lung injury (acute respiratory distress syndrome; ARDS) has been improved with changes in ventilator management, which appear to prevent progression to full multiple organ failure. These gains have not been seen when multiple organ failure includes acute renal failure; despite advances in renal replacement therapies, mortality remains as high as it was 20 years ago. Thus, the duration, progression, and prognosis of multiple organ dysfunction still are directly proportional to the management of the original insult. When sepsis is the inciting event, early source control with appropriate surgical débridement and drainage of infection, targeted empiric antibiotic coverage within 6 hours of sepsis, and adequate resuscitation to restore oxygen delivery are evidence-based strategies for ameliorating MODS. In the setting of acute traumatic injury with hemorrhage, immediate restoration of blood volume with a 1:1 to 1.5:1 ratio of red blood cells to plasma and minimal crystalloid resuscitation is now the standard of care to mitigate the development and progression of MODS to organ failure.

PULMONARY DYSFUNCTION—ACUTE LUNG INJURY

Acute lung injury is the most common element of MODS and usually the first to present. It is characterized by impaired gas exchange, primarily hypoxemia, and is stratified by the ratio of partial pressure of oxygen to the fraction of inspired oxygen (P:F ratio) regardless of the degree of ventilator support. Adult respiratory distress syndrome, the most severe acute lung injury, is defined by P:F less than 100.

Therapy is aimed at maintaining oxygen saturation of greater than 92%, optimizing oxygen delivery, while minimizing toxicity of oxygen, barotrauma, and volutrauma, and minimizing risk of ventilator-associated pneumonia. Ventilatory support that includes positive-end expiratory pressure (PEEP) with low tidal volumes between 6 and 8 mL/kg ideal body weight (IBW) is the standard of care to both prevent and support MODS. This strategy, coupled with maintenance of airway pressures of less than 30 cm H_2O, has significantly reduced mortality from acute lung injury and reduced progression to full-blown ARDS and multiple organ failure.

ACUTE KIDNEY INJURY

Previously labeled *acute renal failure* or *renal dysfunction*, the full spectrum of acute kidney injury is now described. This includes reversible mild to moderate dysfunction up to severe renal failure, which has a high mortality and risk of permanent end-stage renal disease. The degree of acute kidney injury is defined by serum creatinine levels and urine output based on the RIFLE classification (see Table 3).

Therapy for acute kidney injury is primarily focused on maintaining renal perfusion to prevent microvascular damage and tubular necrosis and to avoid nephrotoxic medications. Once severe AKI has set in, continuous renal replacement therapy (CRRT) is the primary mode of support, as it can be used in the hemodynamically unstable patient, without anticoagulation if necessary. CRRT can ameliorate or mitigate severity of MODS in sepsis, pancreatitis, or shock due to rapid clearance of inflammatory mediators. However, hopes that it would improve outcome and mortality have not been borne out in clinical trials. Nor has it been shown to be superior to intermittent hemodialysis. Despite these many advances in renal replacement therapy, the mortality from AKI in the surgical ICU remains as high as it was 25 years ago.

Cardiovascular Dysfunction

The cardiovascular abnormalities of MODS are essentially the vascular features of systemic inflammatory and hypermetabolic state. These include hyperdynamic circulation with decreased peripheral vascular resistance, decreased regional blood flow to organ beds, increased capillary permeability, right ventricular cardiac depression, and diminished heart rate variability. Therapy is primarily supportive with judicious use of pressors, inotropes, and fluids to support physiology such that aerobic metabolism is maintained. Pressors should include norepinephrine or vasopressin; it is unclear if vasopressin has improved outcomes in this situation. This should be monitored and titrated to physiologic parameters such as urine output, central venous pressure, mean arterial pressure, and aerobic metabolism parameters such as mixed venous oxygen saturation or lactate clearance. There is no evidence that achieving supranormal physiology improves or prevents MODS, or that invasive hemodynamic monitoring, such as pulmonary artery catheterization, improves outcomes. Use of bedside echocardiography for hemodynamic

monitoring and titration of therapy holds significant promise, particularly in the setting of right heart failure, but the exact goals of therapy to improve outcome remain unclear. Marshall MODS score includes the PAR, or product of the heart rate times the ratio of atrial pressure to arterial pressure, as a measure of cardiovascular dysfunction, which can be used to monitor progression, but again, its use for prognosis and therapy has not been upheld.

HEPATIC DYSFUNCTION

The liver is classically the second organ system to fail after pulmonary dysfunction sets in. The pathophysiology is poorly understood, but again appears to be related to cellular hypoxia and ischemia, due to splanchnic vasoconstriction and hypoperfusion. Two syndromes are described: one, also known as "shock liver," is characterized by initial elevated transaminases, followed by hyperbilirubinemia, and then synthetic dysfunction with increased international normalized ration (INR). Depending on the severity of the initial insult, this can progress to severe hepatic failure. Treatment is entirely supportive and is focused on minimizing further hepatic damage by avoiding hepatotoxins, providing nutrition, and managing encephalopathy. A subtler form of hepatic dysfunction is more common and is characterized by mild hyperbilirubinemia, with or without cholestasis, but usually synthetic function is unaffected. In most cases, enteral nutrition is tolerated in patients with hepatic dysfunction, but if it is not, other causes of hyperbilirubinemia or jaundice should be sought. This includes biliary obstruction, acalculous cholecystitis, or pancreatitis.

CENTRAL NERVOUS SYSTEM DYSFUNCTION—DELIRIUM

It is now recognized that delirium and cognitive dysfunction in critical illness are the brain's manifestations of multiple organ dysfunction and are important markers of systemic illness and prognosis in MODS. While previously believed to be transient phenomena due primarily to medications, it is now clear from functional magnetic resonance imaging (MRI) studies that these are potentially permanent or long-lasting consequences of structural, physiologic, and functional changes in the brain that result from systemic injury, sepsis, and surgery. These dysfunctions are more likely and more severe if patients are elderly and have premorbid dementia, cognitive dysfunction, or substance abuse. The interaction of pain, anxiety, and sleeplessness, with the noisy environment of the ICU and the very medications used to address these issues, all clearly play a role in this complex syndrome. There are multiple strategies that can prevent or ameliorate brain dysfunction, but few have proven conclusively effective. These include pharmacologics such as atypical antipsychotics, minimizing exposure to benzodiazepines, and measures to promote sleep-wake cycles and early mobilization.

ENDOCRINE AND METABOLIC DYSFUNCTION

Derangements of the hypothalamic-pituitary axis and glucose and protein metabolism are common manifestations of MODS. Acute or chronic inflammation, injury, or surgery lead to hypermetabolism and a persistent catabolic state, which can last for months during and after critical illness. Despite this recognition, it is poorly understood whether these findings represent the driving force of MODS (and should be treated) or are merely side effects of underlying pathophysiology. The clinical presentation includes hyperglycemia, hypothyroidism, and hypoadrenocortical function. Laboratory studies will also reveal low growth hormone levels and testosterone levels. Therapeutic goals include maintaining glucose levels between 120 and 150 with insulin drip to minimize infectious complications, with the risk of hypoglycemia outweighing any benefits of tighter glucose control. Replacement of thyroid hormone and cortisol is of less clear benefit but should be entertained if a true hypothyroidism (low T3 or T4) is present. Replacement of growth hormone, testosterone, or androgens is not indicated in either physiologic or pharmacologic doses; in spite of abnormally low levels, replacement has been shown to be deleterious to patient outcomes.

THERAPEUTIC STRATEGIES—NUTRITION

Evidence-based treatments for MODS remain scarce. The mainstay of therapy is enteral nutrition for all patients, with organ-specific strategies such as low tidal volume ventilator management and a minimal transfusion strategy targeting hemoglobin of 7 gms/dL. Outcome of MODS is clearly improved by initiation of early (within 24 hours) enteral nutrition. Feeding the intestinal tract ameliorates the gut-driven inflammatory response in MODS. It is unclear if feeding the stomach is better or equivalent to feeding the small intestine. Enteral nutrition should provide 15 to 25 kcal/kg/day and 1.2 to 2 gram/kg/day protein, depending on the primary disease process, with sepsis and burns requiring higher calories and protein. Parenteral nutrition is second best, and while it provides calories and protein, it does not improve outcome in MODS in the same fashion, has increased infectious complications, and should be used only if enteral nutrition is not possible.

Specific nutrients provide immunotherapy beyond their basic nutritional functions and should be included in enteral formulae. Glutamine supports gut mucosa and improves outcome in MODS. Omega-3 fatty acids support immune function and decrease infectious complications in MODS, and they should be included in enteral nutrition. Supplementation of vitamins and minerals is important for wound healing, immune function, and support of the hypermetabolic state. This includes zinc, selenium, vitamin C, and folate. Some evidence suggests that pharmacologic doses of these vitamins are therapeutic as antioxidants and can prevent or ameliorate MODS, but this is not standard of care at this time.

PATIENT-CENTERED OUTCOMES AND PALLIATIVE CARE

Early goal-directed therapy, nutrition, and control of infection are the most important determinants of mortality outcome from MODS, although patient age and premorbid conditions also play a role. Despite many advances, mortality remains high, and long-term disability and poor quality of life are prevalent among survivors. Persistent MODS becomes chronic critical illness, requiring prolonged ICU stays or long-term care in skilled nursing facilities. Multiple studies have shown that patients with MODS have a very high symptom burden while in the ICU, including pain, anxiety, posttraumatic stress disorder, thirst, weakness, and fatigue. Evidence-based therapies directed at symptoms include continuous pharmacologic management of pain and anxiety with opioids, benzodiazepines, and management of procedural pain. Nonpharmacologic therapies are equally if not more important and include early mobilization with physical therapy, massage, maintenance of sleep-wake cycle with light therapy, and minimization of night stimulation.

While the mortality of MODS is high, predicting the outcome in any given patient is difficult, so discussions around goals of care and end-of-life decisions need to be started early with families. Strategies to improve communication among physicians, nurses, and family are

beneficial for many outcomes. A first family meeting within 72 hours of admission to the surgical ICU, regardless of prognosis, is standard of care and will decrease the use of nonbeneficial life support at the end of life, decrease conflict in decisions, and improve family satisfaction and bereavement outcomes.

SUMMARY

MODS is a systemic disease of inflammatory response that continues to change as ICU care advances. Despite these advances, the outcome from MODS remains poor, with a high mortality and a high long-term disability for survivors. Its management ultimately requires global therapies that address these systemic disturbances, with additional organ targeted therapies to improve outcome. Currently, surgical therapy is aimed at prevention of MODS with goal-directed therapy for sepsis, trauma, and other conditions. Once MODS develops, management is primarily supportive, both for the patient as a whole and for maintenance of specific organ function. Outcomes can be improved with focus on nutrition, ventilator strategies, early mobilization, and symptom relief.

Antibiotics for Critically Ill Patients

Vanessa P. Ho, MD, MPH, and
Philip S. Barie, MD, MBA, FIDSA, FCCM, FACS

Critically ill surgical patients are at risk for a variety of complicated infections that may lead to morbidity and mortality. Traditionally, surgical infections are those that necessitate surgery for treatment, such as surgical site infections (SSIs), complicated intra-abdominal infections (cIAIs), and skin or soft tissue infections (SSTIs). However, critically ill surgical patients are vulnerable to a variety of other nosocomial infections, including central line–associated bloodstream infections (CLABSIs), urinary tract infections (UTIs), and hospital-acquired/ventilator-associated pneumonia (HAP/VAP).

Antibiotics are the cornerstone of treatment for infection, but dosing in this patient population can be challenging because of day-to-day variations in fluid status, renal function, and hepatic function. In intensive care units (ICUs), this challenge is complicated further when infection is caused by bacteria that are resistant to antibiotics used commonly. A vicious cycle develops in which increasingly broad-spectrum antibiotics must be prescribed empirically to ensure that initial antibiotic treatment is adequate and pathogens acquire more resistance subsequently. Clinicians must be vigilant, accurate, and precise about the diagnosis and proper treatment of these infections, not only to treat patient diseases but also to prevent further development of antibiotic resistance.

DIAGNOSIS OF INFECTION AND EMPIRIC THERAPY

Infection may manifest via a variety of clinical signs and symptoms, including hypotension, tachycardia, tachypnea, confusion, rigors, skin lesions, oliguria, lactic acidosis, leukocytosis or leukopenia, and thrombocytopenia. Fever is usually the trigger for workup of a potential infection, although the definition is variable and some infected patients do not manifest a febrile response; some patients may even be hypothermic in response to infection. Clouding the clinical picture further, fever in a surgical patient is often a manifestation of a non-infectious state of inflammation. In the first 72 hours after surgery (unless surgery was performed to treat an infection), fever is more likely to be a result of atelectasis, venous thromboembolism, tissue ischemia, or adrenal insufficiency than infection, although patients may present with a coincident community-acquired infection, such as pneumonia (CAP). Once more than 96 hours have passed, fever is more likely to represent infection.

When infection is suspected, a careful, thorough, and expeditious search for the source must be performed. Antibiotics should not be given until this evaluation has occurred, including the collection of specimens for culture. Therefore, the evaluation must be performed immediately, as delay in antibiotic administration is associated with an increased risk of death. Current guidelines recommend that initial empiric antibiotic treatment should be administered within 1 hour after the initial suspicion of sepsis.

The patient should be examined for clinically evident infections, including the removal of surgical dressings for examination of incisions. If an incision is opened, a culture specimen should be obtained from the deep wound space (not superficially) to minimize isolation of contaminants. A chest x-ray is optional unless the patient has been ventilated mechanically or exhibits signs or symptoms of a pulmonary infection, such as an abnormal physical examination, tachypnea, pulmonary secretions, or abnormal arterial blood gases. In patients who have been ventilated mechanically, a chest x-ray and lower respiratory cultures should be obtained. Pulmonary disease in the early setting may result from aspiration of gastric contents or CAP. Urinalysis or culture is not mandatory unless a UTI is suspected (e.g., genitourinary trauma, posturologic surgery, urinary catheterization).

Blood cultures should be obtained from patients with any clinical suspicion of infection. These should be obtained via venipuncture, and at least 10 mL/bottle should be collected from adults to ensure adequate sampling. Two to three sets of cultures (two bottles/set)

should be performed from different sites, including one set from any indwelling vascular catheters. The cumulative yield of pathogens is optimized when three sets of blood cultures (10 to 15 mL blood/bottle) are drawn. Multiple sets of cultures allow differentiation between true pathogens and contaminants (e.g., if one of multiple cultures is positive for an organism found commonly on the skin, such as coagulase-negative *Staphylococcus* spp.), and a pathogen from a colonized catheter (i.e., if only the culture drawn from the catheter is positive, with negative peripheral [venipuncture] blood cultures). Fungal blood cultures should be obtained from patients who have received antibiotics recently or have immunosuppression or development of a hospital-acquired infection after a course of antimicrobial therapy.

Inappropriate initial therapy is associated with increased mortality, so empiric antibiotic therapy must be targeted appropriately and given in a dose sufficient to ensure bacterial killing. Deescalation to a narrower spectrum antibiotic should occur as soon as possible (if appropriate) on the basis of microbiologic data and clinical response. Pathogens that require empiric coverage depend on the suspected disease process, whether the infection is community-acquired or hospital-acquired, and whether the patient is likely to have multidrug-resistant (MDR) pathogens (defined as resistance to all agents of at least three classes; e.g., penicillins, cephalosporins, fluoroquinolones) present. Local antimicrobial resistance patterns must also be considered. A variety of agents are available for empiric therapy (Box 1); therapy should be chosen on the basis of clinical suspicion of the spectrum required (broad or targeted, gram-positive or gram-negative, antipseudomonal, antianaerobic) and knowledge of local patterns of susceptibility (antibiogram). Common nosocomial pathogens are presented in Table 1. If a nosocomial gram-positive pathogen is suspected (e.g., from an incision, central venous catheter, or VAP) or methicillin-resistant *Staphylococcus aureus* (MRSA) is endemic, empiric therapy with vancomycin or linezolid is warranted. Combination empiric therapy (e.g., double coverage for *Pseudomonas* pathogens) is recommended by some authorities, but evidence for efficacy is mixed. Some infections such as VAP or hospital-acquired cIAI require combination empiric therapy to cover both gram-positive and gram-negative pathogens. Specific considerations for the major antibiotic classes are shown in Table 2.

Duration of antimicrobial therapy continues to be debated because of the lack of class I evidence. If all cultures are negative, empiric antibiotic therapy should be stopped after 48 to 72 hours. Unnecessary antibiotic therapy increases the risk of future infection with MDR pathogens, so prolonged therapy in the absence of a pathogen is not recommended. If infection is evident, treatment is continued as indicated clinically. Every decision to start antibiotics should be accompanied by an a priori decision regarding duration of therapy; recommended treatment durations for various types of infection are given in Table 3. Clinical evidence of infection past the predetermined treatment endpoint could indicate new infection, development of resistance, or treatment failure with the current regimen. In cases such as these, the clinician should consider discontinuation of antibiotics and reevaluation for infection.

BOX 1: Antibacterial agents for empiric use

Antipseudomonal
Piperacillin-tazobactam
Cefepime, ceftazidime
Imipenem-cilastatin, meropenem, doripenem
Ciprofloxacin, levofloxacin (depending on local susceptibility patterns)
Aminoglycosides
Polymyxins (polymyxin B, colistin [polymyxin E])

Targeted-Spectrum
Gram-positive
Glycopeptide (e.g., vancomycin, telavancin)
Lipopeptide (e.g., daptomycin; not for known/suspected pneumonia)
Oxazolidinone (e.g., linezolid)
Vancomycin
Gram-negative
Aminoglycoside
Third-generation cephalosporin (except ceftriaxone)
Monobactam
Polymyxins (polymyxin B, colistin [polymyxin E])
Antianaerobic
Metronidazole

Broad-Spectrum
Piperacillin-tazobactam
Carbapenems (not ertapenem)
Fluoroquinolones (depending on local susceptibility patterns)
Tigecycline (plus an antipseudoomonal agent)

Antianaerobic
Metronidazole
Carbapenems
Beta-lactam/beta-lactamase combination agents
Tigecycline

Anti-MRSA
Ceftaroline
Daptomycin (not for use against pneumonia)
Minocycline (oral only)
Linezolid
Telavancin
Tigecycline (not in pregnancy or for children under the age of 8 y)
Vancomycin

MRSA, Methicillin-resistant *Staphylococcus aureus.*

PRINCIPLES OF ANTIBIOTIC THERAPY

Antimicrobial therapy is a mainstay of infection management, but these drugs must be used correctly. An understanding of basic principles of pharmacokinetics (PK) and pharmacodynamics (PD) is essential because each medication has specific attributes that affect its interaction with the patient and the pathogen. PK describes the fate of the drug once administered to a patient, including absorption, distribution, metabolism, and excretion. Basic concepts of PK include bioavailability, half-life, clearance, and volume of distribution. *Bioavailability* is the percentage of drug that reaches the systemic circulation; intravenous antibiotics are 100% bioavailable, but oral bioavailability depends on absorption, intestinal transit time, and hepatic metabolism. *Half-life* ($T_{1/2}$) is the time required for the serum drug concentration to reduce by one half. *Volume of distribution* (V_D) is the theoretic volume in which the total amount of drug needs to be distributed uniformly to produce the desired concentration of a drug. V_D can be increased by renal or liver failure and decreased in dehydration; reduced V_D causes a higher plasma drug concentration. *Clearance* is the volume of liquid from which drug is eliminated completely per unit of time, whether by tissue distribution or elimination via metabolism, excretion, or dialysis; knowledge of drug clearance is important for determining the dose of drug necessary to maintain a steady-state concentration. Hydrophilic antibiotics (e.g., aminoglycosides, beta-lactams, glycopeptides, and colistin [polymyxin E]) are affected by increased V_D and altered drug clearance. Lipophilic antibiotics (e.g., fluoroquinolones, macrolides, tigecycline, and lincosamides) are less susceptible to alterations in V_D but may have altered drug clearance in critically ill patients.

PD describes the effect of a drug on the patient or the pathogens and accounts for drug-patient, drug-microbe, and microbe-patient

TABLE 1: Common pathogens isolated from cases of healthcare-associated infections

Pathogen	Percentage	Most common site
Coagulase-negative *Staphylococcus*	15.3	Bloodstream
Staphylococcus aureus	14.5	Surgical site
Enterococcus spp.	12.1	Bloodstream
Candida spp.	10.7	Urinary tract
Escherichia coli	9.6	Urinary tract
Pseudomonas aeruginosa	7.9	Respiratory tract
Klebsiella pneumonia	5.8	Urinary tract
Enterobacter spp.	4.8	Respiratory tract
Acinetobacter baumannii	2.7	Respiratory tract
Klebsiella oxytoca	1.1	Respiratory tract
Other	15.6

interactions; antimicrobial agents are unique medications because the most important interaction is not between the patient and the drug but rather the microbe and the drug. This interaction can be affected by inoculum size, microbial physiology, and resistance mechanisms. The most important PD parameter to consider is the *minimal inhibitory concentration* (MIC), which is the lowest serum drug concentration that inhibits bacterial growth. Dosing strategies with both PK and PD reflect how different antibiotics work. In addition, some antibiotics may suppress bacterial growth at subinhibitory concentrations (postantibiotic effect [PAE]), which can allow the dosing interval to be extended.

Time-dependent bacterial killing with antibiotics requires the concentration of antibiotic to exceed the MIC for a certain proportion of the dosing interval; this is denoted as fT>MIC (proportion of time the plasma concentration is above the MIC). Beta-lactams and carbapenems are examples of time-dependent antibiotics. Concentration-dependent bacterial killing with antibiotics requires the peak concentration to be more than tenfold higher than the MIC; examples include aminoglycosides and polymyxin B. Bacterial killing with time-dependent, concentration-enhanced antibiotics is described by the area of the plasma concentration-time curve above the MIC (AUC); examples include fluoroquinolones, vancomycin, and clindamycin. Table 4 outlines which strategies should be used with specific drug classes and tactics to maximize effectiveness.

SPECIFIC CONSIDERATIONS

Specific circumstances are particularly relevant in the critically ill patient population. Postoperative HAP/VAP, urinary tract infections, CLABSI, and infection from MDR organisms are worthy of consideration.

Postoperative Pneumonia

Critically ill surgical patients are particularly susceptible to HAP/VAP, particularly if they need mechanical ventilation. VAP is defined as pneumonia that occurs at least 72 hours after intubation and is the most common infection that occurs in the ICU among surgical and trauma patients. The incidence of VAP increases with the duration of mechanical ventilation at a rate of 3% per day during the first 5 days, 2% per day during days 5 to 10, and 1% per day after that. Additional risk factors for VAP include age more than 60 years, acute respiratory distress syndrome, underlying pulmonary disease, impaired consciousness, poor nutrition, burn/trauma, blood transfusions, organ failure, supine positioning, large-volume gastric aspiration, sinusitis, and immune suppression.

Despite the high prevalence of VAP, the diagnosis is difficult to make because noninfectious processes may mimic pneumonia. As a result of the low specificity of clinical criteria, culture of the lower respiratory tract is mandatory in the ICU. The method of specimen collection (invasive or noninvasive) and specimen analysis (semiquantitative or quantitative) is debated. Invasive methods (bronchoalveolar lavage [BAL] and protected specimen brush [PSB]) collect samples via bronchoscopy and allow examination of the airway but are expensive and resource intensive. Noninvasive techniques include endotracheal suction aspiration, blinded plugged telescoping catheter, blinded PSB, and mini-BAL. Commonly used thresholds for quantitative culture are 10^3 colony-forming units (CFU)/mL for PSB, 10^4 CFU/mL for BAL, and 10^5 CFU/mL for endotracheal aspirate. Any threshold should be lowered by one order of magnitude if a patient received antibiotics before sample acquisition.

Organisms that may be pathogens in VAP when recovered from the airway include Pseudomonas *aeruginosa, Acinetobacter calcoaceticus-baumannii* complex, Enterobacteriaceae, *S. aureus*, and *Haemophilus influenzae.* Enterococci, viridans streptococci, coagulase-negative staphylococci, and *Candida* spp. are rare causes of HAP/VAP. If a patient was started on empiric therapy for HAP/VAP and the culture is negative for growth, antimicrobial therapy should be discontinued as long as the patient has not had clinical deterioration. If a susceptible pathogen is identified and the patient's condition is improving, the antibiotic may be deescalated to a narrower spectrum agent. If the culture shows a MDR pathogen, the broad-spectrum agent may be continued, or therapy can be escalated if the initial agent was not active against the pathogen.

Once pathogen-specific therapy is underway, the duration of therapy must be planned. Clinical and radiographic parameters typically lag the eradication of infection. A randomized, multicenter trial by Chastre and colleagues of 401 patients (VAP proved with bronchoscopy and quantitative microbiology) showed that an 8-day course (vs 15-day) of initially appropriate antimicrobial therapy is effective, provided that the patient's condition is stable; the exception was that a 15-day course was superior if the pathogen was a nonfermenting gram-negative bacillus (i.e., *P. aeruginosa, Stenotrophomonas maltophilia, Acinetobacter* spp.).

Patients who do show a response to therapy pose a dilemma. Inadequate therapy, misdiagnosis, or a pneumonia-related complication (e.g., empyema, lung abscess) must be considered. The evaluation should be repeated, including repeat quantitative cultures. Broadened empiric antibiotic coverage should be reinstituted thereafter until new data become available.

Urinary Tract Infection

When clinical evaluation suggests the urinary tract as a possible source of fever, a urine specimen collected with sterile technique from the catheter sampling port should be evaluated with direct microscopy, gram stain, and quantitative culture. Urine should arrive in the laboratory promptly to prevent multiplication of bacteria within the transport container, which might lead to the misdiagnosis of infection. Routine monitoring or surveillance cultures have minimal utility. Rapid dipstick tests, which detect leukocyte esterase and nitrite, are unreliable in the setting of catheter-related UTI. The

TABLE 2: Drug classes and dosing considerations

Drug class	Dosing considerations	Adjustment
Aminoglycosides	Examples: gentamicin, tobramicin, amikacin Require a concentration peak : MIC ratio >10 Loading dose is necessary Must check trough concentrations: 0.5-1 μg/mL recommended for gentamicin, tobramycin 5-10 μg/mL recommended for amikacin Not first-line because of toxicity Synergistic against *Pseudomonas*, *Enterococcus*, and MDR gram-negative pathogens Bactericidal Consider single daily-dose therapy to ensure high ratio (not validated in pregnant women, children, burn patients, elderly >70 y)	Renal
Beta-lactams	Includes penicillins, cephalosporins, monobactam (aztreonam), and carbapenems Efficacious when fT>MIC is >40% of dosing interval Activity dependent on class: penicillins have little activity against gram-negatives; cephalosporins should not be used against MDR pathogens, with the exception of possibly cefepime (which is more resistant to hydrolysis by beta-lactamases) Carbapenems (imipenem-cilastatin, meropenem, ertapenem, and doripenem) have the widest clinical utility of any antibiotics, including against gram-positives, gram-negatives, and anaerobes; ertapenem is not useful against *Pseudomonas*, *Acinetobacter*, *Enterobacter*, or MRSA	Variable
Cyclic lipopeptides	Example: daptomycin Bactericidal Concentration-dependent killing Active against aerobic and anaerobic gram-positives 4 mg/kg/d for nonbacteremic infections 6 mg/kg/d for bacteremia Not to be used for pneumonia	Renal
Fluoroquinolones	Examples: ciprofloxaxin, levofloxacin, moxifloxacin Excellent oral absorption and bioavailability Bactericidal Efficacy reflected with the AUC Some activity against gram-negatives, although resistance is increasing Activity against gram-positives is variable (best with moxifloxacin) Moxifloxacin has some antianaerobic activity Can cause cartilage and tendon damage Caution with prolonged QT interval (can precipitate dangerous dysrhythmias [torsades de pointes]) and with patients on warfarin (will markedly increase the International Normalized Ratio)	
Lipoglycopeptides	Examples: Vancomycin, telavancin Active against gram-positives Efficacy reflected by the AUC For vancomycin: Initial dose should be calculated as 15-20 mg/kg, not to exceed 2 g/dose; for patients with sepsis, meningitis, pneumonia, or endocarditis, a loading dose of 25-30 mg/kg may be considered Dose adjustments should be based on trough serum concentrations, obtained before the 4th dose For serious infections or MRSA, trough serum concentrations of 15-20 μg/mL are recommended For telavancin: 10 mg/kg over 60 min, given every 24 h	Renal
Polymyxins	Examples: polymyxin B, colistin Bacteriostatic and bactericidal Concentration-dependent killing Activity only against gram-negative pathogens Dosed as 1.5-2.5 mg/kg daily in divided doses (polymyxin B) Clinical response rates for respiratory infections are lower than other sites of infection Nephrotoxic and neurotoxic	Renal

TABLE 2: Drug classes and dosing considerations—cont'd

Drug class	Dosing considerations	Adjustment
Oxazolidinones	Example: linezolid Bacteriostatic (except against pneumococci) Active against gram-positives, including MSSA, MRSA, VRE, and penicillin-resistant *S. pneumonia* No dose adjustment for renal mild-moderate hepatic disease Nearly 100% oral bioavailability	No adjustment needed
Sulfonamides	Example: trimethoprim-sulfamethoxazole Bacteriostatic Oral absorption rapid and bioavailability nearly 100% Widespread resistance Active against gram-positives, sensitive gram-negatives Treatment of choice for community-acquired MRSA Trimethoprim-sulfamethoxazole is treatment of choice for *S. maltophilia*	Renal
Tetracyclines	Examples: doxycycline, minocycline, tigecycline (a glycylcycline derivative of minocycline) Bacteriostatic Active against anaerobes Tigecycline has broad-spectrum activity Covers MRSA, VRE, gram-negative pathogens including ESBL and MDR organisms Does not cover *Pseudomonas* spp. Not indicated for hospital-acquired pneumonia Active against anaerobes	Hepatic adjustment for tigecycline

AUC, Area of the plasma concentration-time curve above the MIC; *ESBL,* extended-spectrum beta-lactamase; *fT>MIC,* the proportion of time the plasma concentration is above the MIC; *MDR,* multidrug-resistant; *MIC,* minimum inhibitory concentration; *MRSA,* methicillin-resistant *Staphylococcus aureus; MSSA,* methicillin-sensitive *Staphylococcus aureus*; *VRE,* vancomycin-resistant *Enterococcus.*

TABLE 3: Current recommendations for duration of therapy for selected serious infections

Bacterial Meningitis	
Gram-negative bacilli (e.g., postoperative)	21 d
Central Line–Associated Bloodstream Infection	
Coagulase-negative *Staphylococcus*	5-7 d
S. aureus	14 d-6 w (for persistent bacteremia)
Enterococcus	7-14 d
Gram-negative bacilli	7-14 d
Candida spp.	14 d after last positive culture
Complicated Intra-abdominal Infection	**4-7 d**
Pneumonia	
Community-acquired pneumonia	≤5 d
Ventilator-associated pneumonia	7 d
Nonfermenting gram-negative bacilli	14 d
Other bacteria	7 d

leukocyte esterase test correlates with the degree of pyuria, which may or may not be present in a catheter-related UTI. The nitrite test reflects Enterobacteriaceae, which convert nitrate to nitrite, and is therefore unreliable to screen for *Enterococcus* spp., *Candida* spp., and *Staphylococcus* spp.

Catheter-associated bacteriuria or candiduria usually represents colonization, is rarely symptomatic, and is an unlikely cause of fever or secondary bloodstream infection, even in patients with immunocompromise, unless there is urinary tract obstruction; a history of recent urologic manipulation, injury, or surgery; or neutropenia. Traditional signs and symptoms, (e.g., dysuria, urgency, pelvic or flank pain, fever, and chills) that correlate with bacteriuria in patients without catheterization are reported rarely in ICU patients with documented catheter-associated bacteriuria or candiduria ($>10^5$ CFU/mL). In the ICU, most UTIs are related to urinary catheters and are caused by MDR gram-negative bacilli. For confirmed nonbacteremic catheter-associated UTI, a 5-day to 7-day course of treatment is sufficient.

Central Line–Associated Bloodstream Infection

Critically ill patients often need central venous access, but these catheters are prone to infection. Strict adherence to infection control, proper insertion, and catheter care are crucial for prevention; in addition, the need for the catheter should be reassessed daily. Optimal technique for insertion includes chlorhexidine skin preparation and maximal barrier protection (full-bed drape and cap, mask, sterile gown, and gloves for the operator). Catheters placed in suboptimal conditions (e.g., during an emergency resuscitation) should be removed and replaced as soon as the patient's condition permits. Catheters inserted in the femoral vein pose the highest risk of infection; subclavian vein catheters have the lowest risk. Tunneled catheters and peripherally inserted central catheters have lower risk of

TABLE 4: Pharmacokinetics of bacterial killing: implications for antibiotic dosing

Characteristic	Drug	Therapeutic goal	Tactic
Time-dependent (no or minimal PAE) fT > MIC > 70% ideal	Carbapenems Cephalosporins Linezolid Penicillins	Maintain drug concentration	Maximize duration of exposure with prolonged or continuous infusion*
Time-dependent, concentration-enhanced (with PAE) AUC:MIC_{24h} >125; AUC:MIC_{24h} > 400 for MDR pathogens	Clindamycin Glycylcyclines Macrolides Streptogramins Tetracyclins Vancomycin	Maximize effectiveness of bacteriostatic/weak bactericidal antibiotics with prolonged PAEs PAE is concentration-dependent	Maximize drug dosage consistent with avoidance of toxicity†
Concentration-dependent (with PAE)	Aminoglycosides Daptomycin Fluoroquinolones Ketolides Metronidazole Polymixins	PAE is concentration-dependent Achieve Cmax ([peak]:MIC) > 10	Maximize peak concentration‡

AUC, Area under the concentration-time curve; *Cmax,* maximal drug concentration (peak concentration); *fT,* proportion of time; *MDR,* multidrug-resistant; *MIC,* minimum inhibitory concentration; *PAE,* postantibiotic effect.

*Continuous or prolonged infusion of linezolid is not recommended because efficacy has not been established.

†Examples of maximized drug dosages include clindamycin 900 mg every 8 h rather than 600 mg every 6 h and vancomycin 15 mg/kg every 8 to 12 h for patients with normal renal function. Larger doses of tigecycline (a glycylcycline) and streptogramins (e.g., quinupristin/dalfopristin) may be limited by increased toxicity.

‡Examples of dosing to achieve maximized peak drug concentrations include single daily-dose aminoglycoside therapy and metronidazole 1 g every 12 h rather than 500 mg every 8 h. Prolonging the dosing interval is not recommended for polymyxins because of a negligible PAE.

infection than central venous catheters inserted percutaneously. Abrupt signs and symptoms of sepsis or shock should prompt suspicion of infection. Blood cultures positive for staphylococci or *Candida* spp. strongly suggest infection of a vascular catheter, which should prompt removal and culture of the catheter. For febrile patients without other signs of infection, there is no immediate need to remove or change all indwelling catheters. Catheter removal is prudent in a patient with a prosthetic heart valve or a fresh arterial graft and recommended for severe sepsis or septic shock, peripheral embolization, disseminated intravascular coagulation, and acute respiratory distress syndrome. Patients with persistent *S. aureus* bacteremia, or fungemia, should have endocarditis excluded with echocardiography.

MULTIDRUG-RESISTANT ORGANISMS

Patients in the ICU characteristically have multiple risk factors for infections with MDR bacteria (Box 2). The most important factor is a patient's prior antibiotic exposure; even a single dose of antibiotic increases the risk of infection with an organism resistant to that antibiotic, in that person, for up to 1 year. Partial, incomplete, or inappropriate therapy from mistargeted initial therapy or underdosing of antimicrobial agents is also associated with emergence of resistance. Proper infection control practice, in particular hand hygiene, is the most important infection control tactic to control spread of MDR organisms; increased hand-washing compliance decreases rates of infection.

S. aureus evolved rapidly to become resistant to penicillin and methicillin (MRSA). This evolution occurred, concurrently, within and outside of hospitals and created two distinct strains: hospital-acquired MRSA and community-acquired MRSA (CA-MRSA). Increasing prevalence of CA-MRSA in the hospital suggests that the phenotypic differences between these strains will become less marked over time. Vancomycin-resistant *S. aureus* remains rare, but treatment failures can occur with isolates that have intermediate sensitivity with MIC testing or susceptibility close to the MIC cut point (>1 μg/mL). High-dose vancomycin is recommended for MRSA infections; provided renal function is normal, a dose of 15 mg/kg intravenously (IV) every 8 to 12 hours is recommended to achieve a vancomycin trough concentration of ~15 μg/mL (measurement of peak concentration is unnecessary). Clinical failure with vancomycin or a MIC of more than 1 μg/mL should prompt treatment with a different antibiotic, such as high-dose daptomycin (alone or in combination therapy), linezolid, or ceftaroline.

Vancomycin-resistant *Enterococcus* (VRE) first emerged in 1987 and has become a common pathogen in hospitalized patients. Most strains of *Enterococcus faecalis* are inhibited (but not killed) with

BOX 2: Risk factors for acquisition of infection caused by multidrug-resistant pathogens

- Chronic indwelling catheter (vascular or urinary)
- Chronic renal replacement therapy (dialysis)
- Colonization with an MDR pathogen (e.g., nasal colonization with MRSA, fecal colonization with VRE)
- High total or cumulative antibiotic exposure
- High severity of illness/care in an intensive care unit
- Prolonged acute-care hospitalization
- Prolonged endotracheal intubation/mechanical ventilation
- Recent antibiotic therapy (within 3 mo)
- Recent hospitalization (within 3 mo)
- Recent surgery
- Residence in a skilled-nursing or extended-care facility
- Solid-organ or bone marrow transplantation

MDR, Multidrug-resistant; *MRSA,* methicillin-resistant *Staphylococcus aureus; VRE,* vancomycin-resistant *Enterococcus* spp.

attainable concentrations of standard antienterococcal agents, but *E. faecium* is increasingly resistant to vancomycin. VRE can be treated with daptomycin, linezolid, or tigecycline.

P. aeruginosa is a highly prevalent nonfermenting gram-negative bacillus that is a opportunistic pathogen. *P. aeruginosa* acquires resistance by a variety of mechanisms and can develop resistance, even an MDR phenotype, during therapy. Serial cultures and susceptibility testing should be performed during therapy, even when prior cultures have shown susceptible isolates. *Acinetobacter* spp., especially *A. baumannii*, is an aerobic nonfermenting gram-negative coccobacillus that infects debilitated hospitalized patients. They can survive on inanimate surfaces and pose a high risk for spread within hospitals. *Acinetobacter* spp. are innately resistant to many classes of antibiotics, including penicillins, cholamphenicol, and often aminoglycosides; they can also develop resistance to fluoroquinolones during therapy. Carbapenems are the gold-standard therapy, but resistance is increasing worldwide as a result of the increasing prevalence of carbapenemases.

Of further concern are bacteria that produce extended-spectrum beta-lactamase (ESBL). These bacteria are often not detected with automated systems because there is no single definitive marker for production of ESBL, but the phenotype can be found most commonly in the Enterobacteriaceae family (e.g., *Escherichia coli*, *Klebsiella pneumoniae, Proteus mirabilis*) and other bacteria, including *P. aeruginosa* and *Acinetobacter* spp. In general, an isolate can be suspected to produce ESBL when it shows in vitro susceptibility to cephamycins (i.e., cefoxitin) but resistance to third-generation cephalosporins and aztreonam. In addition, one should be suspicious if treatment of a gram-negative infection results in clinical failure despite reported susceptibility in vitro. ESBL-producing bacteria may be treated with a carbapenem, tigecycline, an aminoglycoside, a polymixin, or combination therapy. Proposed combination therapy regimens for MDR infections are shown in Box 3.

Knowledge of administration tactics can be advantageous in treatment of these pathogens. An increasing body of literature has supported the use of prolonged-infusion or continuous-infusion beta-lactams and carbapenems. As these antibiotics exhibit time-dependent bacterial killing, prolonged infusion allows the serum concentration to exceed the MIC for a longer period of time, improving efficacy against difficult-to-treat pathogens. Aminoglycosides, which exhibit concentration-dependent bacterial killing, can be given with single-daily dosing to ensure a high peak concentration and minimized toxicity. Although polymyxins are also concentration-dependent, they should not be given with single-daily dosing because there is negligible PAE and bacteria may reemerge when the antibiotic is not present.

High-dose daptomycin (e.g., 10 to 12 mg/kg/d) can be used for recalcitrant non-VAP gram-positive infections, provided that the small possibility of myositis is monitored with serial determinations of creatine phosphokinase. Infections caused by MDR gram-negative bacilli pose a major problem, and there are few options for therapy. Carbapenems, aminoglycosides, tigecycline, and polymyxins have useful activity against ESBL-producing pathogens; cefepime and piperacillin/tazobactam are less successful. MDR nonfermenting gram-negative bacilli and carbapenemase-producing Enterobacteriaceae may require therapy with a polymyxin or combination therapy.

BOX 3: Combination therapy options for the treatment of recalcitrant or highly resistant multidrug-resistant infections

Management of Persistent MRSA Bacteremia or Vancomycin Treatment Failures

Search for and Eradicate Foci of Infection, Including Débridement or Surgical Drainage, with

High-dose daptomycin (10-12 mg/kg/d)*
alone or in combination with:
Gentamicin 1 mg/kg/d IV, *or*
Rifampin 600 mg IV/PO daily *or* 300-450 mg IV/PO twice daily, *or*
Linezolid 600 mg IV/PO twice daily, *or*
Televancin 10 mg/kg IV once daily, *or*
Trimethoprim/sulfamethoxazole 5 mg/kg IV twice daily, *or*
A β-lactam antibiotic

If Reduced Susceptibility to Vancomycin or Daptomycin are Present†

Quinupristin/dalfopristin 7.5 mg/kg IV every 8 h, *or*
Linezolid 600 mg IV/PO twice daily, *or*
Televancin 10 mg/kg IV once daily, *or*
Trimethoprim/sulfamethoxazole 5 mg/kg IV twice daily

Management of MDR Gram-Negative Bacillary Infections When Effective Conventional Monotherapy is not Available Based on in Vitro Susceptibility Testing or is Contraindicated (e.g., Hypersensitivity)‡

High-dose, prolonged-infusion, or continuous-infusion carbapenem with or without a polymyxin or aminoglycoside
Dual carbapenem therapy
Aminoglycoside combined with a β-lactam agent (antipseudomonal cephalosporin or BLIC agent) or antipseudomonal fluoroquinolone, with or without rifampin
Aminoglycoside plus fosfomycin
Intravenous combined with inhalational aminoglycoside (for pneumonia)
Intravenous combined with inhalational polymyxin B plus a carbapenem, aminoglycoside, fluoroquinolone, or aztreonam (for pneumonia)
Antipseudomonal cephalosporin or BLIC agent combined with an antipseudomonal fluoroquinolone
Polymyxin combined with one or more of a carbapenem, aminoglycoside, fluoroquinolone, or β-lactam agent
Polymyxin or aminoglycoside plus tigecycline
Polymyxin combined with rifampin, an antipseudomonal carbapenem (or both), with or without azithromycin or doxycycline

BLIC, β-Lactamase inhibitor combination; *IV,* intravenous; *MDR,* multidrug-resistant; *MRSA,* methicillin-resistant *Staphylococcus aureus*; *PO,* oral.

ANTIBIOTIC TOXICITIES

Beta-Lactam Allergy

Allergic reaction is the most common toxicity of β-lactam antibiotics. The incidence rate is approximately 7 to 40 per 1000 treatment courses of penicillin. Parenteral therapy is more likely to provoke an allergic reaction. Most serious reactions occur in patients with no

history of penicillin allergy, simply because a history of penicillin allergy is sought commonly and reported by 5% to 20% of patients (far in excess of the true incidence rate). Patients with a prior reaction have a fourfold to sixfold increased risk of another reaction compared with the general population. However, this risk decreases with time, from 80% to 90% skin test reactivity at 2 months to 20% reactivity at 10 years. The risk of cross reactivity between penicillins and carbapenems and cephalosporins is ~5%, and there is negligible cross reactivity to monobactams.

Nephrotoxicity

Aminoglycosides cause nephrotoxicity as a result of ischemic toxicity to the renal proximal tubular cell (PTC). Ultimately, injury is manifested by necrosis of PTCs, reduction of the glomerular filtration rate, and decreased creatinine clearance, although this is usually reversible and progression to dialysis dependence is rare. Aminoglycoside nephrotoxicity is accentuated by frequent dosing, older age, sodium or volume depletion, acidemia, hypokalemia, hypomagnesemia, and coexistent liver disease. The risk of injury is ameliorated with single daily-dose therapy. The offending drug should be discontinued unless treatment is for a life-threatening infection.

Vancomycin nephrotoxicity is on the increase because of higher dosing and concurrent administration of other nephrotoxins. Nephrotoxicity of polymyxins may be an unavoidable consequence of the need to use an agent with known nephrotoxic potential to treat serious infections cause by MDR gram-negative bacilli when alternatives are few or none.

Ototoxicity

Aminoglycosides cause cochlear or vestibular toxicity that is usually irreversible and may develop after the cessation of therapy. Repeated exposures create cumulative risk. Most patients have development of either cochlear toxicity or a vestibular lesion; rarely are both organs injured. Few patients report hearing loss; yet when sought, the incidence rate of cochlear toxicity may be more than 60%. Clinical hearing loss may occur in 5% to 15% of patients. Ototoxicity caused directly by vancomycin is documented poorly in the literature. Hearing loss attributed to vancomycin is better described as neurotoxicity, manifesting as auditory nerve damage, tinnitus, and loss of acuity for high-frequency tones. Synergistic injury is possible with coadministration of other ototoxic drugs, especially aminoglycosides or furosemide. No correlation is found between ototoxicity and nephrotoxicity for drugs that cause both (e.g., aminoglycosides, vancomycin).

AVOIDANCE OF TOXICITY: ADJUSTMENT OF ANTIBIOTIC DOSAGE

Hepatic Insufficiency

The liver metabolizes and eliminates drugs that are too lipophilic for renal excretion. Drug dosing in hepatic insufficiency is complicated by insensitivity of clinical assessments to quantify liver function and changing metabolism as the degree of impairment fluctuates (e.g., resolving cholestasis). Changes in renal function with progressive hepatic impairment add considerable complexity. Renal blood flow is decreased in cirrhosis, and glomerular filtration is decreased in cirrhosis with ascites. Adverse drug reactions are more frequent with cirrhosis than with other forms of liver disease. The effect of liver disease on drug disposition is difficult to predict in individual patients; none of the usual tests of liver function can be used to guide dosage. Generally, a dosage reduction of up to 25% of the usual dose is considered if hepatic metabolism is 40% or less and renal function is normal. Greater dosage reductions (up to 50%) are advisable if the drug is administered chronically, there is a narrow therapeutic index, protein binding is low or reduced substantially (e.g., hypoalbuminemia), or the drug is excreted renally and renal function is impaired severely.

Renal Insufficiency

Renal drug elimination depends on glomerular filtration, tubular secretion, and reabsorption, any of which may be altered with renal dysfunction. Chronic kidney disease or acute kidney injury (AKI) may affect hepatic and renal drug metabolic pathways. Drugs with hepatic metabolism that is likely to be disrupted in renal failure include aztreonam, several cephalosporins, macrolides, and carbapenems. Accurate estimates of renal function are important in patients with mild-to-moderate renal dysfunction and should be measured when a patient's renal function is suspected to have changed. Critically ill patients with AKI who need renal replacement therapy pose a particular challenge because drug dosing can be difficult in the setting of fluctuating renal function and volume status. These patients may have increased V_D from capillary leakage and low protein binding and may need increased doses of antibiotics despite poor renal function; as the patient's condition improves and the volume is removed, doses may have to be adjusted again.

Administration of loading doses of antibiotics that will achieve the target serum concentration based on the expected V_D without adjustment for renal function is generally appropriate; subsequent doses should be based on available literature for specific antibiotics and renal therapy regimens. Doses and regimens should be reassessed frequently with serum concentrations whenever possible. The need to dose patients during or after a renal replacement therapy treatment must be borne in mind; during continuous renal replacement therapy, the estimated creatinine clearance is ~15 to 25 mL/min in addition to the patient's intrinsic clearance. Cefaclor, cefoperazone, ceftriaxone, chloramphenicol, clindamycin, cloxacillin and dicloxacillin, doxycycline, erythromycin, linezolid, methicillin/nafcillin/oxacillin, metronidazole, rifampin, and tigecycline do not require dosage reductions in renal failure.

Endocrine Changes in Critical Illness

Zvonimir Milas, MD, FACS,
Douglas F. Naylor, Jr., MD, FACS, FCCM, and
Kresimira Milas, MD, FACS

OVERVIEW

Critically ill patients treated either in surgical or medical intensive care units (ICUs) experience significant changes in endocrine system functions. All forms of critical illness, whether from injury, surgery, infection, or burns, are subject to these changes. Numerous hormones are released in the acute and prolonged phases of illness (Table 1) that shunt oxygen and substrates to crucial organs, affect the immune system, and lead to hypermetabolism and hypercatabolism that if excessive may exacerbate organ failure and death. This chapter focuses on the two most frequent clinical scenarios of endocrine imbalance with critical illness, adrenal insufficiency and hyperglycemia; highlights recent concepts of thyroid dysfunction as a marker of adverse prognosis in critically ill patients; and draws attention to iatrogenic or drug-induced endocrine disorders in the ICU setting.

ADRENAL INSUFFICIENCY

Adrenal insufficiency represents failure of the adrenal gland itself (primary adrenal insufficiency) or failure of the hypothalamus or pituitary gland to stimulate the adrenal cortex (secondary adrenal insufficiency). Other terms have also been applied to describe adrenal dysfunction in critically ill patients, including relative adrenal insufficiency (RAI) and critical illness–related corticosteroid insufficiency (CIRCI). Table 2 provides etiologies of adrenal insufficiency. Diseases that directly destroy adrenal function are rare; instead, conditions that induce severe stress can frequently precipitate adrenal failure. Adrenal insufficiency is difficult to recognize, and objective criteria of diagnosis have been notoriously difficult to establish. Many factors influence this: lack of pathognomonic features for hypoadrenalism, masking of presentation by other comorbidities, transient changes or treatments in the critical care setting, and inherent limitations to elicit symptoms and examination findings in critically ill patients. No universal, reliable, biochemical reference standard exists for diagnosis with plasma cortisol profiles. Thus, detection requires surgeons to think of the possibility of adrenal insufficiency, actively search for clues, and apply common sense towards management.

Normal function of the hypothalamic-pituitary-adrenal (HPA) axis is for the hypothalamus to secrete vasopressin and corticotrophin-releasing hormone (CRH), which in turn stimulate the anterior pituitary gland to release adrenal corticotrophic hormone (ACTH). Cortisol release from the adrenal is the primary effect of ACTH, as aldosterone and androgen secretion respond more to the renin-angiotensin system and pituitary gonadotropins than to ACTH. Cortisol secretion in normal conditions is pulsatile and has diurnal variation, with highest levels in the morning. Cortisol is not stored in the adrenal cortex. Rather, the HPA axis has a feedback loop in which hypercortisolism inhibits the axis and cortisol deficiency stimulates new cortisol production. The HPA axis activation is essential to normal physiologic responses to stress. The "flight or fight" response is the HPA axis diverting adrenal function from mineralocorticoid to glucocorticoid production. Extremes of stress, as encountered in the critical care setting and with sepsis, can alter all components of this process, including cortisol binding, diurnal variation of secretion, and the feedback loop. Mortality in the critical care setting is influenced both by very high and by very low levels of cortisol.

Primary adrenal insufficiency has the following clinical symptoms: weakness, anorexia, weight loss, depression, fatigue, nausea, vomiting, orthostatic hypotension, and craving for salt. Clinical signs include tachycardia, hypotension, fever, mental status change, amenorrhea, hypovolemia, and hyperpigmentation, which, as a result of ACTH elevation, is seen only with primary adrenal failure. Laboratory abnormalities include hyponatremia, hyperkalemia, hypoglycemia, eosinophilia, and normocytic normochromic anemia. Although similar in overall patterns, secondary adrenal insufficiency lacks hyperpigmentation and mineralocorticoid insufficiency, thus limiting losses of water, sodium, and chloride. The lack of volume and electrolyte disturbances may reduce gastrointestinal reported complaints but may present with hypoglycemia from alterations in glucocorticoid levels. As alluded to previously, classic findings may not always be present in the critically ill. Fever and hypotension may accompany many illnesses; treatments or comorbidities may mask other symptoms (e.g., aggressive electrolyte protocols may eliminate electrolyte laboratory abnormalities).

Most characteristics of adrenal insufficiency are hemodynamic instability and hyperinflammation despite fluid resuscitation and pressor support. Diagnosis is supported when hemodynamics improve on cortisol administration. Biochemical testing for the purposes of diagnosis can be difficult to interpret. For example, HPA reactivity is tested with measurement of a baseline random cortisol level, followed by administration of 250 mcg ACTH (cosyntropin) intravenously and assessment of cortisol levels at 30 and 60 minutes after infusion. The normal adrenal gland responds to stress by producing cortisol levels above 18 to 20 mcg/dL; this definition, however, is derived from high-dose ACTH stimulation or insulin-induced hypoglycemia in patients who are not stressed or critically ill. Another definition of 'normal' is derived from studies of factors correlating with poor outcomes in ICU patients: "normal" is when random serum cortisol levels exceed 25 mcg/dL or increase by more than 9 mcg/dL from baseline after stimulation. With this latter definition, 60% of patients with sepsis have inadequate adrenal responses. The varying definitions and uncertainty of diagnosis of adrenal insufficiency also account for widely different incidence rates reported in studies.

Significant variables still exist in assessment and management of adrenal insufficiency. The basic understanding of whether this is a transient, functional, or structural adrenal problem remains unknown. Differences are seen in sensitivity, accuracy, and reproducibility among commercially available cortisol assays, and factors such as protein binding, cortisol metabolism and clearance, and end-organ resistance can all affect cortisol measurements. High-dose 250-mcg ACTH is a supraphysiologic concentration that can cause normal cortisol response because it overcomes ACTH resistance in the adrenals without adequate functional reserves. But then, the adrenals may already be maximally stimulated at baseline in response to illness and are unable to show an increase of 9 mcg/dL. Outcomes of treatment protocols have varied with the use of high-dose (30 mg/kg) or moderate-dose (200-300 mg/d) glucocorticoid replacement.

A low-dose synthetic 1-mcg ACTH stimulation test may be more physiologic and sensitive for diagnosis. Another option is to test with this low-dose 1-mcg ACTH stimulation first and then use the high-dose 250-mcg ACTH only in patients without response. Data remain limited about the optimal method of biochemical confirmation of hypoadrenalism.

How should a surgeon logically approach this problem, given these limitations? Some generalizations are outlined in Figure 1 and can be supplemented with a review of the American College of Critical Care Medicine consensus statement on the diagnosis and

TABLE 1: Overview of the endocrine system response to acute and prolonged phase of critical illness and potential interventions

management of corticosteroid insufficiency and best practice parameters from the Endocrine Society.

Unexplained hemodynamic instability should raise suspicion of HPA dysfunction. Because administration of steroid therapy in the patient with refractory hypotension is a clinical decision, biochemical confirmation of adrenal failure may not always be required. Testing is recommended for patients with subtle signs of adrenal insufficiency. A random cortisol level of less than 25 mcg warrants high dose (250-mcg) ACTH testing. Failure of cortisol levels to increase by more than 9 mcg/dL over baseline after ACTH stimulation suggests adrenal insufficiency, and cortisol therapy should be implemented. A random cortisol level of less than 10 mcg/dL is also indicative of adrenal insufficiency and justifies glucocorticoid therapy.

If steroid replacement treatment is administered, whether immediately for a clinical decision of septic shock unresponsive to therapy or after testing, steroid therapy is given as follows. Patients with refractory hypotension should receive 200 to 300 mg/d of intravenous hydrocortisone in divided doses. Hydrocortisone should be continued for 7 days and then tapered slowly over the next 7 days. Mineralocorticoid supplementation with 50 mcg/d oral fludrocortisone is optional because the oral route may not be available and because there is sufficient mineralocorticoid activity with more than 50 mg/d hydrocortisone. Surgeons should have a low threshold to reinstitute steroids as needed if symptoms return after the taper.

It cannot be overstressed that hydrocortisone therapy is not warranted as an adjuvant therapy for sepsis without evidence of shock. Diagnostic testing and treatment should be started together in the patient with an unstable condition. Steroid therapy can be started after test results become available in the patient with a hemodynamically stable condition. Steroids are of no benefit in the treatment of sepsis without signs of shock or abnormal cortisol test results. Dexamethasone was once recommended as a bridge to treatment while

TABLE 2: Etiology of adrenal insufficiency in critical illness

Adrenal insufficiency	Etiology
Primary	Bilateral adrenal necrosis and hemorrhage caused by sepsis, hypotension, and hemorrhage
	Unmasking of chronic known or latent primary insufficiency
	Autoimmune adrenalitis in developed countries
	Tuberculous adrenalitis in developing countries
	Infectious diseases (fungal, viral, HIV)
Secondary	Irreversible anatomic damage to the hypothalamus or the pituitary gland
	Necrosis or hemorrhage in sepsis as a result of prolonged hypotension or coagulopathy
	Unmasking of chronic known or latent secondary adrenal insufficiency caused by sepsis
	Hypothalamic or pituitary tumors
	Chronic inflammation
	Congenital adrenocorticotropic hormone deficiency
	Drug therapy
	Inhibition of early increase in adrenocorticotropic hormone caused by high-dose diazepam and fentanyl administration
	Previous treatments with glucocorticoids including topical administration
	Inhibition of steroid genesis with a single dose of etomidate
	Accelerated metabolism of cortisol by ketoconazole and cyclosporine, clarithromycin, rifampicin, and antiepileptic drugs, such as phenytoin and phenobarbital

awaiting results; however, because it inhibits the HPA axis longer and can alter test or therapy outcomes, it is no longer advised. Similarly, a previous approach of use of a short course of high-dose steroids is now viewed as ineffective and possibly harmful. The currently recommended dose range (200 to 300 mg/d) of hydrocortisone seems to reduce time for reversal of septic shock, but effects on mortality remain unproven. Future guidelines may altogether abandon the use of steroids in septic shock.

HYPERGLYCEMIA

In critically ill patients, an acute sustained increase in serum glucose in response to stress is defined as hyperglycemia. Once the acute illness resolves, this "diabetes of injury" ends, and previously euglycemic patients return to their normal physiologic state. Hyperglycemia in this context was thought to be a compensatory response in coping with critical stress, but it also imposes significant adverse consequences: abnormal immune function, increased infection, hemodynamic and electromyocardial disturbances, increased insulin resistance, and higher insulin requirements. The degree of hyperglycemia also depends on an individual's capacity to meet the increased insulin demand. The finding of hyperglycemia during critical illness can unmask borderline diabetes in some patients. The American Diabetes Association and American Association of Clinical Endocrinologists define stress hyperglycemia or hospital-related hyperglycemia as any blood glucose concentration of more than 140 mg/dL (7.8 mmol/L) without evidence of previous diabetes. Up to 60% of patients admitted with new stress hyperglycemia had confirmed diabetes 1 year later. Nearly 1 in 5 adult patients presenting with stress hyperglycemia had unrecognized diabetes identified by admission hemoglobin (Hb) A1c more than 6.1%.

Given the hypermetabolic changes in critically ill or septic patients, hyperglycemia is an understandable consequence. High catecholamine and glucocorticoid hormone levels produce hyperglycemia. Other hormones inhibit hepatic glycogenesis and peripheral glycolysis while promoting gluconeogenesis and lipolysis.

A direct relationship is found between the extent of stress hyperglycemia and mortality in critically ill patients. In a landmark study of surgical ICU patients, Van den Berghe and colleagues showed that intensive insulin therapy to achieve tight glycemic control (80 to 110 mg/dL) reduced in-hospital mortality by 34%, bloodstream infections by 46%, acute renal failure requiring dialysis by 41%, and transfusions by 50%. Patients were also less likely to need mechanical ventilation or intensive care. Other studies have shown that insulin treatment lowers short-term mortality by 15%. Similarly, in medical ICU patients, Van den Berghe and colleagues' study showed reduced morbidity and shorter ICU stay and hospitalization. Lower mortality was observed only for patients staying in the ICU longer than 3 days. Scalea and associates confirmed that hyperglycemia in trauma patients is similarly associated with numerous complications: infections, increased ventilator days/ICU and hospital days, and higher risk of mortality. Most significantly, they showed the importance of early glucose control; regardless of subsequent glucose levels, mortality remained high unless tight glucose control was achieved within the first week of injury.

How should a surgeon logically approach the issue of hyperglycemia in critically ill patients? First is recognition of preferred target glucose levels. Blood glucose levels of more than 180 mg/dL are unacceptable in critically ill patients. Hypoglycemic levels (<40 mg/dL) are likewise undesirable. The optimal target to aim for falls into two ranges: (1) a more conventional range of 140 to 180 mg/dL; and (2) a tighter glycemic range of 80 to 110 mg/dL. No significant differences in overall outcome were observed between these ranges in several large randomized trials, except perhaps that the tighter glycemic range was potentially more beneficial to trauma patients and cardiac surgical patients. The conventional range (140 to 180 mg/dL) remains the most preferred because it avoids the risks of severe hypoglycemia.

Next is the realization that optimal treatment of hyperglycemia in the critically ill population is administration of intravenous insulin. This is more predictable and effective than subcutaneous (SQ) insulin, the adsorption of which may be affected by changes in locoregional blood flow. Insulin infusions can be administered via defined protocols and allow rapid dosing but do require intensive monitoring and frequent glucose measurements (hourly until stable and then every 2 hours). Once a patient's condition stabilizes, transition to SQ insulin treatment can occur.

Finally, planning for glycemic management during the recovery phase of illness and on discharge is important. Measurement of HbA1C concentration during hospitalization can predict the need for insulin or oral antidiabetic agents after discharge. These are usually unnecessary in patients with HbA1C of less than 6.5%. This value can also help differentiate those patients with stress hyperglycemia that developed in the context of previously undiagnosed diabetes and those who need further evaluation and care.

THYROID DYSFUNCTION

Several thyroid abnormalities can develop in critically ill patients. Hypothyroxinemia occurs in the form of low thyroxine (T4) and

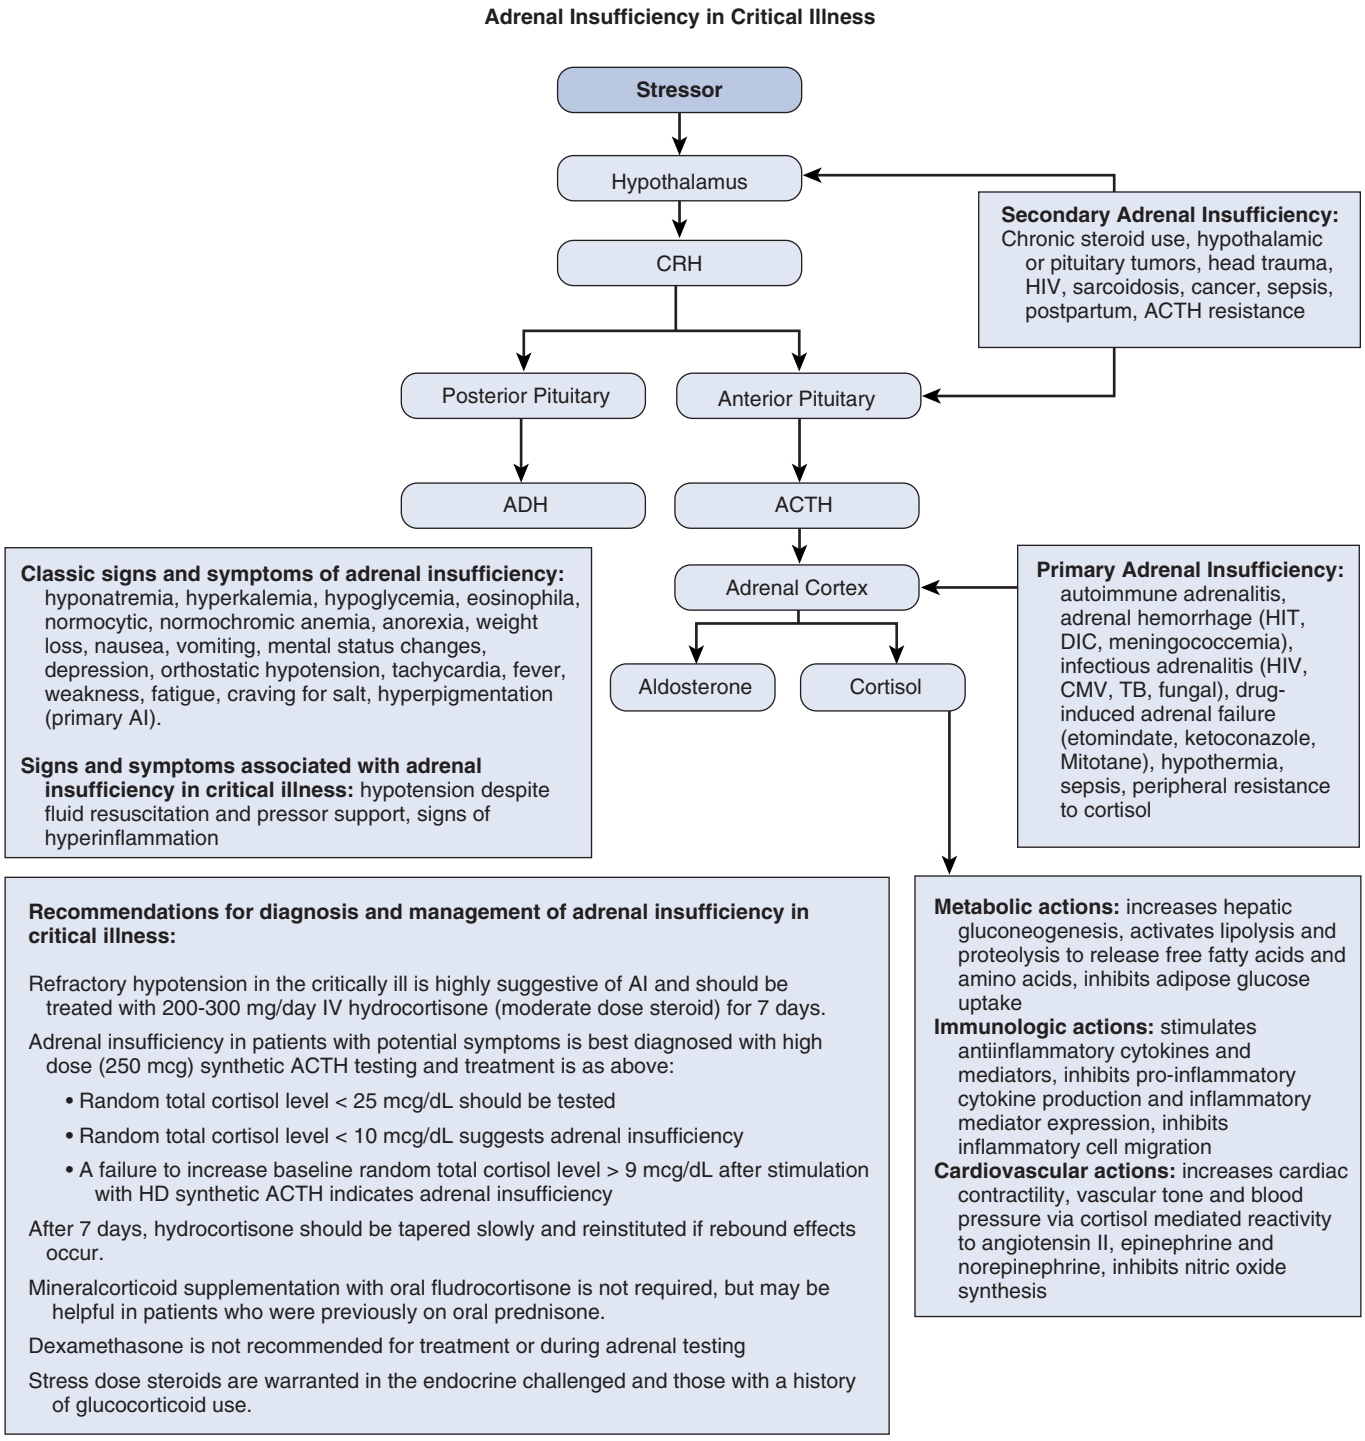

FIGURE 1 A summary of adrenal insufficiency in critical illness.

triiodothyronine (T3) levels in circulation. Because T3 decreases occur earliest and most uniformly during critical illness, the condition has been called the low T3 syndrome, the nonthyroidal illness syndrome (NTI), and euthyroid sick syndrome. Severe and prolonged illness also leads to declines in T4 levels and in pulsatile levels of thyroid-stimulating hormone (TSH; or thyrotropin). This is not a benign condition; hypothyroxinemia has recently been correlated to mortality in critically ill patients and those with surgical sepsis.

Understanding the nature of changes in thyroid axis function is useful. The normal thyroid gland produces T4 and T3 and stores these in large follicles bound to thyroglobulin. In healthy patients, the anterior pituitary secretes TSH in a pulsatile and diurnal fashion, causing thyroid hormones to be released into circulation, 90% as T4 and 10% as T3. Peripheral conversion of T4 to T3 supplies the remainder of T3. Both thyroid hormones are heavily bound to carrier proteins, and the amount of free hormone released is kept constant by matching to levels excreted by the thyroid gland. Free circulating

T4 and T3 are taken up by target cells in peripheral tissues, where enzymes of the iodothyronine deiodinase family (D1, D2, D3) convert T4 into T3, or into the inactive metabolite reverse T3 (rT3). Within the target cells, thyroid hormones bind nuclear receptors to accomplish organ-specific changes. The thyroid hormones form an autoregulatory loop by feedback inhibition at the levels of both the pituitary and hypothalamus to inhibit TSH secretion.

During critical illness or surgical stress, total T3 and free T3 levels in circulation decline during induction of anesthesia and remain low for the first few postoperative days. These levels normalize when a patient recovers but remain suppressed or decline even further with prolonged illness or sepsis. T4 follows a similar pattern that appears during the prolonged illness phase and is related to severity of illness. Random, single-sample TSH levels transiently rise in the first hours of acute illness but then normalize. TSH levels can actually become abnormally low during prolonged illness and, even if normal, lose nocturnal secretion surges and pulsatile fractions, thus exacerbating low states of T4 and T3. Recuperation stages often show elevated TSH levels.

The mechanisms that lead to these abnormalities are varied and may not be uniform among patients. They include variations in thyroid hormone uptake by peripheral tissues, altered metabolism of thyroid hormone by deiodinases, changes in thyroid hormone nuclear receptors in the target cells, set-point changes in the hypothalamic-pituitary axis, depletion of selenium that is required by several intrathyroidal enzymes and the deiodinases, and iatrogenic TSH suppression by drugs used in the ICU, notably dopamine and metoclopramide. Despite these diverse mechanisms, it is thought that the most likely driver of changes in serum T3 levels during critical illness is impaired thyroid hormone production.

When total serum T4 levels fall below 50 nmol/L and 25 nmol/L, mortality risks have been reported to rise up to 50% and even 80%, respectively. Most studies also favor the general concept that decreased thyroid function at baseline of the acute illness may be associated with worse outcomes from sepsis and septic shock, but it is unclear whether altered thyroid function actually participates in these adverse changes or is merely a predictor of poor outcome.

Also unclear are whether treatment to normalize thyroid function in critically ill patients is warranted and what combinations of pharmacologic agents (T4, T3, other novel compounds) are effective without producing harmful side effects. Only four small, randomized trials provide information, and none reveal a clear benefit of normalizing abnormal thyroid hormone parameters. These studies may have been underpowered to detect differences, and interest remains strong to elucidate this issue with future studies. More simple approaches are advocated, such as increasing awareness of iatrogenic side effects of ICU drugs (dopamine and metoclopramide, for example) that can affect thyroid function and modifying their use if appropriate. Currently, no evidence supports treatment of critically ill patients with exogenous thyroid hormone.

DRUG-INDUCED ENDOCRINE DISORDERS IN THE INTENSIVE CARE UNIT

Current emphasis in medicine focuses more so than ever on minimizing iatrogenic complications and avoiding errors. ICU settings are complex and require large numbers of different medications for therapy, some that may be essential for survival. These medications can also have important endocrine side effects. Table 3 summarizes the most common drug-induced changes according to components of the endocrine system that are affected. The surgeon is directed to the Suggested Readings to expand familiarity with these side effects, options in medication usage, and controversies that remain in this field. The crucial point that the authors wish to communicate by adding this topic in the chapter was that daily review of the patient's ICU medication list ought to consider the potential of such endocrine consequences.

TABLE 3: Drug-induced endocrine disorders in the intensive care unit

Endocrine system	Medications	Consequence
Pituitary/adrenal	Etomidate, azole antifungals	Inhibit cortisol synthesis
	Phenobarbital, phenytoin, rifampin	Induce cortisol metabolism
	Opioids, benzodiazepines	Suppress CRH and ACTH
	Glucocorticoids	Suppress CRH and ACTH
	Statins	Decrease cortisol substrate
	Heparin	Suppresses aldosterone
	All anticoagulants	Potential adrenal hemorrhage
	Metoclopramide	Suppresses TRH
Pancreas	ACE inhibitors	Increase peripheral insulin sensitivity
	Fluoroquinolones	Stimulate pancreatic insulin secretion
	Pentamidine, quinine, sulfonylurea, toxicity, salicylates	Increase insulin secretion
	Glucocorticoids	Increase gluconeogenesis and insulin resistance, decrease pancreatic insulin secretion
	Cyclosporine, tacrolimus	Decrease insulin biosynthesis/release
	Antipsychotics	Multifactorial glucose abnormalities
	Vasopressors	Activate glycogenolysis, increase hepatic gluconeogenesis, stimulate glucagon and cortisol

TABLE 3: Drug-induced endocrine disorders in the intensive care unit—cont'd

Endocrine system	Medications	Consequence
Thyroid	Dopamine, dobutamine, octreotide, corticosteroids	Reduce TSH concentration and T4 production
	Amiodarone, iodinated contrast dye	Increase thyroid hormone synthesis, may provoke hyperthyroidism
	Lithium	Decreased thyroid hormone synthesis
	Phenobarbital, phenytoin, rifampin, carbamazepine	Increase thyroid hormone metabolism
	Heparins	Transient increase in free T4 levels
	Furosemide	Displaces thyroid hormone from protein binding sites; in high doses, causes euthyroid sick syndrome
	Metoclopramide	Suppresses TRH

ACE, Angiotensin-converting enzyme; *ACTH,* adrenal corticotrophic hormone; *CRH,* corticotrophin-releasing hormone; *T4,* thyroxine; *TRH,* thyrotropin releasing hormone; *TSH,* thyrotropin or thyroid-stimulating hormone.

Nutritional Support in the Critically Ill

Matthew D. Neal, MD, and Jason L. Sperry, MD

OVERVIEW

Critical illness is associated with a hypermetabolic and catabolic state that can result in significant energy expenditure and complicate the resuscitation and care of the patient in the intensive care unit (ICU). In recent years, an increasing appreciation for the morbidity and mortality associated with malnutrition in the hospitalized patient has emerged, and the concept of nutritional "support" has evolved into a more active practice of nutritional "therapy." As stated in the joint recommendations made by the Society for Critical Care Medicine (SCCM) and the American Society for Parenteral and Enteral Nutrition (ASPEN), the goals of nutritional support include preservation of immune function, avoidance of metabolic complications, and preservation of lean body mass. The new field of nutritional therapy focuses on favorable nutritional modification of the immune response and the attenuation of oxidative stress and cellular injury.

Despite the robust body of literature that has shown an increased morbidity and mortality associated with postoperative malnutrition, postoperative and acutely ill medical patients are still commonly subjected to prolonged periods of starvation. Although many patients tolerate this insult, those patients with preexisting malnutrition, advanced age, obesity, chronic disease, or extreme injury severity are particularly susceptible to the effects of acute malnutrition, which can impair recovery and contribute to a litany of complications.

Guidelines designed specifically to address nutritional support and therapy in the critically ill are targeted to those who have a planned ICU stay of greater than 2 to 3 days or an inability to return to normal enteral intake within 7 days of starvation. Although most of the evidence in the surgical and critical care literature addresses this cohort of patients, it is often difficult to predict the clinical course of these patients in advance, and thus, it is advisable that nutritional status be part of the initial evaluation of every critically ill or postoperative patient, with frequent reassessments to track progress toward clinical goals. Excellent evidence exists to support the use of feeding algorithms in the ICU, such as that found in Figure 1.

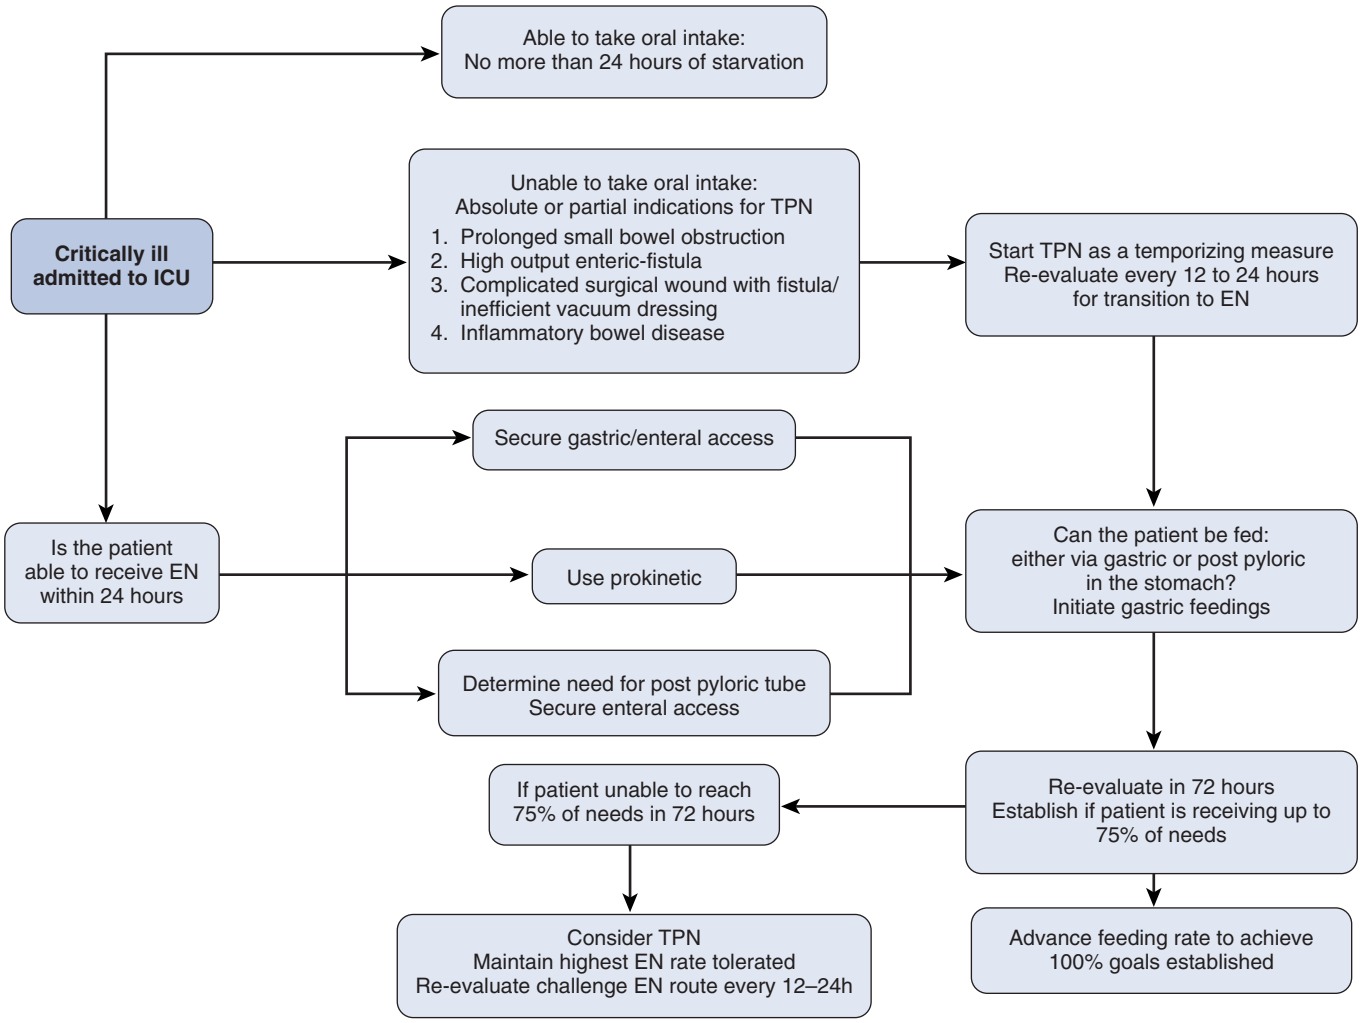

FIGURE 1 Algorithm to implement evidence-based feeding guidelines to improve nutrition practices and reduce mortality in the intensive care unit. *EN,* Enteral nutrition; *ICU,* intensive care unit; *TPN,* total parenteral nutrition. *(Data from Doig GS, Simpson F, Finfer S, et al: Effect of evidence-based feeding guidelines on mortality of critically ill adults: a cluster randomized controlled trial,* JAMA *300[23]:2731-2741, 2008.)*

METABOLIC RESPONSE TO STRESS AND NUTRITIONAL REQUIREMENTS DURING CRITICAL ILLNESS

Multiple organ systems are affected by malnutrition, but the intestine is one of the earliest affected, with resultant mucosal atrophy and an inability to effectively absorb and process nutritional once it is initiated. Enteral nutrition supports the integrity of the intestinal mucosa by maintaining tight junctions and reducing gut barrier permeability. When intestinal epithelial integrity is compromised, as is the case when enteral nutrition is withheld for long intervals, the risks of systemic infection and multiple organ failure (MOF) increase substantially. The overwhelming catabolic state of critical illness also results in the loss of muscle and visceral mass from increased oxidative stress. This oxidative stress, which results from a relative deficiency of antioxidants, can lead to a proinflammatory state in multiple organs. Thus, malnutrition can lead to impaired wound healing, end organ injury, and increased rates of nosocomial infection through functional immunosuppression, which is explored in detail later in the chapter.

Most critically ill patients have in common an increased metabolic rate with an increase in energy requirements that ranges from 30% to 70% above normal; this rate can last for as long as 3 weeks after critical illness. The magnitude of this increase depends on the individual patient and the type and severity of illness. For this reason, it is impossible to assign a general number for caloric requirements in the ICU. Furthermore, the assessment of nutritional status with standard protein markers such as albumin and transferrin has not been validated in critically ill patients because of changes associated with the acute phase response. In general, a range of 20 to 40 kcal/kg/d is necessary, with a range of 1.2 to 2.0 g/kg/d of protein to address the hypercatabolic state and protein wasting. However, a number of predictive equations exist, including common formulas such as the Harris-Benedict, to aid in the assessment of caloric needs. These equations should be used with caution because they were not designed for the care of the modern critically ill patient and may be less accurate than indirect calorimetry, which is the most accurate form of energy expenditure assessment currently available. Unfortunately, indirect calorimetry is labor intensive, difficult to calculate, and not available at many institutions. Thus, the calculation of a nutritional goal is an imperfect science, and the ICU clinician should use a combination of existing tools and clinical assessment of injury severity, prehospital nutritional intake, and weight loss and possible consultation with dietary and nutrition service experts to assign a total caloric goal.

Once a goal is established, an effort to provide 50% to 65% of caloric goals should be made within the first week of hospitalization; this has been shown to improve clinical outcomes. Trophic feeding (also known as "trickle feeding" with 10 to 30 mL/h) does have the benefit of preventing mucosal atrophy but may not reach the clinical benefits seen with approaching 50% to 65% of caloric goals. Ongoing assessments of total caloric and protein needs should be made and altered as the clinical course dictates. Electrolyte levels should be monitored regularly to avoid abnormalities, and care should be taken to include calories delivered through intravenous supplements, such as dextrose or calories contained in propofol infusions, in the total count to avoid overfeeding. Quite possibly the most important aspect of the initial attempts to address nutritional needs is to use enteral feeding whenever possible.

EARLY ENTERAL NUTRITION

Level I evidence exists to support the use of enteral nutrition (EN) over parenteral nutrition (PN) in critically ill patients. Six meta-analyses exist to address this topic, with a consistent observation of reduced morbidity, especially in the form of reduced infectious complications. These studies cover a wide range of critically ill patients, from trauma to burns to pancreatitis, which advocates for the broad implementation of EN in the ICU. No significant reduction appears to exist in mortality associated with the use of EN over PN; however, various studies have documented decreased ICU stay, cost associated with nutrition, and noninfectious morbidity. Some studies do report an increased risk associated with EN, including rates of vomiting, need for nasogastric tube, and some observed increase in pulmonary complications. However, these risks appear to be significantly outweighed by the dramatic benefits outlined previously, and most, if not all, nutrition societies have endorsed the use of EN over PN in critically ill patients when possible.

EN has shown its greatest effectiveness when started early. Even with the significant heterogeneity among the published studies, early enteral nutrition (EEN) is defined as nutrition started within the first 24 to 72 hours of admission to the ICU. Table 1 presents the 10 randomized studies that compared EEN and delayed enteral nutrition (DEN) in critically ill patients. A clear reduction, which reaches significance in some studies and trends in others, in mortality and infectious complications has been shown for EEN. EEN should be initiated as soon as feasible on admission to the ICU, and no literature supports the need to wait for passage of stool/flatus or bowel sounds to initiate EN. One major contraindication to EN is significant hemodynamic compromise. Although some patients with low-dose vasopressor requirements may still tolerate EN, in general, significant hypotension or the need for significant hemodynamic support should be viewed as a contraindication to EN. The risk associated with EN in this population is largely attributed to intestinal ischemia caused by dysfunction of the intestinal microcirculation. When EN is used in patients with labile hemodynamics, they must be monitored closely for signs of intolerance, including distention, high residuals, changes in bowel function, and acidosis.

Multiple options exist for the route of feeding, including nasal, oral, and surgically placed enteral access tubes. The main distinction in the site of feeding is whether it is safe to feed the stomach or whether postpyloric feeding is necessary. In all cases, aspiration precautions should be strictly observed. Those patients with high gastric residuals or documented impaired gastric emptying or motility should have postpyloric tubes placed. Otherwise, multiple studies have shown no difference between gastric and small bowel feeding. Prokinetic agents may provide some benefit in patients with documented dysmotility, but no evidence supports their routine application. Tube feeding associated diarrhea is a common clinical problem that can be managed with well-studied algorithms such as shown in Figure 2. Infectious etiologies, particularly *Clostridium difficile,* must be ruled out before diarrhea in the critically ill patient is attributed to the effects of tube feeding.

TOTAL PARENTERAL NUTRITION

The data reviewed previously lead to the conclusion that enteral nutrition is clearly preferred over total parenteral nutrition (TPN). However, clinical scenarios in which EN must be withheld or significantly delayed are quite common. In the past, TPN was hypothesized to confer a benefit over no nutrition support therapy in patients who could not tolerate or were not candidates for EN. The practice of use of TPN in the absence of preexisting malnutrition was a subject of great debate in the literature; however, two meta-analyses by Braunschweig and colleagues and Heyland and associates showed that the use of TPN was actually detrimental when compared with no nutrition support therapy in the acute setting. Both analyses showed trends towards higher levels of complications with TPN, and Heyland and associates' study showed an increase in mortality with the use of TPN.

Given the clear benefit of EN over TPN and the detrimental outcomes documented in nonmalnourished patients to whom TPN was administered in acute critical illness, the use of TPN has been progressively reduced. Nevertheless, it remains invaluable in the following very specific clinical circumstances: (1) a nonstressed patient who has severe protein-calorie malnutrition is scheduled to undergo surgery (a perfect example is the patient scheduled to undergo esophageal surgery because of obstruction); (2) a patient is malnourished, and TPN given 7 days before surgery is associated with a significant decrease in infection rates; (3) the patient has short gut, and indefinite survival is possible thanks to the use of TPN, which can be used for long-term management or as a bridge to intestinal transplantation; and (4) a patients has failure of oral or enteral nutrition. In fact, the authors of the two meta-analyses mentioned previously went on to document that after a certain duration of critical illness (controversy exists, but the window of time appears to be 7 to 14 days), withholding nutrition altogether begins to lose benefit when compared with TPN. Hospital length of stay and mortality increase in patients who receive no nutrition compared with TPN when duration of critical illness exceeds 7 to 10 days. Thus, the ASPEN and SCCM guidelines suggest that if EN is not feasible in the first 7 days of ICU admission, no nutrition support should be provided. However, in previously healthy patients (before ICU admission) without evidence of malnutrition, a potential benefit exists to the use of TPN when started after 7 days and when EN continues to be unavailable.

TPN should be implemented only after an adequate attempt at EN; however, the patient with complicated abdominal wounds that are clearly worsened by the presence of protracted fistulas that impair any healing may be a candidate for TPN, at least during the early phases of wound care. Often, the combined multidisciplinary care of these wounds and a period of enteral rest allow for the eventual reinitiation of full EN. Currently, no clear guidelines define "failure" of EN; however, it is clear that, at least early on, caloric goals are not necessary through the enteral route to see its benefits. Thus, there is little to no role for combined TPN and EN.

IMMUNONUTRITION

Recommendations regarding an exact composition or type of enteral formula are hard to make because of variations between manufacturers and heterogeneity in the studies that address their effects. However, conclusive and convincing evidence exists to support the use of immune-modulating enteral formulas in select populations. These formulas contain nutrients with pharmacologic properties that serve to enhance immune function and decrease inflammation.

The most important task in deciding whether to use so-called immunonutrition is to determine whether the patient meets criteria for its use. Immunonutrition is generally more expensive than standard enteral formulas; so, although robust cost-benefit analyses have not been completed, it should likely be reserved for the patient populations that have been specifically studied. Fortunately, these include many of the patients seen in surgical critical care settings, including those who have undergone major gastrointestinal surgery; those with trauma, burns (total body surface area, >30%), and head and neck cancer; and those who need mechanical ventilation. Patients with mild-moderate sepsis have also been shown to benefit from these formulations.

Three of the major components of studied and available immune-enhancing formulas included arginine, omega-3 fatty acids, and glutamine. The role of arginine and omega-3 fatty acids appears to be through the regulation of myeloid suppressor cells

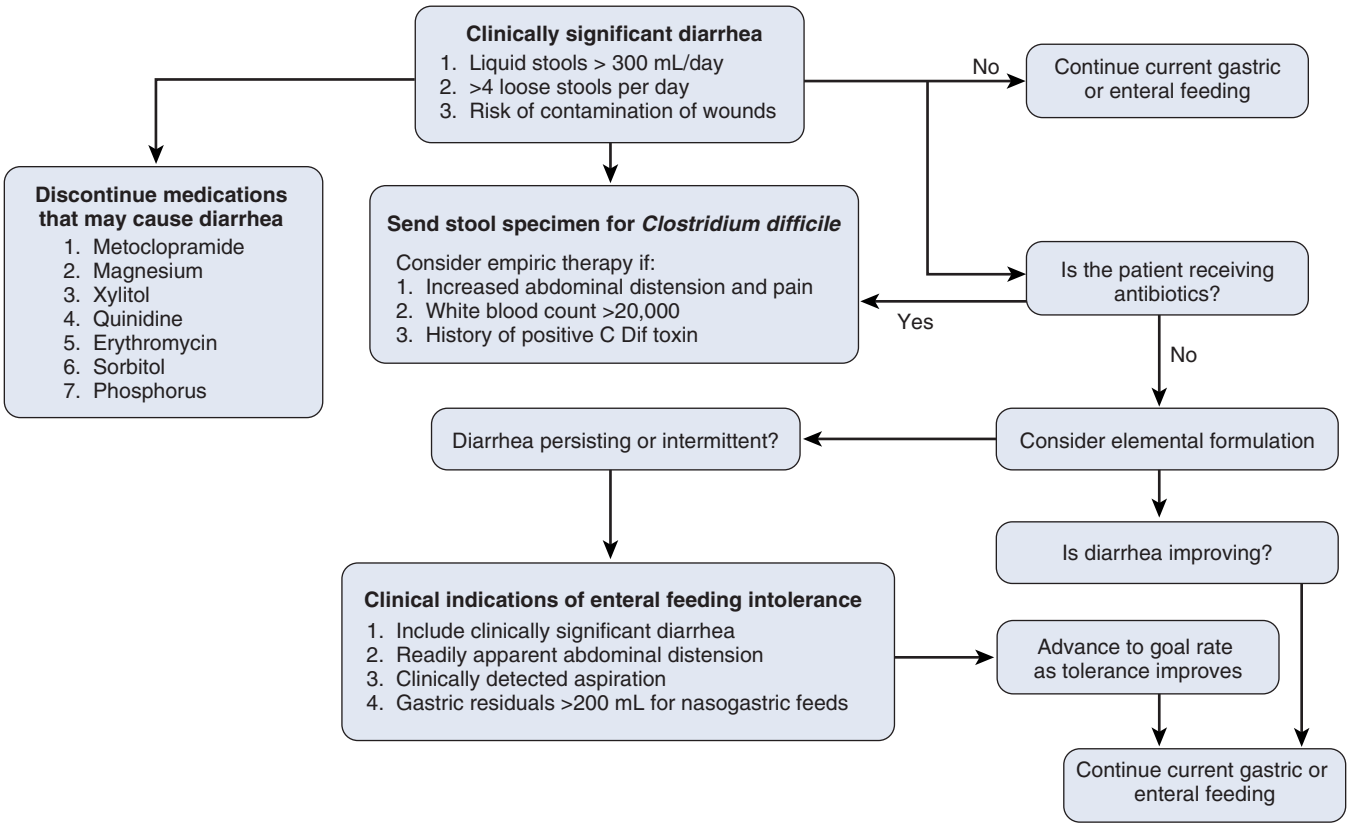

FIGURE 2 Management algorithm for patients with development of tube feeding–associated diarrhea. *(Data from Doig GS, Simpson F, Finfer S, et al: Effect of evidence-based feeding guidelines on mortality of critically ill adults: a cluster randomized controlled trial,* JAMA *300[23]:2731-2741, 2008.)*

through nitric oxide and combating T-cell suppression and decreasing neutrophil adhesion and subsequent inflammation. Glutamine is a key fuel for immune cells, increases human leukocyte antigen-DR expression on monocytes, enhances neutrophil phagocytosis, increases heat-shock protein expression, and serves as a precursor for the de novo production of arginine. Additional micronutrients, such as selenium, and antioxidants, such as vitamin C, are often added to immunonutrition to enhance the positive effects and have been shown to reduce mortality in systematic reviews and meta-analysis, including a recent meta-analysis by Visser and colleagues that reviewed 15 randomized controlled trials for their primary endpoint of mortality.

At least five meta-analyses have shown the benefits of immunonutrition over standard enteral formulas in selected patient populations. Although no benefit for mortality has been shown, multiple morbidities and hospital length of stay have been reduced with immunonutrition. These effects are most pronounced in surgical patients. The use of omega-3 fatty acids and antioxidants also has pronounced effects in patients with acute lung injury (ALI) and adult respiratory distress syndrome (ARDS). One clear limitation may be those patients with severe sepsis, in whom some evidence exists to suggest that the upregulation of nitric oxide seen with arginine supplementation may actually be detrimental. A summary of clinical practice recommendations for immune nutrients for specific patient populations is found in Table 2, which contains the recommendations for each of the four commonly used immune nutrients discussed previously (arginine, glutamine, omega-3 fatty acids, antioxidants) and the recommendations for each from the major nutrition societies: the Canadian Clinical Practice Guidelines (CCPG), the European Society for Parenteral and Enteral Nutrition (ESPEN), and the SCCM/ASPEN.

SPECIAL CIRCUMSTANCES: THE OBESE CRITICALLY ILL PATIENT

Because of the increasing incidence of obesity, especially in the United States and Western countries, and the numerous physiologic problems associated with obesity that complicate ICU care, special attention to the nutritional needs of these patients is warranted. Although randomized data to address the specific needs of the obese are limited, an evolving body of literature suggests that immunonutrition and specific supplements may be of significant benefit in this population. Multiple large clinical studies show that the obese critically ill patient has a higher risk of infectious complications, longer ICU stay, and need for mechanical ventilation. Importantly, multiple metabolic derangements found with obesity create a state of chronic inflammation and significantly increased levels of oxidative stress, at baseline and especially when challenged with an insult such as trauma, surgery, or infection. Recent studies of nutritional supplementation in obese critically ill patients have focused on offsetting this oxidative stress with pharmaconutrition. The use of antioxidants L-arginine, and L-citrulline appears to have positive effects in this patient population for many of the reasons previously outlined in this chapter. In addition, supplementation of L-leucine appears to be of some importance in critically ill obese patients to prevent the development of sarcopenia. One of the most frequent comorbidities associated with obesity is nonalcoholic fatty liver disease (NAFLD), which warrants special consideration in the nutrition regimen of these patients. A combination of basic science and clinical evidence suggests that the use of nutritional supplements rich in polyunsaturated fatty acids (PUFAs) can be of significant benefit through anti-inflammatory effects in patients receiving enteral nutrition. This benefit appears to be particularly enhanced in the setting of NAFLD.

However, at least one study suggests that PUFAs can be detrimental in the setting of alcoholic liver disease, where use of medium-chain triglycerides should be considered as an alternative fat source. Finally, limited evidence exists to suggest that a high-protein, hypocaloric nutritional regimen may result in reduced morbidity in obese critically ill patients. As the incidence of obesity and obesity-related comorbidities increases, close attention must be paid to the metabolic and nutritional needs of these patients, and the use of immunonutrition is highly recommended by many authors.

Coagulopathy in the Critically Ill Patient

Nagamallika Jasti, MD, and Michael B. Streiff, MD

Bleeding and/or abnormal coagulation or platelet function test results are common among critically ill patients. Consequently, a working knowledge of the diagnostic evaluation and management of patients with hemostatic disorders is essential for physicians caring for critically ill patients. The purpose of this chapter is to review (1) a brief description of the hemostatic system, (2) a commonsense approach to critically ill patients with abnormal bleeding, and (3) an approach to the diagnosis and management of platelet, coagulation, and vascular disorders.

A MODEL OF HEMOSTASIS

Hemostasis is the end product of the coordinated and cooperative efforts of pro- and anticoagulant proteins, fibrinolytic proteins, platelets, and the vessel wall. Defects in any component can result in abnormal bleeding or thrombosis. The hemostatic mechanism springs into action when vascular damage exposes subendothelial collagen and tissue factor. Circulating platelets bind avidly to collagen via platelet membrane glycoproteins and von Willebrand factor to form a platelet monolayer at the site of injury. This event triggers platelet activation and the release of platelet granule components that activate surrounding platelets promoting platelet aggregation, formation of a multilayer platelet plug, and vasoconstriction. Defects in platelet adhesion, activation, or aggregation all lead to bleeding disorders of variable severity.

While the classic "waterfall" concept of the coagulation system does not accurately reflect what occurs in vivo, this model is very useful for interpreting coagulation test results (Figure 1). At the same time that platelet adhesion and activation are occurring, the coagulation cascade is activated by the exposure of subendothelial tissue factor that activates factor VII. The extrinsic pathway that consists of factor VII and tissue factor serves as the initiator pathway of hemostasis. The tissue factor-factor VII complex activates factor X, which leads to small amounts of thrombin formation that activates factor XI and VIII (intrinsic pathway) and factor V (common pathway cofactor for factor X). Activation of the intrinsic pathway by thrombin results in formation of large amounts of activated factor X and subsequently thrombin, which triggers fibrin formation and platelet activation. The end result is fibrin clot, which reinforces the platelet plug, stanching blood loss through the vascular defect. Thrombin also activates factor XIII, which catalyzes the formation of covalent crosslinks between fibrin monomers to ensure the formation of a fibrin clot that is resistant to fibrinolysis. The prothrombotic coagulation proteins are balanced by endogenous antithrombotic proteins such as antithrombin (III) (which inhibits thrombin—a reaction that is accelerated several thousand–fold by heparin), and the vitamin K-dependent protein C and protein S complex that inactivates the critical cofactor proteins, factor VIII, and factor V. The fibrinolytic proteins provide additional balance to the hemostatic mechanism by digesting and remodeling existing fibrin clot to focus clot formation at the site of vascular injury and to maintain vascular patency.

AN INITIAL APPROACH TO THE CRITICALLY ILL PATIENT WITH BLEEDING

Optimal management of the critically ill patient with bleeding requires prompt identification of the most likely cause of the bleeding. Bleeding can result from a coagulation factor deficiency, a disorder of platelet function or numbers, an abnormality of vessel walls, or combined defects in more than one of these systems. Identification of the defective system(s) is essential for targeted hemostatic therapy, which is more effective and preserves precious blood product resources that are always in short supply (Box 1). The patient's presentation can provide useful information about the cause of the bleeding. If the bleeding is localized to the operative/procedural site, and particularly if there is large-volume, rapid blood loss, then it is likely that an anatomic defect related to the recent procedure is responsible for the bleeding rather than a systemic hemostatic disorder. In this case, laboratory testing (e.g., complete blood count, including platelet count, prothrombin time (PT), activated partial thromboplastin time (aPTT), etc.) is appropriate to determine the current status of hemostasis, but surgical intervention is the most effective therapy. Conversely, bleeding from multiple locations, slow persistent oozing, and temporally delayed hemorrhage (from invasive procedures) generally indicate the presence of a systemic coagulopathy. Petechiae (small red spots—usually <3 mm in diameter—that do not blanche with pressure) indicate a defect in the number or function of platelets. Large hematomas or ecchymoses that elevate the skin surface or blood collections in deep tissue locations are characteristic of a coagulation factor defect.

If the patient has had a recent surgical procedure, the type of procedure should be considered in the evaluation. Patients returning from a cardiac bypass procedure can have residual heparin present following protamine reversal as a cause of bleeding and abnormal coagulation test results or acquired thrombocytopenia and platelet dysfunction due to the impact of cardiac bypass on platelet function and numbers. Therefore, the approach to these patients should focus on assessing the character of the bleeding (surgical versus coagulopathic) and the results of tests evaluating the patient for the presence of residual heparin or coagulation factor deficiencies (activated partial thromboplastin time, thrombin time, heparin neutralized thrombin time, Hepzyme), thrombocytopenia (complete blood count), and platelet dysfunction (platelet function analyzer 100, PFA-100, Dade-Behring, Inc. Deerfield, Ill).

It is also important to review the patient's medical and surgical history. Although preexisting hemostatic disorders are often identified preoperatively, occasionally coagulation or platelet disorders are not recognized prior to surgery. Therefore, a quick review of the patient's written history as well as questioning family members can be useful. Patients with renal or hepatic disorders often have abnormal hemostasis due to the impact of these disease processes on platelet function (uremic platelet defect) and numbers (cirrhosis) and coagulation factor levels (cirrhosis). Patients with platelet disorders typically suffer from bleeding that affects mucosal sites (history of menorrhagia, epistaxis, gum bleeding), while coagulation defects such as hemophilia typically trigger deep tissue bleeding or hemarthroses. Fibrinolytic defects and factor XIII deficiency typically result in delayed bleeding (days after surgery). Vessel wall disorders such as the connective tissue disease Ehlers-Danlos syndrome and amyloidosis can cause intraoperative or postoperative bleeding due to vascular/tissue fragility. It is also important to get an accurate list of a patient's prescription and nonprescription medications, including vitamins, supplements, and herbal remedies because these can significantly influence hemostasis. If these details are not available in the medical record, interviewing patients (if possible) or family members can be revealing.

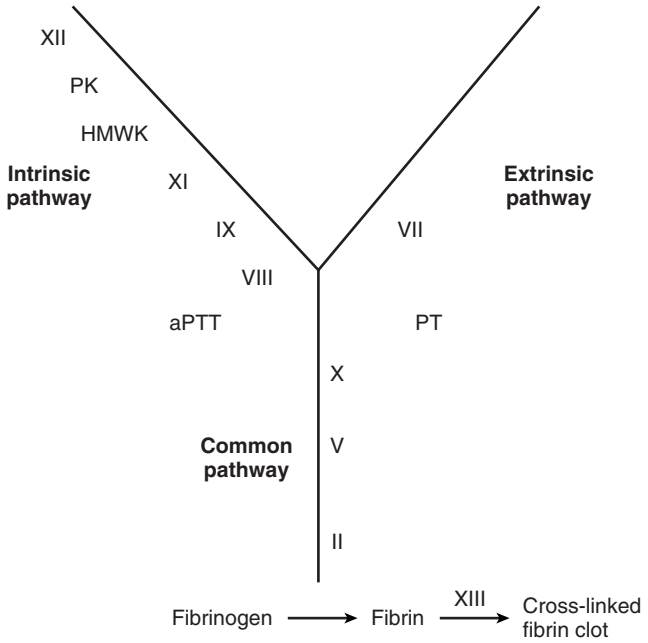

FIGURE 1 The coagulation cascade. *aPTT,* Activated partial thromboplastin time; *HMWK,* high-molecular-weight kininogen; *PK,* prekallikrein; *PT,* prothrombin time.

BOX 1: Evaluation of the bleeding patient

1. Assess character of bleeding: rapid, single location, multifocal, persistent oozing.
 - Surgical bleeding: rapid blood loss, localized to surgical site, bright red blood, pulsatile blood loss.
 - Coagulopathic bleeding: multifocal, persistent slow blood loss.
2. Send blood for hemoglobin, platelet count, PT, aPTT, TT, fibrinogen, D dimer, mixing studies, heparin contamination, thromboelastogram.
3. Review preoperative lab results (including liver and renal function).
4. Review patient's perioperative medications.
 - Antiplatelet agents: aspirin, ticlopidine, clopidogrel, prasurgrel, NSAIDs such as ketorolac, glycoprotein IIb/IIIa inhibitors.
 - Anticoagulants: UFH, LMWH, fondaparinux, lepirudin, argatroban, bivalirudin, desirudin, warfarin, rivaroxaban, dabigatran.
 - Vitamins/dietary supplements/herbal remedies: vitamin E, omega-3 fatty acids, garlic, ginkgo biloba, ginger, willow bark, etc.
5. Review patient's medical/surgical and family history.
 - Platelet-type bleeding: epistaxis, easy bruising, menorrhagia, oropharyngeal bleeding.
 - Coagulation factor bleeding: hemarthrosis, hematomas, soft tissue bleeds.
 - Vessel wall disorder: easy bruisability, joint laxity, poor wound healing.
6. Review compatibility of any intraoperative transfusions.

Basic screening coagulation tests and blood counts are essential to diagnosis of coagulation and platelet disorders. The basic coagulation tests include the aPTT, the PT, the thrombin time (TT), and a fibrinogen level. Platelet testing includes the platelet count (usually available as part of a CBC), the immature platelet fraction (a measure of the percentage of young platelets in the circulation), the bleeding time, or the platelet function analyzer test (PFA-100, Dade-Behring Inc., Deerfield, Ill). Thromboelastography is being increasingly used in some patient settings (liver transplantation, cardiac bypass, major trauma) to assess patients' hemostatic systems, particularly for hyperfibrinolysis. Patient blood samples for hemostatic testing should be obtained, whenever possible, by a peripheral blood stick rather than through a central venous catheter to avoid the common pitfall of heparin contamination that can confuse diagnosis and lead to unnecessary blood product use. In the next sections we review the commonly used tests to assess hemostasis and then the clinical presentation and management of platelet, coagulation factor, and vascular wall disorders.

HEMOSTATIC TESTING IN THE CRITICALLY ILL PATIENT

Coagulation Tests

The most commonly used tests of coagulation are the aPTT, PT, TT, and a fibrinogen level. More specialized, but important coagulation tests to understand include the D dimer assay, mixing studies, coagulation factor assays, heparin contamination (Hepzyme) testing, and von Willebrand factor testing (Box 2). The aPTT measures the function of factors in the intrinsic pathway (factors XII, XI, IX, and VIII, as well as prekallikrein and high molecular weight kininogen) and the common pathway (see Figure 1). The aPTT is performed by adding phospholipid (an in vitro surrogate for activated platelet membranes) and an activator of factor XII, as well as calcium (to reverse the sodium citrate anticoagulant in the blood collection tube) and measuring the time to clot formation. The aPTT is useful for identifying hemophilia A (factor VIII deficiency), hemophilia B (factor IX deficiency of Christmas disease), factor XI deficiency (hemophilia C or Rosenthal's disease), as well as measuring unfractionated heparin and the direct thrombin inhibitors argatroban, bivalirudin, and lepirudin.

The PT measures the function of the extrinsic pathway (factor VII) and the common pathway (factors X and V, prothrombin, and fibrinogen) (see Figure 1). The PT is performed by adding a source of tissue factor and phospholipids (an in vitro surrogate for activated platelet membranes), also called thromboplastin and calcium (to reverse the sodium citrate anticoagulant in the blood collection tube) and measuring the time required for clot formation to occur. In addition to assessing the rare congenital deficiency states of factors VII, X, V, and prothrombin, the PT is also used to measure warfarin anticoagulation. For patients on warfarin, the results of the PT are usually expressed as an international normalized ratio (INR) value, which normalizes PT results for the sensitivity of the laboratory's thromboplastin to reductions in vitamin K–dependent factor levels (factor VII, X, and prothrombin are reflected in the PT) compared with an international reference standard. The INR is not designed for use to express the results of the PT for patients not on warfarin.

The TT is useful for assessing the functional status of fibrinogen, to which the PT and aPTT are much less sensitive. The TT is performed by adding thrombin and calcium to the citrated patient plasma sample and measuring the time to clot formation. The TT is exquisitely sensitive to heparin or direct thrombin inhibitors. Rare antibodies directed against thrombin (thrombin inhibitors) can also result in an abnormal thrombin time. The results of the thrombin time can be confirmed by obtaining a fibrinogen assay. This functional test of fibrinogen is performed by adding a large amount of thrombin to the patient plasma sample and measuring the time to clot formation. There is a linear relationship in this assay between the time to clot formation and the concentration of clottable fibrinogen. Fibrinogen assays are significantly less sensitive to the presence of heparin and direct thrombin inhibitors due to the increased

BOX 2: Laboratory tests of hemostasis

Activated Partial Thromboplastin Time (aPTT)
Used to identify deficiencies or inhibitors of factors in the intrinsic pathway (factors XII, XI, IX, and VIII; HMWK; and PK) and common pathway (factors X, V, and II [prothrombin] and fibrinogen)
Used to monitor unfractionated heparin and direct thrombin inhibitors (argatroban and bivalirudin)
Used to identify lupus inhibitors (antiphospholipid antibodies)

Prothrombin Time (PT)
Used to identify deficiencies or inhibitors of factors in the extrinsic pathway (factor VII) and common pathway (factors X, V, and II [prothrombin] and fibrinogen)
Used to monitor warfarin (use the INR)

Thrombin Time (TT)
Used to identify deficiency or dysfunction of fibrinogen or thrombin inhibitors
Used to identify the presence of unfractionated heparin

Fibrinogen
A sensitive test of fibrinogen function
Insensitive to heparin
Heparin contamination (Hepzyme)
Used to identify the presence of heparin by measuring aPTT before and after heparinase treatment of patient sample

Mixing Studies
Used to discriminate between deficiency states and inhibitors by assessing the correction of a prolonged PT or aPTT after addition of 1 part or 4 parts patient plasma to 1 part normal pooled plasma
Correction of abnormal assay = deficiency state
Failure to correct = factor inhibitor, lupus inhibitor, anticoagulant such as heparin

Factor Activity Assays
Used to determine the activity level of a specific factor using plasma deficient in the factor of interest and the PT or aPTT

D Dimer Assays
Used to detect D dimers, fragments of cross-linked fibrin that have been digested by plasmin—a marker of disseminated intravascular coagulation (DIC) or active thrombus formation.

Template Bleeding Time
Rough in vivo assessment of platelet function
Platelet function analyzer 100
An in vitro assay of platelet function

Platelet Aggregometry
Used to assess platelet aggregation and secretion in response to platelet agonists

Von Willebrand Antigen Assay
Used to measure the amount of von Willebrand protein

Ristocetin Cofactor Assay
Used to measure von Willebrand protein function

Thromboelastography (TEG/ROTEM)
Global tests of coagulation, platelet, and fibrinolytic function, particularly useful for identifying patients with hyperfibrinolysis

amount of thrombin used in the test. However, large concentrations of heparin or direct thrombin inhibitors will result in an abnormal fibrinogen result.

When a patient's coagulation test results are abnormal, it is important to determine whether the abnormal result is due to a deficiency state (such as hemophilia A) or an inhibitor (such as a factor VIII inhibitor). Deficiency states will respond to factor replacement therapy (factor concentrates, fresh frozen plasma, and cryoprecipitate), whereas inhibitors will not respond to this therapy. This distinction can be made in the laboratory by mixing the patient's plasma sample with normal pooled plasma. If a factor deficiency is responsible, then a 1:1 mix with normal pooled plasma will correct the abnormal clotting time. Conversely, if a specific factor inhibitor or a lupus inhibitor is present, then the addition of normal plasma will not correct the clotting time. Coagulation laboratories often perform 4:1 mixes of patient plasma and normal pooled plasma to detect low-titer inhibitors.

Specific factor levels are performed to identify the presence of particular factor deficiency states such as hemophilia A (factor VIII deficiency). These assays are performed by adding patient plasma to factor-deficient plasma. Consequently, the clotting time of such a mix is dependent solely on the patient sample's contribution of the particular factor of interest. If heparin contamination is suspected, a heparin contamination (Hepzyme) assay can be performed. The Hepzyme assay measures the aPTT of a plasma sample before and after the addition of heparinase, an enzyme that digests heparin. In the presence of significant heparin contamination, the aPTT after heparinase addition is significantly shorter than the baseline sample, confirming heparin contamination.

D dimers are a fragment of crosslinked fibrin that is produced by lysis of fibrin clot. It is a marker of clot formation that has been used as a sensitive test for the presence of disseminated intravascular coagulation and acute thrombosis. D dimer assays generally use antibodies directed against this fragment to measure its concentration in plasma by enzyme linked immunosorbent assays (ELISA) or antibody-coated bead agglutination.

Platelet Tests

Common tests of platelet function include platelet numbers as assessed in a complete blood count, the immature platelet fraction (a measure of the percentage of young platelets in the blood), the template bleeding time, the platelet function analyzer test (PFA-100, Dade Behring, Deerfield, Ill), and platelet aggregation studies (see Box 2). Blood cell analyzers can accurately assess the number and size of platelets in a volume of blood. The mean platelet volume is useful because a large mean platelet volume suggests the presence of a large number of immature platelets (young platelets are larger) such as might be seen in disorders associated with excessive platelet destruction. Another estimate of platelet production measured by some blood cell analyzers is the immature platelet fraction percentage (IPF %). The IPF % is assessed by staining platelets with a proprietary RNA avid fluorescent dye that can be measured with appropriately equipped automated hematology analyzers with flow cytometry. Similar to reticulocytes (young red cells), young platelets have higher concentrations of RNA that can be stained with RNA-avid fluorescent dyes. Patients with higher percentages of young RNA-rich (higher staining intensity) platelets have increased platelet production, which suggests the presence of a disorder causing platelet consumption/destruction.

The template bleeding time (TBT) is a rough guide of platelet function reflecting the importance of platelet function to primary hemostasis. The TBT is performed by making a standardized incision in the forearm with a razor blade–containing template device with a blood pressure cuff inflated proximally to 40 mm of mercury and measuring the time required for hemostasis to occur. Unfortunately, this result can be influenced by many factors other than platelet

function, including operator technique and tissue vascularity. Therefore, the TBT is no longer widely used.

The shortcomings of the TBT led to the development of more standardized and convenient tests of platelet function, such as the platelet function analyzer test (PFA-100, Dade Behring, Deerfield, Ill). The PFA-100 assesses platelet function by aspirating whole blood at high shear rates through perforated membranes coated with the platelet agonists collagen and epinephrine or collagen and adenosine diphosphate (ADP). The time required for the aperture in the membrane to occlude correlates with platelet function. Both the TBT and the PFA-100 will be abnormal in patients with thrombocytopenia (platelet count <80-100,000/μL), so the results of these tests cannot be used to assess platelet function in patients with platelet counts at or below this level. The PFA-100 appears to be more sensitive and reproducible than the TBT, but neither test has proven useful in predicting surgical blood loss. Nevertheless, in a patient with ongoing bleeding, an abnormal PFA-100 in the absence of thrombocytopenia indicates an acquired (e.g., aspirin, bypass pump, uremia, etc.) or congenital platelet disorder (e.g., Bernard-Soulier syndrome, etc.).

Platelet aggregation studies assess platelet function by exposing platelet-rich plasma or whole blood to different platelet agonists such as thrombin, epinephrine, ADP, and ristocetin. Platelet aggregation is assessed by measuring the change in electrical impedance or light transmission through the sample after agonist addition. Platelet granule release can be assessed by measuring the amount of granule constituents such as ATP released into the test solution upon platelet activation. Thrombocytopenia (platelets <80,000/μL) will result in abnormal test results. Since platelet aggregation studies require considerable expertise to perform and interpret, they are not generally available at all medical centers or on an emergent basis. Nevertheless, platelet aggregation studies remain an invaluable test in the assessment of platelet function disorders.

Fibrinolytic Tests

The fibrinolytic system can be measured by assessing the amount and function of fibrinolytic proteins such as plasminogen, tissue plasminogen activator, alpha2-antiplasmin, and plasminogen activator 1 (PAI-1). Reductions in alpha2-antiplasmin and PAI-1, two proteins that negative regulate plasmin (the fibrinolytic enzyme) and tissue plasminogen activator (the primary plasminogen activator), respectively, can cause delayed bleeding after invasive procedures. In recent years, there has been a resurgence of interest in the use of thromboelastography (TEG) and rotational thromboelastometry (ROTEM) in the assessment of the total hemostatic mechanism. These tests can be used to assess global function of clotting proteins, platelets, and the fibrinolytic system. TEG and ROTEM have been used as point-of-care tests to identify patients with decreased coagulation or platelet function or hyperfibrinolysis during liver transplantation and cardiac surgery. Further investigation of TEG and ROTEM in the management of hemostatic disorders is warranted before broader application in clinical medicine.

PLATELET DISORDERS

Platelet disorders can be categorized as being quantitative (characterized by a reduced number of normally functioning platelets) or qualitative (characterized by the presence of dysfunctional platelets) (Table 1). Since platelets play an essential role in primary hemostasis, patients with platelet disorders often bleed during or soon after invasive procedures. Findings typical of platelet dysfunction include a history of mucosal bleeding (epistaxis, gingival bleeding, and menorrhagia) or easy bruisability and petechiae or purpura on physical examination. For most surgical or invasive procedures, a platelet count above 50,000/μL is adequate for hemostasis. For neurosurgery, spinal surgery, cardiac surgery, and prostatectomy, platelet counts in excess of 100,000/μL are often preferred. In a patient without bleeding and no recent or planned invasive procedure, a platelet count transfusion trigger of 10,000/μL is often used to guide transfusion therapy. A higher target of 20,000/μL is used for febrile, infected patients, given their more rapid platelet turnover.

In patients with thrombocytopenia undergoing transfusion therapy, it is important to assess the platelet transfusion increment. The platelet transfusion increment is assessed by measuring the platelet count before transfusion and 1 hour posttransfusion. In the typical 70-kilogram patient, an increment of 5000/μL is expected for each random donor unit transfused. An increment of 30,000/μL is expected for each single donor aphaeresis unit transfused. If the platelet transfusion increment is less than calculated, then increased platelet destruction/consumption is present. In disorders characterized by platelet destruction, platelet increments in response to transfusion are negligible and/or short-lived. Identification of increased platelet consumption warrants consideration of platelet destructive disorders such as disseminated intravascular coagulation, platelet transfusion refractoriness due to human leukocyte antigen (HLA) alloimmune antibodies, or drug-dependent or independent immune mediated thrombocytopenia. Nevertheless, platelet transfusions should never be withheld due to poor platelet count increments in urgent situations associated with clinically significant bleeding due to thrombocytopenia.

Quantitative Platelet Disorders

Acquired Quantitative Platelet Disorders

Quantitative platelet disorders can be rapidly identified with a complete blood cell count. Quantitative platelet disorders can result from decreased production, increased destruction, splenic sequestration, or dilution associated with massive transfusions (see Table 1). While most laboratories confirm low platelet counts (platelets <50,000/μL) by visual inspection of a peripheral smear, it is essential for the clinician to make sure this procedure has been performed to avoid being misled by the entity of "pseudothrombocytopenia." Pseudothrombocytopenia is caused by antibodies that aggregate platelets in the presence of sodium ethylenediaminetetraacetic acid (EDTA) (the anticoagulant used in blood collection tubes for blood count measurement), resulting in significant platelet undercounting. This phenomenon is relatively common, occurring in 0.07% of hospitalized patients, so it is likely all clinicians will see this entity. If pseudothrombocytopenia is suspected, platelet counts should be performed simultaneously in sodium EDTA, sodium citrate, and heparin blood collection tubes, and a peripheral blood smear made from these tubes should be reviewed. Often platelet clumping will be significantly less in sodium citrate or heparin tubes, so these tubes can be used for platelet monitoring during the remainder of the hospital stay. Identification of this entity is important to avoid unnecessary transfusion and medical therapy for a laboratory artifact.

If true thrombocytopenia is present, identification of the primary etiology of the thrombocytopenia is essential to guide therapy. Decreased platelet production should be suspected when patients have thrombocytopenia and a normal or low immature platelet fraction and normal increments to platelet transfusions. Thrombocytopenia due to decreased production is typically associated with abnormalities in other counts (anemia or leukopenia) reflecting a diffuse disruption of normal marrow function. Disorders associated with decreased platelet production include acute leukemia, aplastic anemia, myelodysplastic syndrome, myelofibrosis, vitamin B_{12} or folate deficiency, liver disease, and exposure to myelotoxic substances such as chemotherapeutic agents and alcohol (see Table 1). Cell count abnormalities due to these disorders are typically evident to some degree on preoperative screening studies, although cytopenias may worsen in association with major surgery (results increased consumption of all three cell lines) and associated

TABLE 1: Platelet disorders

Quantitative (thrombocytopenia)	Qualitative (platelet dysfunction)
Decreased Production	**Congenital Platelet Dysfunction**
Vitamin deficiencies (vitamin B_{12}, folate deficiency)	Bernard-Soulier syndrome
Bone marrow disease (aplastic anemia, leukemia, myelodysplastic syndrome, etc.)	Glanzmann's thrombasthenia
Drugs (ethanol, chemotherapy)	Storage pool diseases (e.g., gray platelet syndrome)
Infection (human immunodeficiency virus [HIV], tuberculosis [TB])	Platelet-type von Willebrand disease
Liver failure	
Increased Destruction	**Acquired Platelet Dysfunction**
Immune thrombocytopenic purpura	Drugs (Aspirin, ticlopidine, clopidogrel, NSAIDs, etc.)
Infection	Uremia
Disseminated intravascular coagulation (DIC)	Liver disease
Drugs (heparin, quinine, glycoprotein IIb/IIIa inhibitors, etc.)	Post–cardiopulmonary bypass
Thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS)	Primary thrombocytosis (polycythemia rubra vera, essential thrombocythemia)
Posttransfusion purpura	
Catastrophic antiphospholipid syndrome	
Dilutional (massive transfusions)	
Sequestration (hypersplenism)	
Pseudothrombocytopenia	

disorders (e.g., infections) or treatments (blood or intravenous fluid associated dilutional cytopenias, cardiac bypass pump, intraaortic balloon pump). In patients with normal preoperative counts in whom thrombocytopenia associated with decreased production is suspected, infections or myelosuppressive medications should be investigated. Sepsis can result in decreases in platelet production as well as increased destruction. Antibiotics such as linezolid have been associated with myelosuppressive thrombocytopenia. A hematologist can be helpful in the investigation for possible causes of thrombocytopenia due to decreased production to assist in management. Treatment consists of platelet transfusions until definitive therapy targeted at the underlying defect can be initiated.

Dilutional thrombocytopenia can result when patients receive large volumes of blood during resuscitation. Thrombocytopenia and abnormal coagulation tests result because packed red cell units only retain small volumes of plasma (25 to 50 mL/unit) and platelets. This syndrome is most commonly seen in patients with massive gastrointestinal bleeding or trauma. One study found that 75% of patients who received 20 or more units of red cells within a 24-hour period developed significant thrombocytopenia (platelet counts <50,000/μL). No patients receiving less than 20 units of red cells developed platelet counts in this range. However, the use of prespecified triggers (e.g., 6 to 8 random donor platelet units or 1 plateletpheresis unit and 4 units of fresh frozen plasma (FFP) for every 10 units of blood transfused) for platelet and fresh frozen plasma transfusion should be avoided in most clinical situations, as bone marrow and hepatic function differ substantially between patients. Therefore, transfusion practice should be guided by regular measurement of platelet counts and screening coagulation studies and not formulas. One exception to this rule is patients with massive trauma where formula-driven transfusion practice is essential to preservation of adequate hemostatic function and optimal outcomes. In other surgical populations where dilutional hemostatic disorders are less common, formula-driven transfusion practice is liable to result in excessive blood product utilization. Patients with platelet counts less than 50,000/μL and recent surgery or bleeding should be transfused with one to two aphaeresis (or three to six random donor) units of platelets. Routine measurement of the platelet count to assess response to transfusions and determine the need for additional blood products is essential, as many patients with dilutional thrombocytopenia due to massive bleeding also have reduced platelet survival. Platelet count triggers for transfusion therapy are shown in Table 2.

Consumptive thrombocytopenia is a much more common reason for thrombocytopenia in the critically ill patient. Common causes of consumptive thrombocytopenia are infections/sepsis, drug-induced immune thrombocytopenia, disseminated intravascular coagulation (DIC), and, less often, immune thrombocytopenic purpura (ITP). Review of the patient's medical history, medication lists, microbiology, and coagulation test results is useful in pinpointing the cause. Sepsis can be associated with rapid (within hours) dramatic reductions in platelet numbers that are coincident with clinical manifestations of bacteremia. Even in the absence of obvious signs of sepsis, it is important to consider infection as a cause of thrombocytopenia because ongoing, inadequately treated, or unrecognized infections are a common cause of consumptive and/or inadequate production thrombocytopenia. Therapy should focus on identification of the bacteria responsible, provision of broad-spectrum antibiotics directed at the most likely and serious pathogens, and blood product

TABLE 2: Recommended platelet transfusion thresholds

Indication	Platelet transfusion threshold
No recent surgery, afebrile	10,000/μL
No recent surgery, febrile	20,000/μL
Recent surgery or active bleeding	50,000/μL
Spinal anesthesia	50,000/μL
Massive transfusion	50,000/μL
Anticoagulation	50,000/μL
Disseminated intravascular coagulation (DIC)	50,000/μL
Eye surgery	100,000/μL
Multiple trauma/ central nervous system injury	100,000/μL
Cardiac surgery with cardiopulmonary bypass	100,000/μL
Neurosurgery or spinal surgery	100,000/μL

support. In severe cases of sepsis, particularly cases associated with gram-negative organisms and large amounts of lipopolysaccharide release, disseminated intravascular coagulation can occur, which is heralded by consumptive thrombocytopenia and coagulopathy accompanied by thrombocytopenia and abnormalities in screening coagulation tests (PT, aPTT, fibrinogen), as well as elevations of D dimer levels. Therapy should be multidimensionally directed at the proximate cause of disseminated intravascular coagulation and supportive to correct the thrombocytopenia and coagulopathy.

Drug-induced thrombocytopenia is an increasingly common cause of thrombocytopenia that must be considered in any critically ill patient developing thrombocytopenia. In general, drug-induced thrombocytopenia usually occurs within the first 2 weeks of drug exposure. Therefore, identification of possible agents should focus upon drugs started within the preceding 14 days. However, given the large number of medications that critically ill patients are exposed to, the list of potential suspects can be large. While laboratory testing to identify causative agents is available, it is generally time-consuming and only available through reference laboratories. Medications commonly associated with thrombocytopenia are presented in Table 3. The best approach to drug-induced thrombocytopenia is to eliminate potential suspects promptly. In severe cases, intravenous immunoglobulin (IVIG), anti-D immunoglobulin (Winrho SDF, Baxter Healthcare Corp., Deerfield, Ill), and, to a lesser extent, corticosteroids can be useful therapeutic maneuvers in severely affected patients. When using IVIG, it is important to use low-osmolality products, particularly in patients at heightened risk for renal toxicity (preexisting renal dysfunction, diabetic and elderly patients). Anti-D should be avoided in patients with concomitant autoimmune hemolytic anemia or positive direct antiglobulin testing.

Among causes of medication-associated thrombocytopenia, identification of heparin-induced thrombocytopenia (HIT) is particularly important. HIT is an antibody-mediated consumptive form of thrombocytopenia that occurs in 1% to 5% of patients most commonly after 4 to 14 days of heparin therapy and is associated with a substantial risk of thromboembolism (50% risk at 30 days). The diagnosis can be confirmed with laboratory testing for HIT antibodies (heparin-platelet factor 4 ELISA assay, serotonin-release assay). Any patient suspected to have HIT should avoid all heparin (and low-molecular-weight heparin) exposure and be treated with a direct thrombin inhibitor (argatroban, bivalirudin, lepirudin). In the absence of bleeding, platelet transfusions should be avoided because they are generally ineffective and may precipitate thrombotic complications. The presence of subclinical thrombosis should be sought with routine screening duplex ultrasound on diagnosis because 50% of patients diagnosed with HIT have asymptomatic thrombosis, and the presence of thrombosis changes the duration of warfarin therapy. Since HIT is associated with a high incidence of thrombosis within 30 days of diagnosis, many recommend anticoagulation for at least a month in patients diagnosed with HIT. Warfarin should not be initiated until platelet counts have recovered to normal levels, as early warfarin therapy has been associated with extensive venous thrombosis/gangrene.

Immune thrombocytopenic purpura is caused by antibodies directed at platelet surface glycoproteins such as glycoprotein IIb/IIIa or Ib/IX. These antibodies precipitate platelet destruction in the reticuloendothelial system (spleen, liver, bone marrow). Generally, patients with ITP have thrombocytopenia of some degree noted on preoperative testing. Less commonly, immune thrombocytopenia will be triggered during the postoperative period. Patients with autoimmune disorders such as systemic lupus erythematosus or viral infections such as human immunodeficiency virus (HIV) or hepatitis C are at higher risk for ITP. Typically, ITP patients have significant thrombocytopenia (platelet counts <20,000/μL) but a normal hematocrit and white blood cell count. Direct platelet antibody testing demonstrates the presence of antiplatelet antibodies in many patients, and bone marrow examinations reveal normal numbers of platelet progenitor cells (megakaryocytes). Not surprisingly, platelet transfusions are generally ineffective but should not be withheld in the setting of life-threatening bleeding. Effective therapies include intravenous immunoglobulin or anti-D immunoglobulin (Winrho SDF, Baxter Healthcare Corp., Deerfield, Ill) or corticosteroids. Rituxamab (Rituxan, Genentech, Inc., San Francisco, Calif) and splenectomy are highly effective chronic therapy for persistent disease. More recently, thrombopoietin agonists such as eltrombopag and romiplostim have been shown to be very effective for ITP.

Rare consumptive causes of thrombocytopenia are thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), posttransfusion purpura, and catastrophic antiphospholipid syndrome. TTP is caused by a deficiency of ADAMTS 13, an enzyme that processes large, highly adhesive von Willebrand factor (VWF) multimers into smaller, less adhesive fragments. In its absence, large von Willebrand factor multimers accumulate triggering the spontaneous formation of platelet aggregates that cause consumptive thrombocytopenia, a mechanical hemolytic anemia (from the physical cleavage of red cells as they traverse the microcirculation), and microvascular plugging/ischemia-induced renal and neurologic dysfunction. Diagnosis rests upon clinical recognition of these diagnostic features, confirmation of a microangiopathic picture on the peripheral smear, and laboratory testing confirming the absence of ADAMTS13 in the patient's plasma. Plasmapheresis is the most effective form of treatment. Platelet transfusions should be avoided except in the case of life-threatening bleeding because they can precipitate a dramatic worsening of the patient's clinical condition. HUS is most commonly caused by with calcineurin inhibitors (cyclosporine, tacrolimus), used for organ transplantation immunosuppression and, less commonly, with chemotherapeutic agents such as mitomycin C and gemcitabine (see Table 3). Calcineurin inhibitor–associated HUS usually responds to discontinuation of the offending agent.

Posttransfusion purpura (PTP) is a rare antibody-mediated consumptive form of thrombocytopenia that occurs in patients after transfusion with blood products. PTP is caused by alloantibodies-directed platelet glycoproteins. The vast majority of cases affect women because they are exposed to the causative antigen during childbirth. A typical presentation is the development of sudden,

TABLE 3: Drug-associated thrombocytopenia

Drug-associated immune thrombocytopenia	Drug-associated TTP/HUS
Unfractionated heparin	Ticlopidine
Low-molecular-weight heparin	Mitomycin C
Quinine/quinidine	Cyclosporin
Rifampin	Tacrolimus
Trimethoprim/sulfamethoxasole	Cisplatin
Acetamenophen	Gemcitabine
Digoxin	Quinine
Danazol	
Vancomycin	
Abciximab

Note: These lists include common causes of drug-associated thrombocytopenia but are by no means all-inclusive.

dramatic, and severe thrombocytopenia overnight, approximately a week after a blood product transfusion. Identification of antibodies directed against the causal antigen and typing the affected patient's platelets are diagnostic. Platelet transfusions are ineffective and can cause severe allergic reactions in affected individuals. IVIG has proven effective in shortening the course of thrombocytopenia.

Catastrophic antiphospholipid syndrome (CAS) is another uncommon cause of thrombocytopenia that can have devastating consequences. Affected patients typically have systemic lupus erythematosus or another autoimmune disorder associated with antiphospholipid antibodies or the primary form of antiphospholipid syndrome unassociated with another rheumatologic condition. Antiphospholipid syndrome is a hypercoagulable disorder associated with recurrent venous and/or arterial thromboembolism, recurrent pregnancy losses, and thrombocytopenia. CAS is typically triggered by discontinuation of anticoagulation or immunosuppressive medications for associated autoimmune disorders, severe infections, or major surgery. Clinical manifestations include disseminated microvascular thrombosis with evidence of peripheral ischemia, multiorgan dysfunction (including renal and neurologic dysfunction), and consumptive thrombocytopenia. Diagnosis is made based upon the characteristic clinical presentation and laboratory testing demonstrating the presence of antiphospholipid syndrome. Multimodality treatment is essential for optimal outcomes and includes anticoagulation, immunosuppression with high dose corticosteroids, and plasmapheresis.

Splenic Sequestration

Thrombocytopenia may also result from splenic sequestration of platelets in patients with significant splenomegaly. Normally, one third of the circulating platelet mass resides in the spleen. This proportion may grow substantially in patients with significant splenomegaly and result in moderately reduced platelet counts, as well as lower-than-expected responses to platelet transfusions. Splenic sequestration is commonly seen in patients with liver cirrhosis and hypersplenism due to hematologic disorders such as myelofibrosis. While splenectomy or operative portosystemic shunting may result in a reduction in the severity of thrombocytopenia, production defects also contribute to thrombocytopenia in these patients, so such major surgical procedures are rarely considered solely for treatment of thrombocytopenia due to splenic sequestration.

INHERITED QUANTITATIVE PLATELET DISORDERS

Inherited platelet disorders are a rare cause of bleeding in critically ill patients because these conditions are often identified prior to surgical procedures. Inherited aplastic anemia syndromes such as Fanconi's anemia, and inherited disorders affecting platelet production such as inherited amegakaryocytic thrombocytopenia, the thrombocytopenia with absent radius (TAR) syndrome, and Wiskott-Aldrich syndrome (WAS) result in chronic thrombocytopenia of varying severity. These patients can be identified by the presence of reduced peripheral blood counts and abnormal bone marrow examinations showing reductions in all three progenitor cell lines and hypersensitivity to DNA-damaging agents (Fanconi's anemia), or selective reductions in megakaryocytes, the platelet progenitor cells (inherited amegakaryocytic thrombocytopenia, TAR syndrome). The WAS is an X-linked disorder characterized by microthrombocytopenia—for example, the production of reduced numbers of small platelets, eczema, and immunodeficiency. Any male with thrombocytopenia and a small mean platelet volume on his complete blood count should be suspected of having WAS.

Qualitative Platelet Disorders

Acquired Platelet Dysfunction—Drug-Induced Platelet Dysfunction

Platelet dysfunction can also contribute to bleeding in critically ill patients. The most common qualitative disorders of platelet function are acquired (see Table 1). Use of medications or supplements with antiplatelet effects is a common cause of unanticipated surgical bleeding. Medications such as aspirin, clopidogrel, prasugrel, or ticlopidine should be discontinued 7 to 10 days prior to surgical procedures unless contraindicated by severe coronary artery disease or cardiac stents. It is always important to assess the indication for antiplatelet therapy prior to surgery, as inappropriate discontinuation can lead to fatal coronary thrombotic events. In patients with significant coronary artery disease or cardiac stents, it is advisable to discuss discontinuation of antiplatelet therapy with their cardiologist before surgery. Nonsteroidal antiinflammatory drugs (NSAIDs) can cause significant reversible platelet dysfunction, the duration of which varies by drug half-life. Ibuprofen, indomethacin, and ketoprofen have short half-lives (2 to 6 hours), so discontinuation 1 to 2 days preoperatively is sufficient. In contrast, naproxen and meloxicam have much longer half-lives (12 to 17 hours and 15 to 20 hours, respectively), so discontinuation 3 to 4 days preoperatively is warranted to avoid the presence of residual antiplatelet effects at the time of surgery. Dietary supplements and herbal remedies, particularly vitamin E and omega-3 fatty acids, are known to have antiplatelet effects. Exposure to these medications should be considered in any critically ill patient with bleeding. Although the TBT and the PFA-100 can measure the effects of antiplatelet medications, these tests should not be relied upon to identify patients at increased risk of bleeding

with invasive procedures because these tests are not sensitive or specific enough for this purpose.

In patients with significant bleeding, platelet transfusions, and/or desmopressin (1-Desamino-8-D-Arginine Vasopressin or DDAVP), an arginine vasopressin analog that induces factor VIII and von Willebrand factor secretion can be used to improve hemostasis in the setting of antiplatelet therapy. In life-threatening bleeding, recombinant human factor VIIa (NovoSeven, Novo Nordisk, Inc., Princeton, NJ) has been used successfully to treat patients with acquired platelet dysfunction. Given the expense and prothrombotic risk associated with this agent, it should only be used for this purpose when conventional therapy has been ineffective.

Uremia/Myeloproliferative Disorders

Uremia is a common cause of platelet dysfunction among critically ill patients. The bleeding tendency in patients with renal insufficiency is multifactorial. Some contributing factors include increased production of the platelet inhibitory factors prostacyclin and nitric oxide by the endothelium, acquired defects in von Willebrand factor activity, decreases in platelet adhesive glycoproteins on the platelet surface, anemia (red cells serve as a sink for nitric oxide), and altered clearance of antithrombotic medications (heparin, low-molecular-weight heparin, aspirin, etc.). The TBT and/or the PFA-100 is usually prolonged in patients with uremic platelet dysfunction. Screening coagulation testing, including a PT and aPTT, should be included in any investigation of bleeding in a uremic patient to exclude the possibility of persistent heparinization associated with hemodialysis or acquired vitamin K deficiency. Bleeding in uremic patients can be improved by regular dialysis and increasing the hematocrit to 30% to 35% with transfusions or erythropoietin supplementation. Administration of DDAVP can also transiently improve hemostasis due to platelet dysfunction in dialysis patients by increasing the amount of von Willebrand factor available to assist in platelet adhesion/aggregation. Cryoprecipitate is also effective but carries a risk of transfusion-borne infectious illnesses and therefore should be avoided for this purpose. Conjugated estrogens produce slower but more durable responses at the cost of hormonal side effects.

Acquired platelet dysfunction is also common among patients with chronic myeloproliferative disorders such as polycythemia vera and essential thrombocythemia in association with markedly elevated platelet counts (typically exceeding 1,000,000/μL). Von Willebrand antigen levels (measures the amount of von Willebrand factor protein) and ristocetin cofactor activity (measures the function of von Willebrand factor) as well as TBT and the PFA-100 can be used to confirm the presence of this entity. Acute therapy for symptomatic patients includes administration of DDAVP or use of von Willebrand factor containing factor VIII concentrates or platelet transfusions. Cryoprecipitate should be avoided. Reduction of platelet counts with chemotherapeutic agents is often beneficial for long-term treatment.

INHERITED QUALITATIVE PLATELET DISORDERS

Inherited qualitative platelet disorders include the Bernard-Soulier syndrome, Glanzmann's thrombasthenia, and the platelet storage pool diseases such as Gray platelet syndrome. Patients with these conditions have platelet dysfunction that can vary from mild to severe. Common historical complaints include chronic epistaxis, gum bleeding, menorrhagia, easy bruisability, and excessive bleeding with invasive procedures, including dental extractions and minor surgery. The TBT and the PFA-100 are usually abnormal in these patients. In patients with severe Bernard-Soulier syndrome or Glanzmann's thrombasthenia, a TBT should probably be avoided if the diagnosis has been previously documented, as the TBT can be extremely prolonged and lead to significant bleeding. Platelet aggregometry and platelet flow cytometry are invaluable in the diagnosis of inherited qualitative platelet disorders and thus should be ordered for definitive diagnosis. Platelet transfusions, DDAVP, and antifibrinolytic medications such as epsilon-amino caproic acid (Amicar, Wyeth-Ayerst, Collegeville, Penn) have all been used to achieve hemostasis in patients with these disorders. In general, platelet transfusions should be reserved for major surgery or serious bleeding in patients with platelet receptor disorders (Bernard-Soulier syndrome, Glanzmann's thrombasthenia), because these patients have a propensity to develop platelet alloantibodies, which can make them unresponsive to platelet transfusions in the future. Whenever possible, local hemostatic agents (e.g., fibrin sealants) should be employed. Preoperative hematology consultation is essential to achieve optimal surgical outcomes.

Coagulation Disorders

Five Basic Patterns of Coagulation Test Results

Coagulation factor disorders are a common cause of bleeding in the critically ill patient. Similar to platelet disorders, inherited and acquired coagulation factor disorders must be considered in the differential when approaching a bleeding patient. Rapid accurate interpretation of screening coagulation tests is key to identifying coagulation disorders. Five basic patterns of coagulation test results can be identified: a prolonged PT, a prolonged aPTT, a prolonged TT, a prolongation of the PT and the aPTT, and prolongation of all three screening tests.

An isolated prolonged PT occurs only in the presence of factor VII deficiency or a factor VII inhibitor. The most common cause of factor VII deficiency in the postoperative period is early vitamin K deficiency. Later vitamin K deficiency is characterized by reductions in factor IX, factor X, and prothrombin levels, which result in a prolonged aPTT and PT. If vitamin K deficiency is suspected, intravenous or oral vitamin K supplementation is the best initial management approach, as correction of the PT will likely take place before other diagnostic laboratory results return. If the PT fails to correct, then a factor VII activity assay can be used to confirm the presence of factor VII deficiency. Factor VII inhibitors are rarely seen except in patients with inherited factor VII deficiency. The presence of an inhibitor can be identified using mixing studies that demonstrate the failure of the PT to correct after the addition of normal pooled plasma.

An isolated prolonged aPTT can be seen in association with any deficiency state or factor inhibitor affecting one of the intrinsic pathway coagulation proteins (factors XII, XI, IX, VIII, prekallikrein, and high-molecular-weight kininogen). Specific factor assays can confirm the identity of the responsible factor. Knowledge of the incidence and clinical manifestations of coagulation disorders can help to prioritize factor testing. Factor VIII deficiency (hemophilia A) is the most common intrinsic factor deficiency disorder, followed by factor IX deficiency (hemophilia B) and factor XI deficiency (hemophilia C). Therefore, factor testing should proceed in this order in most patient populations. However, in patients of Ashkenazi Jewish ethnicity, factor XI testing should be considered early because the prevalence of heterozygous factor XI deficiency can be as high as 8%. Deficiencies of factor XII, prekallikrein, or high-molecular-weight kininogen are not associated with a clinical bleeding disorder, so factor assays for these coagulation disorders should be performed later.

The only deficiency state associated with a prolonged TT is a deficiency of fibrinogen. Confirmation of this result can be obtained by ordering a fibrinogen assay. Thrombin inhibitors develop rarely as a result of exposure to bovine thrombin. Combined prolongation of both the aPTT and the PT in the presence of a normal TT generally indicates that there is a deficiency of a common pathway factor (factor X, factor V, or prothrombin). Less commonly, this result is a

consequence of factor deficiencies affecting both the extrinsic (factor VII) and intrinsic pathways (factors XII, XI, IX, and VIII; prekallikrein; and high-molecular-weight kininogen). Vitamin K deficiency can cause this clinical picture. Likewise, prolongation of the PT, aPTT, and TT generally represents severe fibrinogen deficiency or an inhibitor of thrombin (factor II inhibitor, heparin, etc.), although abnormalities in multiple factors could also generate this result.

INHERITED COAGULATION DISORDERS

The most common inherited factor deficiency states are the different hemophilias and von Willebrand disease (Table 4). Hemophilia A (factor VIII deficiency) is an X-linked recessive trait that affects 1 in 5000 male births. Disease severity correlates closely with factor levels. The normal range for factor VIII levels is generally 50% to 150%. Severe hemophilia A is characterized by factor VIII levels less than 1% and places affected individuals at high risk for spontaneous joint and soft tissue bleeds. Moderate hemophiliacs have factor VIII levels between 1% and 5% and usually bleed after trauma or invasive procedures. Minor hemophilia patients have factor levels greater than 5% and usually bleed only after significant trauma or surgical procedures. The diagnosis of hemophilia A can be confirmed with a factor VIII assay. Factor VIII inhibitors occur in approximately 15% to 25% of severe hemophiliacs, so mixing studies and factor VIII inhibitor assays should be assessed before surgical procedures and whenever a patient does not appear to respond appropriately to factor VIII replacement therapy. Plasma-derived and recombinant factor VIII concentrates are the principal treatment for patients with hemophilia A (Table 5 and Box 3). Although cryoprecipitate contains factor VIII, this product should not be used for treatment of hemophilia because it is a less concentrated source of factor VIII and is associated with a risk of transmission of blood-borne infectious diseases. Recombinant factor concentrates are generally preferred over plasma-derived concentrates for most patients because they are associated with a lower risk of transfusion-associated infections. DDAVP, which induces release of factor VIII and von Willebrand factor, can be used for hemostasis in mild hemophiliacs undergoing minor surgical procedures. When using DDAVP for treatment of mild hemophilia or von Willebrand disease, it is important to note that it is only effective for three or four doses, after which tachyphylaxis develops due to exhaustion of preformed stores of factor VIII and von Willebrand factor in the endothelium and liver. Antifibrinolytic medications such as epsilon aminocaproic acid (Amicar, Wyeth-Ayerst, Collegeville, Penn) are useful adjuvant hemostatic agents for hemophiliacs undergoing mild mucosal surgery.

TABLE 4: Coagulation disorders

Inherited coagulation disorder	Acquired coagulation disorders
Von Willebrand disease	Vitamin K deficiency
Hemophila A (factor VIII deficiency)	Liver disease
Hemophilia B (factor IX deficiency)	Anticoagulation-associated coagulopathy
Hemophilia C (factor XI deficiency)	Unfractionated heparin
Factor VII deficiency	Low molecular weight heparin
Factor X deficiency	Fondaparinux
A-, hypofibrinogenemia	Direct thrombin inhibitors
Factor V deficiency	Disseminated intravascular coagulation (DIC)
Factor II deficiency	Acquired factor inhibitors
Factor XII deficiency*	Factor V/thrombin inhibitors associated with bovine thrombin exposure
Factor XIII deficiency	Factor VIII inhibitors
High-molecular-weight kininogen deficiency*	Cardiac bypass coagulopathy Acquired von Willebrand disease (Heyde's syndrome) associated with severe aortic stenosis
Prekallikrein deficiency*	Dilutional coagulopathy (massive transfusions)

*Indicates disorders that can cause a markedly prolonged aPTT but do not cause clinical bleeding.

For major surgery, factor VIII levels should be raised to 80% to 100% preoperatively and maintained there for the first 3 days and then maintained at 50% or more for 10 to 14 days. Daily trough factor VIII activity assays should be obtained to ensure that minimum factor VIII levels for hemostasis are maintained. For cardiac surgery and neurosurgery, trough levels should be maintained at 100% for the first 72 hours and then at 80% to 100% for the first week. Trough levels of 50% to 80% are adequate for days 8 to 14.

Factor IX deficiency (hemophilia B) is inherited in a X-linked recessive fashion and is about sevenfold less common than hemophilia A. Factor levels correlate with clinical severity similar to hemophilia A. Laboratory diagnosis relies upon factor IX assays, and plasma-derived and recombinant factor IX concentrates are used for therapy. The duration of therapy for surgery is similar to patients with factor VIII deficiency. Factor IX inhibitors are much less common, affecting only 2% of patients. Allergic reactions to factor IX concentrates often herald the development of a factor IX inhibitor.

Factor XI deficiency (hemophilia C) is an uncommon disorder except in patients of Ashkenazi Jewish descent, in whom as many as 8% carry one mutated allele. Fortunately, most individuals have mild to moderate deficiencies of factor XI, in whom bleeding symptoms are mild. Consequently, many individuals with factor XI deficiency are first identified on preoperative testing or after developing bleeding with invasive procedures. Unlike hemophilia A and B, very low factor XI levels do not always correlate with a bleeding tendency. Those patients who do bleed do so after significant trauma or major surgery. Factor XI inhibitors are rare except in patients with severe factor XI deficiency (<1%) who have been exposed to previous replacement therapy. Diagnosis is made by factor XI activity assays. Although factor XI concentrates are used in Europe, fresh frozen plasma is the only replacement product available in the United States. Generally, 15 mL/kg of plasma are transfused prior to invasive procedures. Factor XI levels of 20% to 25% are typically adequate for hemostasis. Daily assessment of factor XI levels and plasma replacement to maintain adequate factor levels for at least 3 to 5 days and 10 to 14 days are used to treat patients undergoing minor surgery and major surgery, respectively. Since factor XI is important in regulation of fibrinolysis, antifibrinolytic medications such as epsilon aminocaproic acid (Amicar, Wyeth-Ayerst, Collegeville, Penn) have been found to be useful for prevention of bleeding in patients with mild factor XI deficiency.

Von Willebrand disease (vWD) is caused by inherited autosomal deficiency of von Willebrand factor (vWF), a protein that plays a key

TABLE 5: Treatment of coagulation factor disorders

Bleeding disorder	Target factor level	Plasma product
Hemophilia A		
Minor surgery	>50% for 3-7 days	
Major surgery	>80% to 100% for 3 days, then >50% for next 7-11 days	Recombinant (preferred) or plasma-derived monoclonal factor VIII concentrates
Cardiovascular, prostate and neurosurgery	>100% for 3 days, then 80% to 100% for days 4-7 and >50% for days 8-14	
Hemophilia B		
Minor surgery	>50% for 3-7 days	
Major surgery	>80% to 100% for 3 days, then >50% for next 7-11 days	Recombinant or monoclonal plasma-derived factor IX concentrates
Cardiovascular, prostate and neurosurgery	>100% for 3 days, then 80% to 100% for day 4-7 and >50% for days 8-14	
Von Willebrand disease		
Minor surgery Major surgery	>50% for 1-3 days Keep 50% to 100% for 7-14 days	DDAVP or vWF-containing factor VIII concentrates (e.g., Humate P)
Factor XI deficiency		
Minor surgery Major surgery	>30% for 3-4 days >45% for 7-10 days	Fresh frozen plasma (FFP)
Factor VII deficiency		
Minor surgery Major surgery	>15% >25%	FFP or recombinant human factor VIIa
Factor X deficiency		
Minor surgery	>15%	FFP or prothrombin
Major surgery	>50% perioperatively, then >30%	Complex concentrates
Factor V deficiency		
Minor surgery Major surgery	>25% >50% perioperatively, then >25%	FFP
Prothrombin deficiency		
Minor surgery Major surgery	20% to 40% 20% to 40%	FFP or prothrombin complex concentrates
A-fibrinogenemia or hypofibrinogenemia		
Minor surgery Major surgery	>50-100 mg/dL for 3 days >50-100 mg/dL for 2 weeks	Cryoprecipitate or fibrinogen concentrate (Riastap)
Factor XIII deficiency		
Minor surgery Major surgery	>5% >5%	FFP or cryoprecipitate

role in platelet adhesion and serves as a carrier protein for factor VIII, protecting it from degradation by activated protein C. Reflecting its primary role in platelet function, vWD patients generally suffer mucosal bleeding (epistaxis, gum bleeding, menorrhagia, bleeding with dental surgery). The best laboratory assays for diagnosis of von Willebrand disease are the von Willebrand antigen assay, which measures the amount of vWF protein, and the ristocetin cofactor assay or the collagen-binding assay, both of which measure vWF protein function. Factor VIII levels are generally normal or only mildly reduced, so the aPTT is not a useful screening test for vWD.

Most patients with mild disease can be treated with DDAVP, but confirmation of DDAVP response preoperatively is important to avoid bleeding complications in nonresponders. In addition, it is important to remember that DDAVP cannot be used for extended

BOX 3: Hemostatic agents

Fresh Frozen Plasma (FFP)
Contains all coagulation factors in low concentrations (1 unit/mL)
Used for treatment of factor deficiency states without available factor concentrates
Used for treatment of coagulopathies associated with deficiency of multiple factors (e.g., liver disease, cardiac surgery, dilutional coagulopathy, etc.)

Cryoprecipitate
Contains factor VIII, von Willebrand factor, fibrinogen, factor XIII
Used for treatment of fibrinogen and factor XIII deficiency
Should *not* be used for treatment of factor VIII deficiency or von Willebrand disease *unless* factor VIII/von Willebrand–containing concentrates are not available
Factor VIII concentrates (recombinant, plasma derived)
Used for treatment of hemophilia A (factor VIII deficiency) and von Willebrand disease (e.g., Humate P and other von Willebrand factor containing factor VIII concentrates)
Factor IX concentrates (recombinant, plasma derived)
Used for treatment of hemophilia B (factor IX deficiency)

Prothrombin Complex Concentrate
Contains vitamin K–dependent factors II, IX, and X
Used for reversal of warfarin anticoagulation in patients with serious bleeding

Activated Prothrombin Complex Concentrates
Contain activated factors II, VII, IX, and X
Used for treatment for factor VIII inhibitors

Recombinant Human Factor VIIa (NovoSeven)
Licensed for treatment of factor VIII inhibitors (used off-label for treatment of bleeding in patients with inherited platelet dysfunction, cardiac surgery coagulopathy, etc.)

Fibrinogen Concentrate (Riastap, CSL Behring)
Licensed for treatment of A- or hypofibrinogenemia

Fibrin Sealants (e.g., Tisseel)
Contains fibrinogen, thrombin, factor XIII
Used as a local hemostatic agent

Antifibrinolytic Agents (Epsilon Aminocaproic Acid, Aprotinin)
Inhibit the fibrinolysis by inhibiting plasmin activity or generation

Desmopressin (DDAVP)
Induces release of von Willebrand factor and factor VIII
Used for treatment of mild von Willebrand disease and factor VIII deficiency

replacement therapy (>72 hours) because of tachyphylaxis. Therefore, for extended therapy or treatment of patients with severe disease, vWF containing factor VIII concentrates should be used. Cryoprecipitate should not be used for treatment of vWD because of its greater risk of transfusion-transmitted infectious diseases. A functional measure of vWF, such as the ristocetin cofactor assay, should be used to monitor therapy.

Inherited deficiency states involving other factors are rare, affecting in general less than 1 in 500,000. Except for factor VII deficiency, for which recombinant human factor VIIa (NovoSeven, Novo Nordisk, Princeton, NJ) can be used, and fibrinogen deficiency, for which a plasma-derived fibrinogen concentrate (Riastap CSL, Behring, King of Prussia, Penn) is available, fresh frozen plasma is the only available replacement product for these rare inherited deficiency states. The available plasma products for treatment of coagulation disorders and the appropriate doses and durations of therapy for bleeding and surgical procedures are listed in Table 5.

Fibrin sealants are a useful hemostatic adjunct to traditional blood products for critically ill patients with bleeding. Although fibrin sealants have traditionally been made in the operating room by adding bovine thrombin to cryoprecipitate, these "bedside" products are associated with the development of inhibitors against factor V and thrombin. More recently, human thrombin (Evithrom Ethicon, Summerville, NJ) and recombinant human thrombin (Recothrom, Zymogenetics, Seattle, Wash) have been developed that can be used with cryoprecipitate to make fibrin glue and are associated with a lower risk of coagulation factor inhibitors. Commercial fibrin sealants such as Tisseel VH (Baxter HealthCare, West Lake Village, Calif), which contain virally inactivated human fibrinogen and thrombin supplemented with aprotinin, an antifibrinolytic agent, are also effective local hemostatic agents and have not been associated with coagulation inhibitors. In addition, commercial fibrin sealants are pathogen-inactivated, so they are associated with a lower risk of transfusion-associated infections.

ACQUIRED COAGULATION DISORDERS

Acquired coagulation disorders are a common cause of coagulopathy in the critically ill patient (see Table 6). Among acquired coagulopathies, disseminated intravascular coagulation is among the most common and difficult to treat. Although there are a large number of stimuli that can trigger it (e.g., sepsis, snake venom, trauma, cancer, heparin-induced thrombocytopenia), disseminated intravascular coagulation ultimately, is a syndrome of excessive thrombin production. The end result is diffuse fibrin clot and platelet plug formation, consumption of fibrinogen, platelets and coagulation factors, and activation of the fibrinolytic system. Clinically, disseminated intravascular coagulation has at least three different presentations: diffuse microvascular thrombosis characterized by cool, cyanotic, or necrotic digits or extremities; diffuse hemorrhage manifested by bleeding from sites of previous invasive procedures; or asymptomatic. Clinical manifestations are dictated by the degree of activation of the coagulation cascade and the balance between clot formation and fibrinolysis. Laboratory markers of disseminated intravascular coagulation include thrombocytopenia; a prolonged aPTT, PT, or TT; elevations of D dimers or fibrin degradation products; and hypofibrinogenemia. Although rarely measured, antithrombin, protein C, and protein S levels are often reduced in disseminated intravascular coagulation as well. Although the aPTT and PT are the most commonly ordered tests when investigating patients for disseminated intravascular coagulation, D dimer levels are the most sensitive assay for this entity.

Therapy for disseminated intravascular coagulation should be directed principally against the underlying cause. Antibiotics and supportive therapy (intravenous fluids, vasoactive medications, blood products, etc.) should be employed in disseminated intravascular coagulation associated with infections. Aggressive blood product support is also reasonable for patients with disseminated intravascular coagulation and bleeding. While anticoagulation has generally not improved outcomes for most patients with thrombotic forms of disseminated intravascular coagulation, it is essential for patients with HIT and DIC or catastrophic antiphospholipid syndrome, and DIC as anticoagulation is essential to suppress the prothrombotic stimulus responsible for these forms of disseminated intravascular coagulation.

Vitamin K deficiency is a common cause of acquired coagulopathy in the intensive care unit, as critically ill patients often have limited vitamin K intake, exposure to broad-spectrum antibiotics, and disrupted hepatobiliary recirculation of vitamin K. The primary

sources of vitamin K are green vegetables such as broccoli and spinach and supplemental vitamin K produced by intestinal flora. Therefore, patients who are not eating well and are being treated with broad-spectrum antibiotics are at high risk for this acquired coagulopathy. Several antibiotics containing the N-methyl-thiotetrazole side chain (e.g., cefamandole, cefotetan, cefoperazone, etc.) that inhibits vitamin K epoxide reductase, an enzyme in the vitamin K recycling pathway, place patients at particularly high risk of this complication. Vitamin K is essential to the production of functional forms of the coagulation factors prothrombin (factor II), factor VII, factor IX, and factor X, as well as the anticoagulant proteins, protein C, and protein S. Since factors such as factor VII have a half-life of 6 hours, prolongation of the PT can occur rapidly once vitamin K stores are depleted.

Clinically, vitamin K deficiency is manifested by the development of ecchymoses and bleeding from the site of blood draws or invasive procedures. Since factor VII has the shortest half-life of the vitamin K–dependent coagulation factors, the PT is the first test to become abnormal, followed by prolongation of the aPTT. Mixing studies will demonstrate complete correction of the laboratory abnormalities. Administration of vitamin K results in rapid correction of the coagulopathy. Since oral vitamin K_1 is as effective as subcutaneous vitamin K_1 in patients without biliary disease and poses no risk of anaphylaxis, this route should be used in patients without serious bleeding or biliary disease. Patients with serious or life-threatening bleeding should be treated with intravenous vitamin K_1 because it can result in substantial correction of the PT within 4 to 8 hours. Any time intravenous vitamin K_1 is administered to a patient, it should be given slowly (no more rapidly than 1 mg per minute), with close monitoring for evidence of anaphylaxis (estimated absolute risk 1 out of 3000). FFP should only be used for treatment of vitamin K deficiency in situations of life-threatening bleeding when rapid correction is necessary.

Anticoagulant-Associated Bleeding

Anticoagulants are an important cause of bleeding that should be investigated in any patient presenting with bleeding during anticoagulation. The most common anticoagulants in the inpatient environment are unfractionated heparin, low-molecular-weight heparin, and warfarin. Newer anticoagulants that are being used increasingly in inpatients are direct thrombin inhibitors such as argatroban (Novastan, GlaxoSmithKline, Research Triangle Park, NC) and bivalirudin (Angiomax, The Medicines Company, Parsippany, NJ), which are used for treatment of HIT, and desirudin (Iprivask, Canyon Pharmaceuticals, Hunt Valley, Md), which is approved for VTE prevention. Fondaparinux (Arixtra, GlaxoSmithKline, Research Triangle Park, NC), an indirect antithrombin-dependent parenteral factor Xa inhibitor, is approved for treatment and prevention of venous thromboembolism and acute coronary syndromes. More recently, dabigatran (Pradaxa, Boehringer Ingelheim, Ridgefield, Conn), the first oral direct thrombin inhibitor, and rivaroxaban (Xarelto, Janssen Pharmaceuticals, Titusville, NJ), the first oral direct factor Xa inhibitor, have been approved by the FDA for thromboprophylaxis in patients with nonvalvular atrial fibrillation (both medications) and in patients undergoing hip or knee arthroplasty (rivaroxaban only).

Unfractionated Heparin

Unfractionated heparin results in anticoagulation by virtue of its interaction with the endogenous anticoagulant protein antithrombin (III). Heparin accelerates the inhibitory interaction of antithrombin with thrombin and activated factors X, IX, and XI by several thousand–fold. Due to its broad spectrum of activity, unfractionated heparin results in a prolongation of the aPTT. The TT is also exquisitely sensitive to its effects. Definitive demonstration that heparin is responsible for a coagulopathy can be obtained by repeating the aPTT after exposing the patient's plasma to heparinase. A dramatic correction of the aPTT is conclusive evidence of heparin contamination. The most frequent clinical situations when heparin is associated with clinical bleeding include patients immediately after cardiac bypass surgery, patients undergoing hemodialysis, and patients receiving heparin for venous thromboembolism prophylaxis or treatment. Protamine administered intravenously in a dose of 1 mg per 100 units of heparin can be used to reverse heparin-associated coagulopathy.

LOW-MOLECULAR-WEIGHT HEPARIN

Low-molecular-weight heparin (LMWH) can also precipitate bleeding complications. The three LMWHs available in the United States are dalteparin (Fragmin, Eisai, Inc., Woodcliff Lake, NJ), enoxaparin (Lovenox, Sanofi-Aventis, Bridgewater, NJ, and multiple generic enoxaparin manufacturers), and tinzaparin (Innohep, Celgene Corporation Boulder, Colo). LMWH-associated bleeding most commonly develops in patients receiving LMWH for treatment or prevention of VTE who develop worsening renal function or undergo unanticipated invasive procedures. LMWH exerts its anticoagulant effects by accelerating the antithrombotic effects of antithrombin (III), primarily against factor Xa and to a lesser extent thrombin. Since it has significantly less inhibitory activity toward thrombin, LMWH does not typically prolong the aPTT. LMWH concentrations can be measured using specialized assays measuring the activity of factor Xa. However, these assays are generally less rapidly available than routine assays such as the aPTT. Protamine can reverse a variable amount of LMWH activity (enoxaparin 54%, dalteparin 74%, tinzaparin 86%), depending on the agent used. The intravenous dose of protamine should be 1 mg per 100 units (of dalteparin or tinzaparin) or 1 mg per each mg of enoxaparin if the LMWH dose was given within 8 hours. If the LMWH was given more than 8 hours ago, then 0.5 mg of protamine should be given for each 100 units (of dalteparin or tinzaparin) or each mg of enoxaparin. If life-threatening bleeding is occurring and incomplete protamine reversal is a concern, recombinant human factor VIIa (NovoSeven, Novo Nordisk, Inc., Princeton, NJ) has been used successfully in this situation. However, the potential for prothrombotic effects associated with rhFVIIa should be weighed against the severity of bleeding.

WARFARIN

Millions of Americans are treated with warfarin each year for chronic anticoagulation. Warfarin results in anticoagulation by virtue of its inhibition of two enzymes in the vitamin K recycling pathway: vitamin K epoxide reductase and vitamin K reductase. The result is acquired vitamin K deficiency and significant reductions in the functional levels of the vitamin K–dependent coagulation factors prothrombin, factor VII, factor IX, and factor X, as well as protein C and protein S. The impact of warfarin on the coagulation cascade can be assessed using the PT/INR. In situations where rapid reversal is not needed, oral vitamin K can be used to reverse warfarin within 24 hours. If rapid reversal is needed, combined modality therapy with intravenous vitamin K and a prothrombin complex concentrate should be used. Prothrombin complex concentrates are plasma-derived factor concentrates that contain the vitamin K–dependent coagulation factors in high concentrations and can be prepared and administered within minutes. In contrast, plasma requires several hours to administer because it is often stored frozen and large volumes are required for PT/INR reversal.

DIRECT THROMBIN INHIBITORS

The available direct thrombin inhibitors (DTIs) include the parenteral medications argatroban (Novastan, GlaxoSmithKline, Research Triangle Park, NC), bivalirudin (Angiomax, The Medicines Company, Parsippany, NJ), desirudin (Iprivask, Canyon Pharmaceuticals, Hunt

Valley, Md), and the oral DTI dabigatran (Pradaxa, Boehringer Ingelheim, Ridgefield, Conn). Each of these agents directly binds and inhibits thrombin. Argatroban has a half-life of 45 minutes and is cleared by hepatic metabolism. Bivalirudin clearance is 80%, depending on plasma hydrolysis, and 20% renal clearance. It has a half-life of 25 minutes in patients with normal renal function. Desirudin has a half-life of 2 to 3 hours and undergoes renal elimination. Dabigatran has a half-life of 11 to 23 hours, depending on renal function.

The anticoagulant effects of argatroban, bivalirudin, and desirudin can be measured by the aPTT. Therapeutic concentrations of dabigatran can be detected using the aPTT, but it is best measured using a dilute thrombin time assay: the Hemoclot thrombin inhibition assay. No reversal agent is available for any of the DTI. Activated charcoal lavage can be used to prevent absorption of dabigatran in patients who have ingested the drug within the last 2 hours. Hemodialysis can be used to remove bivalirudin and dabigatran in the event of life-threatening bleeding. Argatroban clearance is not accelerated by hemodialysis. rhFVIIa (NovoSeven, Novo Nordisk, Inc., Princeton, NJ) and activated prothrombin complex concentrates (FEIBA NF, Baxter Healthcare Corp., Westlake Village, Calif) have been used with variable success for the reversal of the anticoagulant effects of DTI. Therefore, these reversal agents should be used only in cases of life-threatening bleeding because both agents are associated with an increased risk of thromboembolic complications. A specific reversal agent for dabigatran is in development.

Factor Xa Inhibitors

Fondaparinux (Arixtra, GlaxoSmithKline, Research Triangle Park, NC) is a parenteral indirect factor Xa inhibitor whose activity is mediated by accelerating antithrombin inactivation of factor Xa. It is used in the prevention and treatment of VTE and acute coronary syndromes. It is cleared renally and has a half-life of 17 to 21 hours in patients with normal renal function. It cannot be measured using the aPTT or PT. It should not be used in patients with compromised renal function (creatinine clearance less than 30 mL/min). There is no reversal agent available for fondaparinux, although rhFVIIa has been demonstrated to partially reverse its anticoagulant activity. Rivaroxaban (Xarelto, Janssen Pharmaceuticals, Titusville, NJ) is a direct oral factor Xa inhibitor. It has an elimination half life of 5 to 9 hours in young adults to age 45 years and 11 to 13 hours in older subjects. Rivaroxaban is cleared by hepatic metabolism and renal clearance. Rivaroxaban should be avoided in patients with severely reduced renal function (<15 mL/min) and moderate to severe hepatic function (Childs's class B and C hepatic dysfunction). There is no specific reversal agent for rivaroxaban, although activated prothrombin complex concentrates or rhFVIIa may have some utility in reducing its anticoagulant effects. Activated charcoal can be used to prevent absorption from the gastrointestinal tract in patients who have ingested rivaroxaban within the past 2 hours. Rivaroxaban is not dialyzable.

LIVER DISEASE

The liver is the principal synthetic organ for all of the coagulation factors except for von Willebrand factor and factor VIII and the main source of thrombopoietin, the platelet growth factor. In addition, the liver is responsible for clearance of activated coagulation factors, plasmin, fibrin split products, and D dimers, and it produces fibrinolytic inhibitors such as alpha2-antiplasmin and plasminogen activator inhibitor –1. Consequently, patients with significant liver disease are at high risk for bleeding due to multiple acquired factor deficiencies, thrombocytopenia, platelet dysfunction due to the inhibitory effects of circulating fibrin split products, and a tendency toward hyperfibrinolysis. The PT, aPTT, and TT, as well as the fibrinogen level and platelet count, are useful parameters to assess the bleeding risk associated with liver disease. The thromboelastogram or euglobulin lysis time can help to identify excessive fibrinolytic activity. D dimer levels will often be moderately elevated but do not indicate disseminated intravascular coagulation unless markedly elevated because the liver plays an important role in clearance of D dimers and fibrin split products.

Factor deficiencies associated with liver disease are amenable to FFP replacement. Factor replacement should be guided by clinical findings and coagulation test results. Generally, 15 mL of FFP per kg body weight is an adequate replacement dose. It is important not to strive to normalize the results of coagulation studies, particularly the PT, because factor VII has a short half-life, and attempting to achieve normal levels often results in fluid overload. Generally factor VII levels of 10% to 15% are adequate to stop bleeding. Factor VII levels of 15% to 20% are sufficient for surgical procedures. Often, reducing the PT and aPTT ratio to less than 1.5 is sufficient for most procedures.

If the fibrinogen level is less than 100 mg/dL, transfusion of cryoprecipitate or fibrinogen concentrate (Riastap, CSL Behring King of Prussia, Penn) is more efficient to achieve correction. In a 70-kg patient, each bag of cryoprecipitate will result in a 10 mg/dL increment in the fibrinogen level. On average 3 units of cryoprecipitate must be transfused on a daily basis to maintain fibrinogen levels above 100 mg/dL, but transfusions should be guided by fibrinogen levels. Fibrinogen concentrate is FDA-approved for congenital afibrinogenemia and hypofibrinogenemia, but its use for fibrinogen replacement in acquired fibrinogen deficiency would seem reasonable given its lower risk for transfusion-associated infectious diseases. The dose of fibrinogen concentrate is calculated using the following equation:

Dose mg/kg body weight = Desired fibrinogen level (mg/dL) – Current fibrinogen level (mg/dL)/1.7 mg/dL per mg/kg body weight

Example: 100 mg/dL – 40 mg/dL/1.7 mg/dL per mg/kg body weight = 60/1.7 × 70 kg = 2470 mg of Riastap

The target for fibrinogen replacement should be 100 mg/dL because excessive supplementation may result in a heightened risk of thrombosis. Platelet transfusions should be given to any afebrile patient with a platelet count less than 10,000/μL or a febrile patient with platelets less than 20,000/μL. Patients with active bleeding or planned surgery should have platelet counts increased to 50,000/μL. Table 2 provides the recommended platelet thresholds for different clinical situations.

To ensure that unsuspected vitamin K deficiency is not contributing to a patient's coagulopathy, all patients with liver disease and bleeding who do not have contraindications should be treated with vitamin K. Use of antifibrinolytic agents should be considered in any patient suspected of having primary fibrinolysis as a cause of bleeding. The presence of DIC or active thrombosis should be ruled out prior to initiating antifibrinolytic therapy because these medications can precipitate widespread microvascular thrombosis in patients with DIC. The dose of epsilon aminocaproic acid is a 5-g intravenous loading dose followed by 1 g/hr for 8 hours. The maximal daily dose is 30 g.

ACQUIRED FACTOR INHIBITORS

Factor V and Thrombin Inhibitors

Inhibitors to factor V and, less commonly, thrombin can develop in patients exposed to bovine thrombin. Most commonly this exposure occurs during cardiac surgery or neurosurgery when bovine thrombin is mixed with cryoprecipitate to make fibrin glue for topical hemostasis. Bovine thrombin is commonly contaminated with factor

V. Exposure, particularly repeated exposure, is associated with development of antibodies to bovine thrombin and factor V, which occasionally cross-react with human factor V and, less commonly, thrombin. These antibodies typically arise approximately a week postoperatively and occasionally have been associated with significant hemorrhagic consequences. Factor V and thrombin inhibitors should be considered in any patient who develops an abnormal PT and aPTT in the postoperative period. Thrombin times will be markedly prolonged in these patients, and mixing studies will demonstrate the presence of an inhibitor. Factor V and/or prothrombin levels can be reduced. In the absence of symptoms, patients should not be treated with blood products or immunosuppressant agents. In patients with bleeding, IVIG and corticosteroids have demonstrated utility in eliminating the inhibitor and reducing bleeding symptoms. Patients with life-threatening bleeding should receive multimodality therapy, including immunosuppression and plasmapheresis. Fortunately, bovine thrombin–associated factor inhibitors are transient, persisting for a mean of 2.3 months. The risk of factor V and thrombin inhibitors is less with newer bovine thrombin preparations. In addition, human thrombin (Evithrom, Ethicon, Summerville, NJ) and recombinant human thrombin (Recothrom, Zymogenetics, Seattle, Wash) and commercial fibrin sealants such as Tisseel VH (Baxter HealthCare, West Lake Village, Calif) appear to be much less likely to be associated with coagulation factor inhibitor development.

CARDIAC SURGERY–ASSOCIATED BLEEDING

Cardiac bypass is associated with significant perturbations of the hemostatic mechanism. Excessive bleeding, defined as a blood loss of greater than 1 liter, occurs in 5% of cardiac surgery patients. The reasons for post–cardiac surgery bleeding are multifactorial. Large doses of heparin are used to prevent thrombosis of the bypass circuit. Platelet number and function decline during and after cardiac bypass due to activation and consumption. Coagulation protein levels drop, and activation of the fibrinolytic system also occurs. Each of these abnormalities contributes to an increased risk of bleeding after cardiac surgery. The approach to bleeding after cardiac surgery depends on the rate of bleeding and the clinical status of the patient. Unstable patients with rapid blood loss (≥500 mL/hr) should be resuscitated and surgically explored for a bleeding vessel. Since residual heparin may contribute to excessive bleeding, a second dose of protamine can be given to reverse any residual heparin present. If rapid access to point-of-care or conventional laboratory testing is available, the presence of residual heparin can be measured using an aPTT, thrombin time, or heparin neutralized thrombin time.

In stable patients with excessive bleeding, use of laboratory testing to guide therapy is appropriate. A heparin neutralized thrombin time; PT; aPTT; complete blood count, including platelet count; and fibrinogen should be measured. Patients with evidence of residual heparin (elevated thrombin time, aPTT, reversal with heparinase) should receive a second dose of protamine. Patients with platelet counts less than 50,000/μL should be transfused with platelets. Platelet counts in excess of 50,000/μL are generally not associated with excessive bleeding in the absence of platelet dysfunction. If other laboratory testing does not reveal an abnormality, platelet transfusions should be considered for patients with platelet counts less than 100,000/μL because cardiac bypass can result in dysfunctional spent platelets. Patients with hypofibrinogenemia (fibrinogen <100 mg/dL) should be treated with cryoprecipitate or a fibrinogen concentrate to achieve a fibrinogen level of greater than 100 mg/dL (each bag of cryoprecipitate will raise the fibrinogen level 10 mg/dL in a 70-kg patient). Patients with abnormal aPTT and PT test results unassociated with heparin or hypofibrinogenemia should be transfused with fresh frozen plasma (initial dose 10-15 mL/kg). Since hyperfibrinolysis can result after cardiac bypass, use of antifibrinolytic agents such as epsilon-amino caproic acid or aprotinin should be considered for patients without significant thrombocytopenia (platelets >100,000/μL) and normal or minimally impaired PT and aPTT test results (PT and/or aPTT ratio <1.4). Thromboelastography can be useful in identifying patients with hyperfibrinolysis, although studies demonstrating superior outcomes with TEG-guided management are lacking. Occasional patients with severe aortic stenosis will develop acquired von Willebrand disease (Heyde's syndrome). Von Willebrand disease results from activation of ADAMTS13, resulting in excessive cleavage of vWF. Ristocetin cofactor and vWF antigen studies can be used to identify these patients. Preoperative identification is optimal because bleeding generally takes place during the operative procedure and the abnormality resolves after correction of aortic stenosis. vWF-containing factor VIII concentrates such as Humate P (CSL, Behring, Kankakee, Ill) can be used for replacement therapy.

DDAVP and rhFVIIa have been used to improve hemostasis in cardiac surgery patients. DDAVP, an analog of arginine vasopressin, is most useful as a hemostatic agent when applied to patients with platelet dysfunction. Case series of patients with critical bleeding after cardiac surgery suggest rhFVIIa may have utility in selected patients unresponsive to standard treatments. However, rhFVIIa should be used with caution for this indication given its association with thromboembolism.

VESSEL WALL DISORDERS

Disorders of vascular function are unusual causes for excessive surgical bleeding. Nevertheless, awareness of these disorders can be invaluable for the management of the occasional patient with a vessel wall disorder. Some of the inherited and acquired disorders of vascular function are presented in Table 6. Among the inherited disorders of vascular function, Ehlers Danlos syndrome is the most common to cause hemostatic difficulties. These patients have an inherited defect in collagen synthesis that results in a propensity to easy bruisability, skin and joint tissue laxity, arterial aneurysm formation, and poor wound healing. Some patients will display evidence of abnormal platelet function. A history of platelet-type bleeding is useful for identifying affected individuals in addition to the characteristic clinical findings. Generally, coagulation testing is normal. In patients with abnormal bleeding associated with surgical procedures, DDAVP has proven useful for improving hemostasis. Since patients with Ehlers-Danlos syndrome have poor wound healing, surgery should be undertaken only when absolutely necessary.

An unusual but important acquired cause of excessive surgical bleeding is amyloidosis. Amyloidosis is most often caused by a

TABLE 6: Vascular disorders

Inherited disorders	Acquired disorders
Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome)	Amyloidosis
Congenital hemangiomas	Hypercorticosteroidism (Cushing's syndrome, Cushing's disease)
Connective tissue disorders Ehlers-Danlos syndrome Loewy-Dietz syndrome Marfan syndrome Osteogenesis imperfecta Pseudoxanthoma elasticum	Vitamin C deficiency (scurvy)

monoclonal proliferation of plasma cells that produce light chains, a fragment of immunoglobulin that can collect in vessel walls and organs such as the kidney, liver, spleen, heart, and tongue. In addition to causing organ dysfunction, infiltration of the amyloid protein can cause vascular fragility and acquired factor X deficiency as a consequence of adsorption of factor X by exposed vessel wall amyloid fibrils. Patients with acquired factor X deficiency typically have a prolonged PT and aPTT and reduced factor X levels. Treatment with FFP is often associated with only transient increases in factor X levels because the amyloid fibrils avidly adsorb the transfused factor. RhFVIIa has also been used anecdotally to achieve hemostasis in these individuals. Patients with amyloidosis can be diagnosed by the presence of urinary monoclonal light chain proteins on urine protein electrophoresis and biopsy evidence of amyloid fibrils in skin or affected organs (kidney, heart, liver, bone marrow). Reduction of the amyloid protein with chemotherapy or, occasionally, splenectomy in patients with massive splenic amyloid deposits has been associated with amelioration of bleeding manifestations. Some additional acquired vascular disorders are listed in Table 6.

Laparoscopic Cholecystectomy

L. Michael Brunt, MD

INTRODUCTION

Cholecystectomy is one of the most common operations performed by general surgeons; as many as 900,000 of these procedures are performed in the United States annually. Gallstones are also the most costly disorder of the gastrointestinal tract: approximately $5 billion annually. When laparoscopic cholecystectomy was first introduced into general surgery practice in the early 1990s, the advantages were obvious to patients and treating physicians alike, and it very quickly became the new "gold standard" for removal of the gallbladder. Today, few patients are not considered candidates for laparoscopic cholecystectomy, and alternative approaches such as single-incision techniques and natural orifice transluminal endoscopic surgery (NOTES) approaches have been developed and are under evaluation. Despite the maturation of this procedure in surgical practice and training, injuries to the common bile duct (CBD) continue to occur at a higher rate than in the open cholecystectomy era and remain the major disadvantage of this very common procedure. This chapter reviews the indications for and basic technique of laparoscopic cholecystectomy and intraoperative cholangiography, with a special emphasis on difficult cases and avoidance of biliary injury.

INDICATIONS FOR CHOLECYSTECTOMY

The indications for cholecystectomy are listed in Box 1. Large database analyses in the United States indicate that approximately 90% of all cholecystectomies are performed laparoscopically. The ability to remove the gallbladder laparoscopically with a high degree of success has probably resulted in a lowering of the decision threshold for operation. Despite this, of patients who are truly symptom free, 10% to 25% experience progression to symptoms, and prophylactic cholecystectomy is therefore not generally warranted unless the gallstone is large or there are associated medical conditions or related circumstances, such as candidacy for organ transplantation, the presence of hemolytic processes (sickle cell anemia, hemolytic anemias), and frequent travel to remote parts of the world. In a patient with asymptomatic gallstones, the presence of diabetes mellitus does not increase risk and is not an indication for cholecystectomy.

Biliary colic is the most common indication for cholecystectomy. The typical presentation is one of discrete episodes of epigastric/right upper quadrant abdominal pain that can last from several minutes to several hours. The pain may radiate around to the side, to the subscapular region, or to the substernal and lower chest area; in some patients, the pain prompts an initial cardiac evaluation to rule out a myocardial infarction. Episodes tend to be more frequent in the evening or nighttime because that is when most patients eat their largest meal of the day, and it is not unusual to be awakened at night with an attack. Because gallstones are so common in the population, patients with nonspecific symptoms of predominantly nausea, weight loss, or continuous abdominal pain should be considered for additional diagnostic evaluation with upper gastrointestinal endoscopy or other cross-sectional imaging such as computed tomographic (CT) scan, or both, before proceeding with cholecystectomy.

IMAGING DIAGNOSIS

Ultrasonography is the preferred imaging test for the evaluation of suspected cholelithiasis and is highly sensitive and specific (>95%) for the diagnosis (Figure 1). CT is less sensitive for detecting gallstones and should be reserved primarily for patients with acute abdominal pain in whom gallstones are less likely to be the cause and for patients with severe acute cholecystitis. Biliary scintigraphy is used primarily in patients without demonstrable stones in whom biliary colic is suspected, in order to evaluate gallbladder emptying, as discussed subsequently. In acute cholecystitis, the gallbladder is typically not visualized on scintigraphy; however, this modality is not often needed to establish the diagnosis if one or more gallstones are seen sonographically and the clinical presentation is appropriate. Endoscopic retrograde cholangiopancreatography (ERCP) should be reserved for patients with ongoing biliary obstruction, those in whom a CBD stone is visualized on ultrasonography, or postoperatively to remove CBD stones seen on cholangiography.

COMPLICATED GALLSTONE DISEASE

Complications of gallstones occur in a significant percentage of patients. The most common manifestation of complicated gallstone disease is acute cholecystitis, which accounts for approximately 20% of cases. The typical manifestation is of right upper quadrant pain with localized peritoneal signs, including tenderness with guarding, a positive Murphy's sign, and, in some cases, a palpable gallbladder. Many affected patients also have inflammatory signs of fever and an elevated white blood cell count, although neither is essential for the diagnosis. Ultrasonography may show a stone impacted in the neck of the gallbladder along with a thickened gallbladder wall, pericholecystic fluid and a distended gallbladder (Figure 2). Initial management of the patient with acute cholecystitis consists of nothing by

BOX 1: Indications for cholecystectomy

- Symptomatic cholelithiasis (biliary colic)
- Complicated gallstone disease
 - Acute cholecystitis
 - Gallstone pancreatitis
 - Common bile duct stones
- Asymptomatic cholelithiasis (large gallstone, immunosuppression, hemolytic anemias, impending remote travel)
- Biliary dyskinesia (with typical biliary colic symptoms and low gallbladder ejection fraction)
- Gallbladder polyps (>10 mm, enlarging, or symptomatic)

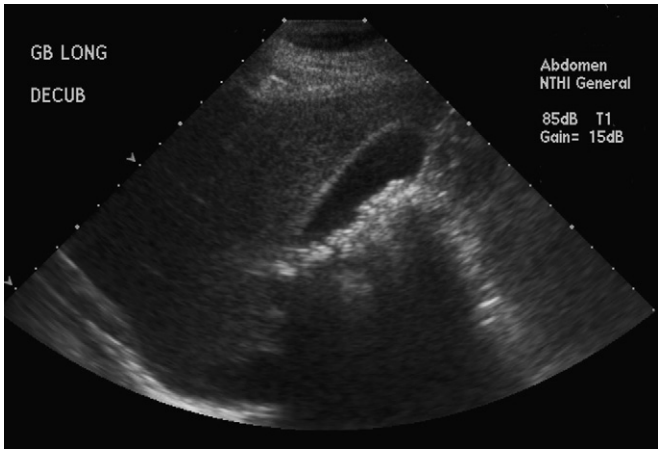

FIGURE 1 Ultrasound image of the gallbladder that shows multiple gallstones with posterior acoustic shadowing.

FIGURE 2 Gallbladder ultrasound image in a patient with acute cholecystitis that shows two large stones (S); the stone on the left is impacted in the neck of the gallbladder. The cursors demarcate the gallbladder wall, which is thickened.

mouth and intravenous antibiotics. The timing of surgery and other aspects of management of acute cholecystitis are discussed in further detail later.

About 10% of patients who have undergone cholecystectomy have or have had a CBD stone. In terms of pain, the presentation is much like that of an acute attack of biliary colic, although the presentation can be atypical, especially in elderly patients. In an acute presentation, there is often an associated elevation in liver enzymes, most notably the transaminases, whose levels become elevated before those of bilirubin and alkaline phosphatase. In any patient who presents with acute epigastric/right upper quadrant pain and laboratory values that show a threefold or higher elevation in the transaminase levels, a CBD stone should be suspected until proven otherwise. Initial ultrasound examination at that time may not show a dilated CBD or a stone in the duct. Most small stones pass spontaneously, but if the obstruction persists, the bilirubin and alkaline phosphatase levels increase, and biliary dilation becomes evident on ultrasonography. The majority of patients in whom a stone in the CBD is visible on ultrasonography are currently managed by preoperative ERCP and stone extraction. Patients with stones found at operation can be managed either by transcystic CBD exploration or by postoperative ERCP. Small stones can sometimes be flushed from the duct by administration of glucagon (1 mg intravenously), followed by saline irrigation of the duct.

An obstructing CBD stone can manifest as ascending cholangitis with fever, right upper quadrant pain, and jaundice (Charcot's triad). Affected patients should be treated conservatively, initially with intravenous antibiotics; ERCP with sphincterotomy and stone extraction should be carried out if clinical improvement is not rapid or if there is evidence of impending sepsis with hypotension and mental status changes.

Patients with gallstone pancreatitis often have midepigastric pain that penetrates to the back. In addition to elevated amylase and lipase levels, the transaminase enzyme levels are often elevated early in the presentation as a result of a distal obstructing CBD stone. In 10% to 25% of cases, the gallstone pancreatitis is severe, which may result in pancreatic necrosis, pseudocyst, or abscess. Most patients with mild gallstone pancreatitis can be managed with cholecystectomy during the index admission once their condition is stabilized and the symptoms and enzyme levels are improving. In one retrospective study, early laparoscopic cholecystectomy within 48 hours of admission was associated with a shorter length of hospital stay and lower rate of ERCP.

BILIARY DYSKINESIA/CHRONIC ACALCULOUS CHOLECYSTITIS

Up to 30% of cholecystectomies in recent years have been performed for biliary dyskinesia or chronic acalculous cholecystitis. For patients with typical symptoms and a reduced gallbladder ejection fraction, symptomatic outcome has been better after cholecystectomy than after medical treatment. However, in one retrospective review with a minimum follow-up of 6 months, 30% of patients had persistent symptoms after cholecystectomy. When pain symptoms are reproduced with administration of cholecystokinin, cholecystectomy has also been associated with symptomatic relief. Patients who have nontypical symptoms or a minimal decrease in gallbladder ejection fraction in comparison with normal should be managed cautiously and undergo a thorough gastrointestinal evaluation and treatment for other disorders such as irritable bowel syndrome before being subjected to surgery.

GALLBLADDER POLYPS

Most gallbladder polyps are benign cholesterol, inflammatory, or adenomatous hyperplastic polyps. Small (<10 mm) polyps should be monitored by periodic ultrasonography. In one series of 143 patients who had repeated ultrasonography follow-up, growth of the polyps was observed in only 9 (6% of cases). Indications for surgery include polyp growth during follow-up or large (>10 mm) polyps that are

solitary. Because most gallbladder polyps are cholesterol in origin, the decision to perform cholecystectomy is often based on the presence or absence of typical symptoms.

The risk of gallbladder cancer in the setting of a porcelain gallbladder has been debated and appears to be less than 5%. If the patient's surgical risk is reasonable, it would be appropriate to proceed with laparoscopic cholecystectomy in this setting. Larger gallbladder masses that are suspect for gallbladder cancer should be approached using an open procedure.

LAPAROSCOPIC CHOLECYSTECTOMY TECHNIQUE

Initial Access

Initial laparoscopic access for laparoscopic cholecystectomy is most commonly achieved with an open Hasson cannula technique at the umbilicus. This approach also facilitates extraction of the gallbladder from the abdomen. If the patient has had previous abdominal surgery at the periumbilical midline, an alternative access site should be considered because of the potential for bowel to be adherent to the abdominal wall at that site. This procedure can be performed in either an open or closed manner. Preferably, access should be either closed (with the use of a Veress needle) in the right subcostal region, if that quadrant of the abdomen is expected to be free of adhesions, or open with an epigastric insertion site. The other ports are then placed under direct laparoscopic vision. Even in patients with multiple prior abdominal operations, a laparoscopic approach is usually possible if initial access can be gained and one ancillary port can be placed to start the adhesiolysis.

Basic Technique

Laparoscopic cholecystectomy is usually performed via four working ports. Only one of these need be 10 mm in diameter (for the clip applier and gallbladder extraction); the others can be 5 mm or smaller. The author's preference is to use a "mini" approach in uncomplicated cases with a 10-mm Hasson port at the umbilicus, a 5-mm epigastric port, and two 3-mm right subcostal ports, as shown in Figure 3. Adhesions to the gallbladder are first removed either by blunt stripping or with judicious application of monopolar electrosurgery (with a Bovie device). The fundus of the gallbladder should then be retracted cephalad and the infundibulum retracted laterally to expose the hepatocystic triangle. Cephalad retraction on the neck of the gallbladder should be avoided because it may tent the CBD and make it more vulnerable to injury. In cases in which the gallbladder is distended or tense with bile, contents should be aspirated before it is grasped (Figure 4) in order to avoid perforation of the wall and spillage of bile and stones, which also makes the subsequent visualization and dissection more difficult.

Critical View of Safety Method of Ductal Identification

The critical view of safety (CVS) as originally described by Strasberg has become the standard method of ductal identification during laparoscopic cholecystectomy. The CVS has three criteria: (1) the hepatocystic triangle should be cleared of fat and fibrous tissue; (2) the gallbladder should be dissected off the liver bed to the cystic plate; and (3) there should be only two structures entering the gallbladder, as illustrated in Figure 5. The CVS does not entail dissection or exposure down to the CBD.

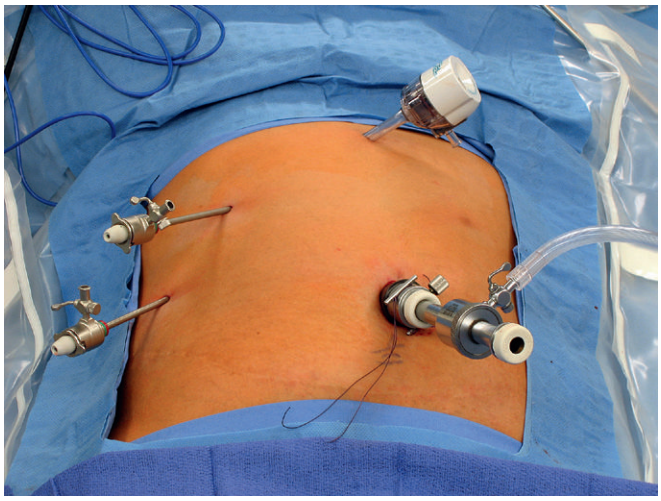

FIGURE 3 Port configuration for laparoscopic cholecystectomy. There is a 10-mm Hasson-type cannula at the umbilicus, a 5-mm epigastric port, and two 3-mm right subcostal ports.

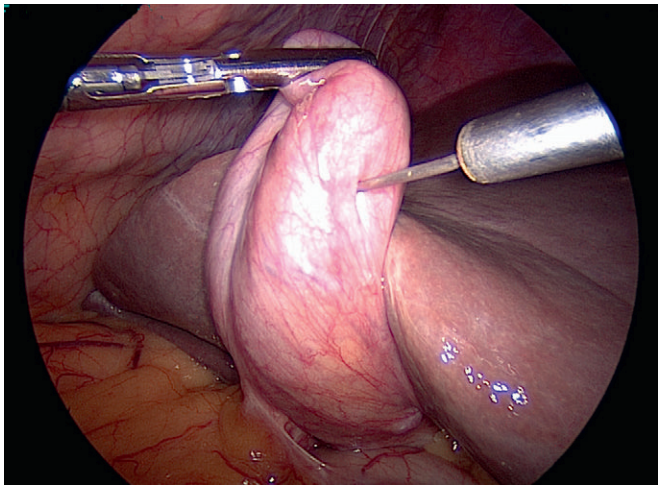

FIGURE 4 Technique of needle aspiration of a distended gallbladder. This approach is useful in the setting of a tense, distended gallbladder to avoid perforation from a grasper and spillage of bile and stones.

The rationale for the CVS is actually based on the ductal identification method that was and continues to be used for open cholecystectomy. The approach in open cholecystectomy entailed isolation of the cystic duct and cystic artery in the hepatocystic triangle. The gallbladder would then be dissected off the liver bed in its entirety, so that the only remaining attachments were the duct and artery entering the gallbladder. This approach is not feasible during laparoscopic cholecystectomy because of the greater difficulty in getting the entire gallbladder off the liver bed before the cystic structures are clipped.

The dissection to the CVS may be performed through a variety of techniques. In most cases, this involves a combination of (1) judicious use of electrosurgery with a hook device to elevate and divide the peritoneum over the gallbladder and the fat, fibrous tissue and small vessels and (2) blunt dissection with stripping of the fat and spreading between the duct and artery and between the artery and liver bed. The lowest possible electrosurgical power setting should be used (≤25-W setting), and the application should be in short bursts of no more than 2 to 3 seconds. Only small amounts of tissue should be divided at a time because of the risk of injuring an accessory biliary structure or blood vessel.

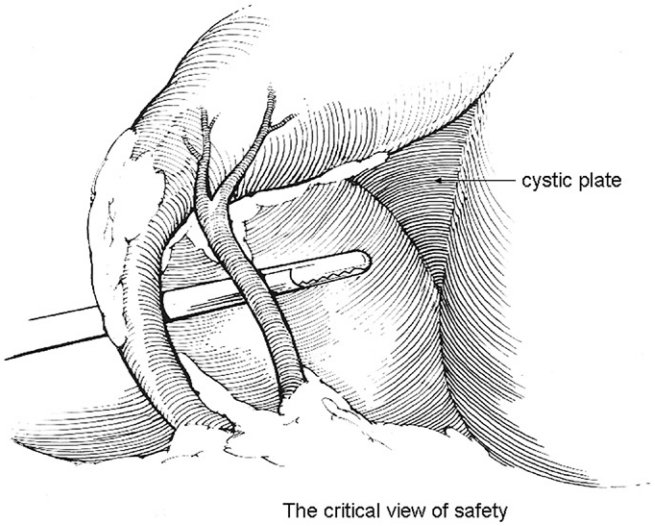

FIGURE 5 Schematic illustration of the critical view of safety. The hepatocystic triangle is clear of extraneous fat and fibrous tissue, only two structures are seen entering the gallbladder, and the gallbladder has been taken off the liver bed to the cystic plate. *(From Strasberg SM, Brunt LM: Rationale and use of the critical view of safety in laparoscopic cholecystectomy,* J Am Coll Surg *211:133, 2010,* Figure 1.*)*

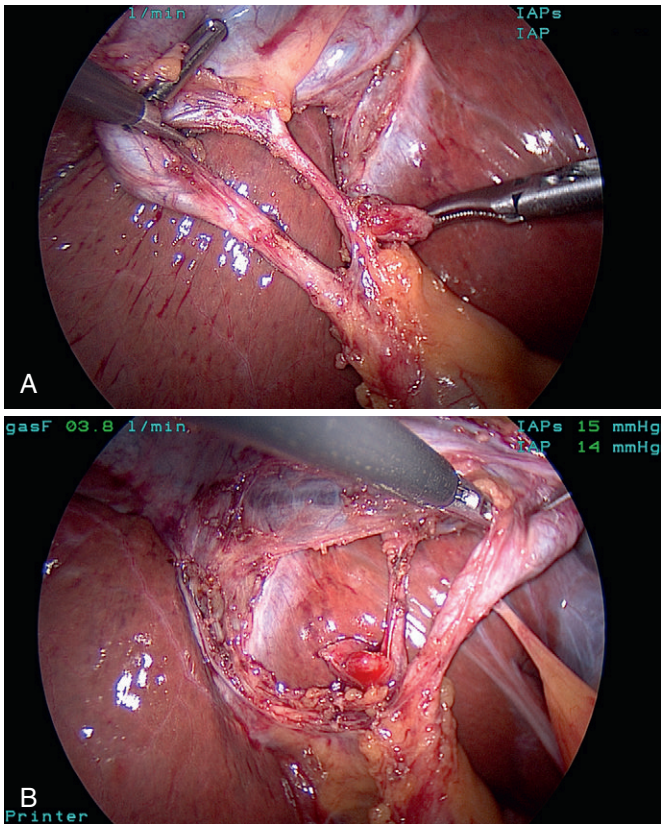

FIGURE 6 Operative photographs of the critical view of safety during laparoscopic cholecystectomy. **A,** Anterior view. **B,** Dorsolateral, or reverse Calot's, triangle view.

Visual documentation of the CVS should be made both from the anterior and the dorsal or reverse Calot's view (Figure 6). The Dutch Society of Surgery has recommended routine photodocumentation of the CVS. Currently, no level I evidence exists to show a reduction in biliary injury with the CVS method. However, large retrospective reviews have shown lower-than-expected injury rates with this approach. It is still possible to injure a biliary structure in the attempt to dissect to the CVS, but once the CVS has been obtained, the risk of biliary injury should be essentially nil.

Intraoperative Cholangiography

Whether intraoperative cholangiography should be performed routinely or selectively has been widely debated in the surgical literature. The classic indications for performing cholangiography during cholecystectomy include a history of gallstone pancreatitis, abnormal liver function test results, and a dilated CBD seen either on preoperative ultrasonography or at operation. In addition, if a stone is found in the cystic duct at operation, then the patient should also undergo cholangiography because of the higher association with a CBD stone. Surgeons should also consider use of cholangiography routinely in the setting of the more difficult cholecystectomy, as with acute cholecystitis.

Cholangiography is performed typically after the CVS is obtained. A clip is placed on the neck of the gallbladder, and a small incision is made in the cystic duct. It may be necessary to open the valves within the cystic duct by spreading with fine scissors. A variety of cholangiographic catheters are available, including balloon-tipped catheters. The author's preference is to use a 4.0F ureteral catheter and a cholangiographic clamp device (Figure 7). Cholangiography is then performed under fluoroscopic imaging. With experience, this step in the operation can be performed routinely in 5 minutes.

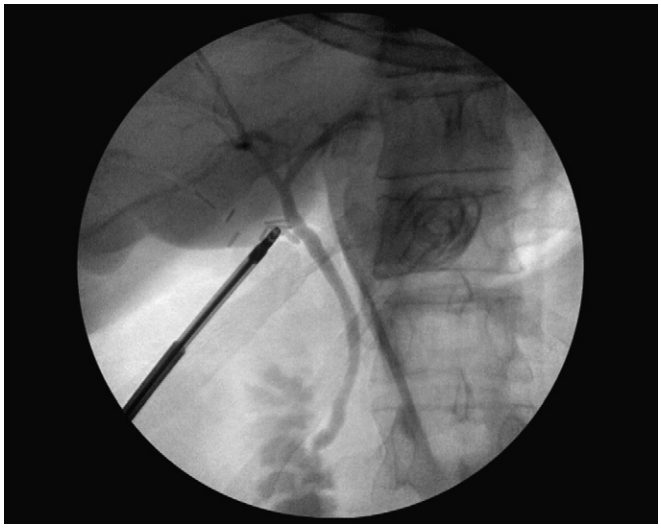

FIGURE 7 Intraoperative cholangiogram obtained during laparoscopic cholecystectomy. Intraoperative view of cholangiographic catheter being inserted within a locking cholangiographic clamp type of grasper.

Four arguments have been posited in favor of the use of routine over selective cholangiography: (1) routine use of cholangiography is essential for developing the expertise to perform it consistently and for proper interpretation of the findings on imaging; (2) cholangiography is a prerequisite for laparoscopic transcystic CBD exploration; (3) at the population level, routine use of intraoperative cholangiography has been associated with a reduction in biliary injury by approximately 30% in studies across multiple continents; and (4) when findings are interpreted correctly, cholangiography should prevent higher level CBD injuries and also increase the chance of injury detection and timely repair. However, a limitation is that it may not always identify aberrant ducts.

THE DIFFICULT CHOLECYSTECTOMY

A number of risk factors have been identified to predict the difficulty of cholecystectomy and therefore the necessity for conversion to an open operation (listed in Box 2). Of these, acute cholecystitis is the most common condition associated with difficulty and conversion and is further discussed later. In addition, conversion rates are higher early in a surgeon's experience (first 50 cases). In a setting of elective laparoscopic cholecystectomy, conversion rates are typically low, less than 3% to 5%. The major risk factor in elective cholecystectomy is thickening of the gallbladder wall, especially in combination with thickening and contraction of the gallbladder, as in patients with repeated episodes of chronic cholecystitis. Patients should be counseled preoperatively about the risk of needing conversion to open cholecystectomy, and conversion should be viewed not as a complication but rather as good surgical judgment. In a patient who has undergone multiple prior abdominal procedures, the risk of needing enterotomy should also be discussed.

Obesity is the most common factor that can increase the difficulty of cholecystectomy. Because the umbilicus is displaced inferiorly, supraumbilical port site for the camera should be considered, in some cases several centimeters proximal to the umbilicus. Longer trocars may be necessary in some patients, and it may be necessary to add a fifth port to provide caudal retraction on the omentum and duodenum, particularly in obese men. The liver is often extensively infiltrated with fat in obese patients and can be difficult to elevate, thereby making the exposure more difficult. In addition, the gallbladder may be intrahepatic and have little if any associated mesentery for dissection from the liver bed.

Multiple Prior Abdominal Operations

In a patient who has undergone previous abdominal surgery at the periumbilical midline, an alternative access site should be considered. Any attempted access site in such a patient should be inspected for injury, especially if adhesions were encountered during access. Likewise, once the initial port has been placed, each subsequent port must be placed under direct laparoscopic vision. Surgeons should be extremely careful in retracting adherent bowel and should limit or avoid the use of electrosurgery or other energy devices for adhesiolysis.

Acute Cholecystitis

Acute cholecystitis is the most common presentation of complicated gallstone disease and accounts for up to 20% of cholecystectomies. Approximately 120,000 gallbladders are removed in the United States annually for acute cholecystitis. About 60% of these cases are in women, but the presentation tends to be more severe in men. Most affected patients have had prior episodes of biliary colic, and the incidence of this presentation may be falling somewhat as a result of earlier laparoscopic cholecystectomy and surgical intervention.

BOX 2: Patient risk factors for the need for conversion from laparoscopic to open cholecystectomy

- Acute cholecystitis
- History of acute cholecystitis
- Multiple (>10) prior episodes of biliary colic
- Morbid obesity
- Male sex
- Older age (>65 years)
- Previous upper abdominal surgery
- Portal hypertension or cirrhosis

The timing of early surgery versus conservative treatment has been addressed in a number of small, prospective randomized trials. Meta-analyses of these trials have shown that early cholecystectomy is associated with a shorter overall hospitalization. Approximately 20% of patients who undergo initial conservative treatment develop persistent or recurrent symptoms before surgical intervention. No differences in conversion rates, morbidity (including bile leaks), or mortality have been shown between early versus late surgery.

The current status of surgical treatment in the United States was reviewed with the use of a national hospital discharge sample of 1 million cholecystectomies for acute cholecystitis. In this study, 9.5% of the laparoscopic cholecystectomies were converted to open procedures, and open cholecystectomy was associated with a 1.3-fold increase in perioperative morbidity. In another multicenter trial from Belgium of 1089 patients, 93% of operations were performed laparoscopically and 6.8% open. The conversion rate from laparoscopic to open cholecystectomy was 11.4% and was twice as high in male patients (14.9%) as in female patients (7.5%). Complications occurred in 5.5% of patients, and the incidence of biliary injury was 1.2%, which is substantially higher than the 0.4% typically associated with elective operation. Of particular concern was the rate of biliary injury in the 116 patients whose procedure was started laparoscopically and then converted to open: The rate of CBD injury was 6.0%, the rate of biliary fistula was 7.7%, and the total incidence of biliary complications was 13.7%. Therefore, this study highlights both the risks and difficulty when a challenging laparoscopic cholecystectomy becomes a difficult open cholecystectomy, especially in view of the infrequent experience of today's trainees with the open approach.

Patients with acute cholecystitis who are at greatest risk for conversion or in whom the operation is predictably more difficult are those with a white blood cell count greater than 18,000/μL, if the time from onset of symptoms is more than 72 hours, if the gallbladder is palpable, and if the patient is older and sicker. Other ultrasound features that may also predict difficulty are gangrenous changes with sloughing of the mucosa, emphysematous cholecystitis, and a gallbladder abscess or perforated gallbladder. Conservative measures, including percutaneous cholecystostomy and operation electively at 2 to 3 months, should be considered in this setting.

Percutaneous Cholecystostomy

Percutaneous cholecystostomy is associated with resolution of acute symptoms and inflammatory signs in more than 90% of cases. The tube must usually be left in until the cholecystectomy and, therefore, this is best reserved for patients at higher risk, especially elderly and critically ill patients. Laparoscopic cholecystectomy after percutaneous cholecystostomy is still a more difficult procedure, with conversion rates typically in the range of 10% to 15%. In one retrospective review in which percutaneous drains were compared with cholecystectomy from 2001 to 2010, patients who underwent percutaneous drainage were older, had higher white blood cell counts, and had more prolonged stays in the intensive care unit. They also experienced more complications per patient and had higher readmission rates (31.4% vs 13.3%). The authors concluded that percutaneous cholecystostomy should be reserved for patients who have a prohibitive surgical risk.

If during cholecystectomy a surgeon encounters severe inflammation in the area of the neck of the gallbladder and porta hepatis, the best strategy is to avoid entering that area because of the increased risk of an injury. Options include placing a cholecystostomy tube surgically or performing a partial or subtotal cholecystectomy. Lee and colleagues (2012) reviewed 10,872 gallbladder-damaged control cases from the National Inpatient Sample cohort from 2000 to 2008. About 50% of these patients had open partial cholecystectomies, 27% had laparoscopic partial cholecystectomies, and 25% had trocar cholecystostomies. Despite this approach, the CBD injury rate was 3.7%, and the overall total mortality rate was 7.4%. These observations

emphasize the increased risk in this patient population and the extreme care required to avoid injury in this setting.

Portal Hypertension and Cirrhosis

The combination of portal hypertension and cirrhosis can be challenging, and affected patients are at much higher risk for the need for cholecystectomy. Consideration should be given to preoperative CT with portal phase contrast sequences to determine whether varices are present and where they are located. These may occur at the umbilicus through a recanalized umbilical vein, in the portal hepatis, and along the gallbladder bed. Surgeons should be especially careful with initial access in these patients because of the risk of injuring a large collateral vein at the umbilicus. Hepatic function should be optimized, and any coagulation deficits or ascites corrected. If there are collateral vessels around the gallbladder and liver bed, a subtotal or partial cholecystectomy should be considered. The use of advanced energy devices such as advanced bipolar or ultrasonic coagulation should also be considered in this setting.

ALTERNATIVE APPROACHES: SINGLE-INCISION LAPAROSCOPIC AND NOTES CHOLECYSTECTOMY

Single-incision laparoscopic cholecystectomy (SILC) and NOTES cholecystectomy have been promoted as potentially less invasive alternatives to conventional four-port laparoscopic cholecystectomy. NOTES cholecystectomy today is preferentially performed via a transvaginal access route. Although the NOTES technique is technically feasible, operative times are longer, and the advantages other than less visible scarring are unproven. Because NOTES cholecystectomy is technically challenging and the advantages are unproven, its performance in the United States has been limited primarily to centers participating in investigative trials.

The advantages of SILC are that it can be performed with conventional laparoscopic instrumentation and dissection techniques and a nearly scarless outcome can be achieved. However, disadvantages are the loss of triangulation, an in-line view of the operative field, and restricted freedom of movement of the instruments. The potential for more umbilical wound complications, including hernias, has also been voiced in view of the larger fascial incision at the umbilicus. A number of small, prospective randomized trials have been carried out to compare SILC with standard four-port laparoscopic cholecystectomy. Although the results of these trials have varied somewhat, most indicate that the single incision approach is associated with longer operative times and more postoperative pain but improved cosmesis. A robotic platform has been developed to facilitate single-incision approaches, but trials in which this is compared with conventional laparoscopic approaches are lacking. None of the SILC trials have been adequately powered to study the rate of CBD injury. However, one literature review of 45 published studies of more than 2600 patients showed a CBD injury rate with SILC of 0.72%, in comparison with 0.4% to 0.5% with multiple-port laparoscopic cholecystectomy. These data are of concern and, at a minimum, merit further trials to address this issue.

COMPLICATIONS

CBD injury continues to be the most feared complication of laparoscopic cholecystectomy, with reported injury rates of approximately 0.4% to 0.5%. Leaks from cystic duct stumps can also be a major source of morbidity after laparoscopic cholecystectomy. In one series, after more than 5751 laparoscopic cholecystectomies, 12 patients with such leaks were reported (incidence, 0.2%). These patients presented at a mean of 2.3 days postoperatively, and abdominal pain was the most common complaint. Most of these leaks can be managed with ERCP and stent placement, although some may also necessitate percutaneous drainage if fluid collection is significant. However, deaths have been reported after leaks from cystic duct stumps, and prevention is therefore the best strategy. Risk factors for leaks from cystic duct stumps include thickening of the cystic duct (which often occurs in acute cholecystitis), distal obstruction from a CBD stone, and a history of transcystic exploration. In the surgical setting, a pretied loop suture (ENDOLOOP; Ethicon Inc., Somerville, NJ) should be used to secure the cystic duct. Bile leaks after laparoscopic cholecystectomy may also arise from superficial ducts in the bed of the liver if the plane of the dissection has gone too deep. True leaks from the ducts of Luschka are rare, and most leaks from the liver bed are related to improper dissection plane.

Intestinal injury and enterotomy may occur during initial laparoscopic access, may result from adhesiolysis in patients with prior surgery, or may arise from the duodenum because of its closeness to the gallbladder. Trocars are the most common device named in medical malpractice injury claims associated with laparoscopic procedures, and cholecystectomy is the procedure most frequently associated with both fatal and nonfatal trocar injuries. Surgeons must also be wary of creating an injury out of the field of view by blind instrument insertion or as a result of untimely activation of the electrosurgical device (which is often controlled by a foot pedal on the floor) by the surgeon or another team member. The duodenum often adheres to or is close to the gallbladder. When working near the duodenum, surgical energy devices should be avoided. Surgeons must be cognizant of the adhesion with a narrow attachment to the duodenum because of the risk of concentrating the energy source at that site.

Any untoward or unexpected deviation from the usual postoperative course in a patient who has undergone laparoscopic cholecystectomy should be investigated immediately. Patients with severe or generalized abdominal pain or pain with nausea, vomiting, and fever should undergo prompt evaluation with laboratory testing and imaging to rule out a biliary injury or a missed enterotomy.

SUMMARY

Laparoscopic cholecystectomy has been the most significant advance in the management of symptomatic gallstones in several decades. This approach is associated with a high degree of success, low complication rates, and a rapid return to full physical health and activity. Every laparoscopic cholecystectomy should involve the CVS ductal identification method to minimize the risk of biliary injury and should be accompanied by the liberal use of intraoperative cholangiography. Strategies for managing the difficult cholecystectomy as outlined in this chapter may help reduce the rate of biliary injury and other complications.

Laparoscopic Common Bile Duct Exploration

Yee Wong, MD, and Bipan Chand, MD, FACS, FASMBS, FASGE

INTRODUCTION

Every year, approximately 750,000 cholecystectomies are performed in the United States. Of these, approximately 10% to 15% are performed in patients who present with choledocholithiasis. The true incidence may be higher given that not all procedures involve ductal imaging. The probability of finding a common bile duct (CBD) stone may even increase to above 70% in patients who are elderly, those with an elevated bilirubin level, and those in whom a CBD appears dilated on abdominal ultrasonography. Patients who present with symptomatic cholelithiasis may not have signs or symptoms of CBD stones, and stones may be discovered only with preoperative imaging or intraoperatively. Preoperative diagnostic modalities used for detecting CBD stones include transabdominal ultrasonography, computed tomography, and magnetic resonance cholangiopancreatography (MRCP).

Transabdominal ultrasonography is most commonly used, and its sensitivity ranges from 55% to 91%. Dilation of the CBD to more than 6 mm is associated with an increased incidence of CBD stones. Advantages of transabdominal ultrasonography include its low cost, its noninvasive nature, and its availability at most centers; however, results are highly operator dependent. Abdominal computed tomography has sensitivity up to 95.5% for detecting CBD stones. However, it exposes the patient to radiation and also to the risk of contrast agent–induced nephropathy. It is not currently a standard diagnostic modality in the evaluation of acute cholecystitis and biliary calculi in the United States. In cases in which the findings on ultrasonography and computed tomography are inconclusive, MRCP may be used to detect CBD stones. Its accuracy is comparable with that of intraoperative cholangiography (IOC) and endoscopic retrograde cholangiopancreatography (ERCP), with sensitivity of 81% to 100% and specificity of 92% to 100%. MRCP is more expensive and may not be available at some centers.

Endoscopic modalities for use in biliary imaging include endoscopic ultrasonography and ERCP. Endoscopic ultrasonography has sensitivity of 88% to 97% and specificity of 96% to 100% in detecting CBD stones. It is less often used than MRCP because it is more invasive; however, it has similar accuracy. When choledocholithiasis is diagnosed preoperatively, most clinicians proceed with ERCP for stone extraction and then perform laparoscopic cholecystectomy. ERCP has the advantage of not only detecting CBD stones but also providing therapy with stone extraction or biliary drainage when patients present with jaundice or cholangitis secondary to ductal obstruction. With the advent of laparoscopic techniques and devices, laparoscopic CBD exploration is becoming utilized more frequently (Figure 1).

INTRAOPERATIVE EVALUATION OF COMMON BILE DUCT STONES

IOC remains the "gold standard" in detection of choledocholithiasis and can also assist in the identification of complex biliary ductal anatomy. Controversy remains about whether IOC should be performed routinely or selectively. In a systematic review from the United Kingdom, researchers compiled data from eight randomized controlled trials. This analysis failed to show a benefit of IOC in preventing retained CBD stones or bile duct injury. Nevertheless, IOC is necessary before CBD exploration. For selective IOC, indications include evidence of CBD dilatation to more than 7 mm on preoperative imaging, elevated results of cholestatic liver function tests, a history of gallstone pancreatitis, and jaundice. Surgeons who choose to perform IOC should be familiar with identifying different ductal anatomy and filling defects that may suggest presence of CBD stones or air bubbles within the biliary system (Figure 2).

Another option in the evaluation of CBD stones is laparoscopic ultrasonography (LUS), developed in 1990s after the introduction of laparoscopic cholecystectomy (see Figure 2). In this method, a 10-mm ultrasound probe is inserted through the subxyphoid port. After dissection of adhesions but before ductal dissection, bile ducts are scanned from the hepatic hilum to duodenum. Intrahepatic biliary ducts can also be evaluated by placement of the probe on the anterior surface of the liver. A review of 12 prospective studies in which LUS and IOC were compared showed that LUS is as accurate as IOC in diagnosing biliary calculi, with success rates ranging from 88% to 100% and a low false-positive rate. It requires less time (average, 4 to 10 minutes) to perform in comparison with IOC (10 to 17 minutes). Some advantages of LUS include its low cost, avoidance of radiation and exposure to contrast agents, and the potential for unlimited use. It also allows for imaging of surrounding structures and organs, such as the pancreas, hepatic artery, and portal vein. However, results are highly dependent on the surgeon's interpretation of images and experience in scanning techniques. Availability of LUS probes is also limited, and, unlike IOC, LUS cannot readily evaluate the flow of contrast material into the duodenum. As surgeons become better trained in laparoscopic techniques and resources become more readily available, LUS will be more commonly utilized as an intraoperative diagnostic tool for CBD stones.

TECHNIQUES

When CBD stones are identified during laparoscopic cholecystectomy, there are multiple different management options: open CBD exploration, laparoscopic CBD exploration, intraoperative ERCP, and postoperative ERCP. A decision to proceed with one option over another is usually based on the surgeon's experience with laparoscopic techniques, resource availability, and findings on IOC. Several factors that may influence the choice of management include the size, number, location, and characteristics of the stones. When stones are larger than 2 cm, the success rate of stone clearance with ERCP is decreased from 92% to 78%, with an increase in complications, including post-ERCP pancreatitis, papillae hemorrhage, biliary infection, and hypoxemia. ERCP has also been shown to be less effective in clearance than is laparoscopic CBD exploration for multiple or impacted stones, faceted stones, or ductal anatomy that renders cannulation difficult. Conversion from laparoscopic to open surgery is more likely to occur if stones are larger than 2 cm and if the clinician is less experienced in advanced laparoscopic skills. Location of stones can often present a challenge to the surgeon in the decision of management options. Intrahepatic stones are often difficult to clear by ERCP, and radiologic clearance or an open surgical approach may be required. The preference of one laparoscopic technique over another may also be influenced by the size and number of stones, presence of biliary sludge, and diameter of CBD. Failure to clear the duct is higher in the transcystic approach when the CBD diameter is greater than 6 mm or the stone is larger than 5 mm. Rates of recurrence and inadequate clearance are also higher in this approach when more than three CBD stones and biliary sludge are present.

Two major techniques for laparoscopic CBD exploration have been employed: transcystic exploration and choledochotomy. In the transcystic approach, which is usually preferred by most surgeons, the common duct is accessed through the cystic duct close to its insertion (Figure 3). Stones can be irrigated out of the common duct with saline and the intravenous use of glucagon to relax the sphincter of Oddi. Glucagon facilitates the flow of stones into the duodenum. Dilation of the cystic duct may be necessary to allow passage of baskets or balloon catheters as well. Typically, a guidewire is advanced through the cystic duct into the CBD, and dilators are inserted over the wire. Serial dilations can be performed with balloon catheters or graduated bougies. Care should be taken to avoid dilating the cystic duct more than the diameter of the CBD. Helical stone baskets or balloon-tipped catheters can then be used to extract stones under fluoroscopic guidance. If the cystic duct is of adequate caliber, some

surgeons utilize a choledochoscope to increase the success rate of CBD exploration and verify clearance. Choledochoscopes are available in different sizes ranging from 3F to 10 F and have access channels to allow simultaneous use of baskets or balloon-tipped catheters. The choledochoscope can also be used to push stones into the duodenum and allows for visualization of common hepatic, right hepatic, and left hepatic ducts after stone removal. Using a choledochoscope often requires an additional 5-mm trocar and continuous irrigation of the ducts. However, in the extraction of CBD stones, its use increases the success rate from 77% to 97% in comparison with blind exploration. Completion cholangiography should be performed after transcystic exploration to ensure stone clearance.

The advantage of the transcystic approach is that it avoids choledochotomy, although when transcystic exploration is unsuccessful, choledochotomy may be necessary. However, it should be performed only when the CBD is dilated greater than 7 mm. Other factors that may influence a surgeon to proceed directly with choledochotomy include size of stones, presence of multiple stones, stones in the proximal duct, and faceted stones. This technique begins with a longitudinal incision along the anterior surface of the CBD to avoid the blood supply. The blood supply is often at the 3 and 9 o'clock positions on the CBD. Incision should be at least as long as the diameter of the largest stone. Stay sutures on either side of the incision may be used, as in open exploration. The duct should be irrigated initially to remove smaller stones. Larger stones can be extracted proximally through the choledochotomy with laparoscopic nontraumatic graspers. Biliary balloon-tipped catheters can also be used to sweep stones out of the bile duct. As in the transcystic approach, choledochoscopes may be used for impacted stones to pass helical stone baskets and balloon catheters through the working channel (Figure 4). Again, completion cholangiography is necessary to evaluate for residual stones.

Once the stones are extracted through the choledochotomy, the CBD can be closed primarily or over a T-tube. Primary closure requires expertise in intracorporeal suturing. Absorbable sutures should be used to prevent ductal stenosis from a foreign body response. Studies demonstrate that primary closure by experienced surgeons is just as safe as closure with a T-tube. However, some authorities argue that the advantage of a T-tube is that it allows for confirmation that no residual stones remain. If a T-tube is left in place, cholangiography is performed 3 to 4 weeks after the initial surgery and before tube removal to confirm clearance. A T-tube may also prevent complications from primary closure such as bile duct leak, biloma, or abscess. However, placement of a T-tube is not without complications. Morbidity rates as high as 15% with complications of sepsis, tube dislodgment, bile leak, biliary peritonitis, biliary fistula, and delayed bile duct stricture have been reported with the use of T-tubes. The authors have tended not to use T-tubes in their practice when laparoscopic closure has been satisfactorily achieved.

In addition to a choledochotomy or transcystic approach, new techniques have been developed for difficult cases, including the presence of multiple CBD stones, common hepatic duct stones, and papillary stenosis. Laparoscopic antegrade sphincterotomy involves a combination of laparoscopic CBD exploration with sphincterotomy. It requires collaboration with an endoscopist to confirm correct position of the papillotome, which is passed from above through the cystic duct or CBD. In this scenario, the laparoscopist is performing the biliary cut. Another technique described as the *rendezvous technique* was first introduced by Cavina and associates (1998). Access to the papilla is made by passing a long wire, often used in ERCP, into

FIGURE 6 Intraoperative endoscopic retrograde cholangiopancreatography with endoscopy and stone extraction at the time of laparoscopic cholecystectomy.

the duodenum through the cystic duct. The endoscopist with a duodenoscope, positioned in the second portion of the duodenum, retrieves the wire through its working port and performs the sphincterotomy. In this scenario, the endoscopist performs the biliary cut (Figures 5 and 6). Cavina and associates reported a 100% cannulation rate in 15 patients. In a more recent randomized controlled trial, Tzovaras and colleagues compared the rendezvous technique with preoperative ERCP followed by laparoscopic cholecystectomy. They showed that hospital stays were significantly shorter with a single-stage approach, and safety and efficacy were similar, in comparison with the two-stage approach.

Researchers in multiple studies who compared different techniques of laparoscopic CBD exploration have demonstrated similar effectiveness in removal of CBD stones, in comparison with open surgery; however, adoption of the laparoscopic technique has been slow. The success of the approach remains dependent on the surgeon's experience, the institution's resources, and availability of an endoscopist. Most centers today are still managing CBD stones with either preoperative or postoperative ERCP, depending on the timing of stone detection and presence of acute cholangitis or gallstone pancreatitis. ERCP has known morbid effects, including bleeding, post-ERCP pancreatitis from cannulation of pancreatic duct and

contrast injection, duodenal perforation, papillary stenosis after sphincterotomy, cholangitis from reflux of duodenal content into CBD, and retained stones. Major morbidity and mortality rates are often quoted as 5% and 0.4%, respectively. Cannulation failure rates range from 4% to 18%. Therefore, with the advent of laparoscopic tools (often in standard commercially available kits) and standardized techniques, a single-stage approach is an attractive option in the treatment of choledocholithiasis.

AFTER CHOLECYSTECTOMY

In rare instances, patients present with retained CBD stones after cholecystectomy. Often ERCP is the initial treatment if stone disease is suspected. The timing of stone detection after operative intervention usually dictates therapy. If the time from operation to detection is more than 2 years, these stones may be considered primary. ERCP is still employed in most instances, and stone retrieval is successful. True primary CBD stones may be better treated with stone extraction and biliary-enteric bypass. For a laparoscopic choledochoduodenostomy, CBD must be dilated (at least 1.0 cm) and a surgeon must be technically competent to perform a complex anastomosis. The anastomosis can be either end-to-side or side-to-side, with the stoma being larger than 2 cm in order to prevent anastomotic stenosis. If performed by an experienced surgeon, this procedure is safe and produces good results for patients with retained biliary stones or recurrent choledocholithiasis.

EFFICACY OF LAPAROSCOPIC COMMON BILE DUCT EXPLORATION

Multiple comparisons of the safety and efficacy of single- and two-stage approaches to CBD management have been reported. In a systematic review published in 2006, data were compiled from 13 randomized controlled trials, and three approaches to the management of CBD stones were compared: ERCP versus open surgical clearance, preoperative ERCP versus laparoscopic bile duct clearance, and postoperative ERCP versus laparoscopic bile duct clearance. Results showed that ERCP was less effective in stone clearance than was an open approach and that laparoscopic CBD exploration was just as efficacious in stone removal as preoperative or postoperative ERCP, with no significant difference in morbidity and mortality. All laparoscopic trials demonstrated a shorter hospital stay in the comparison of surgery recipients. Results of a more recent prospective randomized trial in 2010 conducted by Rogers and associates echoed similar findings of the systematic review. Patients were randomly assigned to undergo either laparoscopic cholecystectomy with CBD exploration or preoperative ERCP with sphincterotomy followed by laparoscopic cholecystectomy. Rates of stone clearance were equivalent in both groups. However, hospital stays were significantly shorter for the patients who underwent laparoscopic CBD exploration, with an average of 55 hours in contrast to 98 hours for the ERCP recipients. Cost analysis was also studied; charges for the single-stage approach were significantly lower ($4820 vs $6139). Overall, surgical management of biliary duct stones at the time of laparoscopic cholecystectomy appears to be just as safe and effective as the "gold standard" of preoperative or postoperative ERCP. Advantages of laparoscopic CBD exploration are shorter hospital stay and perhaps lower cost; however, the skill sets are highly variable and are clearly related to morbidity and efficacy. Surgeon expertise and available resources may be the limiting factors in adoption of a laparoscopic approach to managing choledocholithiasis.

Because ERCP has become the "gold standard" in the management of bile duct stones, open CBD exploration has been used less frequently. Open surgery often entails an increased rate of morbidity, longer hospital stay, and increased postoperative pain. Nevertheless, comparison between laparoscopic CBD exploration and open exploration has been evaluated in a randomized controlled trial in a single-center study. Patients were randomly assigned to undergo one of two procedures: laparoscopic CBD exploration and open CBD surgery. Diagnosis of choledocholithiasis was made preoperatively through ultrasonography, ERCP, or MRCP. The decision to use the transcystic approach or choledochotomy during laparoscopic CBD exploration was made intraoperatively on the basis of number, size, and location of stones and the anatomy of cystic ducts and CBDs. In comparison with open surgery, the laparoscopic approach again demonstrated significantly shorter length of hospital stay and less blood loss. The rates of complications such as intraabdominal bleeding, bile leak, intrahepatic abscess, reoperations, and morbidity were similar in the two groups, with the exception of wound infection, the rate of which was significantly higher in the patients who underwent the open procedure. Two different methods used for laparoscopic CBD exploration were also compared. Stone clearance via choledochotomy was more successful (94% vs 71%) but with the expense of longer operative time (90 minutes vs 62 minutes) and longer hospital stay (7.6 days vs 3.4 days) in comparison with the transcystic approach. The difference in operative time and length of stay may have been attributable to the presence of larger and multiple stones, which would make the transcystic approach unfeasible or more challenging. For single-stage laparoscopic or open management of choledocholithiasis, the less invasive approach is also just as efficacious and again has decreased hospital stay, blood loss, and rate of wound infection.

Even though laparoscopic management of CBD stones is associated with shorter hospital stay and is more cost effective, the rate of residual stones has ranged from 2.6% to 8%. Some of the reasons leading to failure of stone clearance in a transcystic approach may be the larger size of stones (>5 mm), the presence of multiple stones, and complex ductal anatomy. An impacted stone may also be a challenge in either a transcystic approach or a laparoscopic choledochotomy. Some authorities suggest that laparoscopic CBD exploration may be more difficult in patients with acute cholecystitis secondary to surrounding inflammation, which may contribute to a higher failure rate. The role of single-stage management in these patients remains controversial. Chiarugi and colleagues compared multiple outcome measures of laparoscopic transcystic exploration in patients with acute cholecystitis and those without inflammation of the gallbladder. Success rates in achieving stone clearance were 80% and 84%, respectively. Conversion rate, morbidity rate, mortality rate, length of hospital stays, readmission rate, and rate of residual stones were similar in both groups with the exception of significantly longer operative time in the group of patients with acute cholecystitis (175 minutes vs 141 minutes). Increases in operative times were probably caused by dissection of an inflamed gallbladder rather than bile duct exploration. The authors concluded that laparoscopic transcystic exploration in the setting of acute cholecystitis is just as safe and efficacious as when performed in elective laparoscopic cholecystectomy.

In addition to retained stones, other complications of laparoscopic CBD exploration include bile leak, biloma, intraabdominal hematoma, and biliary peritonitis. However, ERCP is not without its risks and significant morbidity. It is associated with a mortality rate of 0.4% and a postprocedure complication rate of 5.1%, mainly post-ERCP pancreatitis. Because single-stage management of CBD stones requires advanced laparoscopic skills, it is ultimately surgeons' decision to provide the safest approach for their patients according to their comfort level and experience.

ALTERNATIVE MANAGEMENT

In rare cases, patients present with intrahepatic stones or CBD stones larger than 1.5 cm. These stones may be difficult to remove via ERCP or laparoscopic exploration. The holmium laser was originally developed for management of renal calculi; however, it has been adapted

for treatment of complex biliary stones. In this technique, a 200-μm laser fiber that generates 0.6 to 1.0 J at frequency of 6 to 10 Hz is used under video guidance with a flexible choledochoscope. Completion cholangiography is performed to confirm stone clearance. In a retrospective study published in 2007, the efficacy of this procedure was evaluated, and a 100% success rate in stone clearance in 13 patients was reported. The procedure required prolonged biliary access and multiple separate attempts to completely clear the calculi. This technique may also be combined with laparoscopic exploration in cases of impacted stones not removed by standard laparoscopic tools. Five patients who underwent this combined treatment in a retrospective review had successful clearance of impacted CBD stones.

SUMMARY

Advancements in techniques and devices enable the management of choledocholithiasis with multiple modalities, including laparoscopy, endoscopy, and combined approaches. The single-stage approach in treating CBD stones is comparable with two-stage management with preoperative or postoperative ERCP in terms of its safety profile and efficacy when performed by a surgeon with advanced laparoscopic training. Many studies demonstrated a shorter hospital stay and lower overall cost. Rates of mortality and morbidity are similar with the two approaches despite different complications. However, the requirement of expertise in laparoscopic skills contributes to the limited use of single-stage management. This issue will eventually resolve itself as more surgeons become proficient in minimally invasive procedures, and more institutions will probably provide the resources for laparoscopic CBD exploration.

Laparoscopic 360-Degree Fundoplication

S. Scott Davis, Jr., MD, FACS, and
Rachel L. Medbery, MD

BACKGROUND

Gastroesophageal reflux disease (GERD), which accounts for 4 to 5 million physician office visits per year, is one of the most commonly diagnosed medical conditions in the United States. The widely accepted definition of GERD is that of the 2008 Montreal consensus, which states it is a condition that develops when the reflux of stomach contents causes troublesome symptoms (those that adversely affect an individual's wellbeing) or complications for the patient. An estimated two thirds of all U.S. adults experience heartburn at least once in their lifetime. Among the 19 million Americans currently suffering from GERD, approximately 40% have symptoms 3 times a week, and 10% have symptoms daily.

SYMPTOMS AND COMPLICATIONS

Symptoms of GERD can be classified as either typical or atypical (Table 1). The most common symptom, heartburn, is reported by 80% of patients. Symptoms can often be difficult to elucidate from patients, and thus, a careful history is essential to diagnosis, in addition to consideration of other potential medical conditions. Left untreated, complications of GERD (both esophageal and extraesophageal) can lead to serious health problems (Table 2).

MEDICAL THERAPY

The appropriate first-line therapy for uncomplicated GERD is medical treatment with proton pump inhibitors (PPIs). Resolution of symptoms after initiation of medical therapy is considered confirmatory for the diagnosis of GERD. However, for patients with persistent symptoms or additional signs of complex disease, further workup may be necessary.

DIAGNOSTIC WORKUP

Endoscopy

In many cases, flexible esophagogastroduodenoscopy (EGD) can be used to diagnose GERD and rule out other conditions. For this reason, it should be the first test of choice to confirm the diagnosis of GERD (Table 3). Direct visualization of mucosal abnormalities (slough or erythema clearly demarcated from normal adjacent mucosa), ulcers, or stricture can be considered acceptable objective evidence of GERD in the appropriate clinical setting. All ulcers or strictures must be biopsied to rule out malignancy disease. Histologic evidence of Barrett's esophagus may also be considered objective proof for GERD.

Barium Swallow

Barium swallow (BS) is the second test that all patients should undergo before surgical intervention. Although BS is not necessary for diagnosis of GERD in and of itself, it is invaluable for definition of patient anatomy and for general characterization of gastric and esophageal motility. It is especially useful for ruling in or out large hiatal hernias and a shortened esophagus, which allows surgeons to better plan their operation.

pH Testing

When the diagnosis of GERD cannot be confirmed with EGD, esophageal pH testing should be the next testing modality pursued. Considered the gold standard for objective diagnosing of GERD, the test requires placement of a small pH sensor electrode 5 cm above the proximal border of the lower esophageal sphincter (LES). In the traditional 24-hour ambulatory test, a small transnasal catheter is attached to the pH sensor. Alternatively, the Bravo device (Medtronic, Inc., Shoreview, Minn) is a wireless radiotelemetric capsule that transmits pH data to a receiver on the patient's belt. In both methods, the frequency of reflux episodes, the number of episodes that last longer than 5 minutes, the duration of the longest reflux episode, and the cumulative time the esophageal pH is below 4 (both supine and upright) are all measured and reported. The transnasal catheter provides the added benefit of a second sensor located in the upper esophagus, which gives data to evaluate for possible laryngopharyngeal reflux disease (LPR).

Impedance Testing

Multichannel intraluminal impedance (MII) testing is a newer technology that allows for the detection of intraluminal bolus movement without the side effects of radiation. Multiple electrode pairs are used to detect changes in resistance to flow as a bolus moves across the electrode. The specific resistance can be used to interpret the nature of the bolus (liquid vs gas). MII can be combined with manometry to gather functional data, such as peristalsis and contractile pressures in the body of the esophagus, and the resting tone and relaxation of both the upper and the lower esophageal sphincters. Because esophageal manometry alone does not measure acid reflux, it cannot be used to diagnose GERD. However, it is a necessary preoperative tool for evaluation of patients with dysphagia or chest pain associated with GERD to exclude a primary esophageal motility disorder that may necessitate an alternate surgical plan. Furthermore, new technology allows for simultaneous MII and pH monitoring. Correlation of impedance data with pH measurements facilitates both the recording of acid and nonacid reflux episodes the proximal extent of the refluxate.

SURGICAL THERAPY

Reasons for Surgery

GERD is a mechanical disorder that results from one or more of the following: an incompetent LES (anatomically or functionally), impaired gastric emptying, or ineffective esophageal peristalsis. Although numerous treatment options exist for GERD, laparoscopic 360-degree fundoplication is the gold standard for reconstruction of a functioning LES. However, objective evidence of GERD is essential before any surgical intervention takes place. Once the diagnosis of GERD has been objectively confirmed, surgical intervention should be considered in the following circumstances: (1) the patient has failed medical management; (2) the patient opts for surgery despite successful medical management; (3) the patient has extraesophageal manifestations; or (4) the patient has complications such as Barrett's esophagus or peptic stricture.

TABLE 1: Symptoms of gastroesophageal reflux disease

Typical	Atypical
Heartburn	Asthma
Dysphagia	Hoarseness
Regurgitation	Cough
	Recurrent pneumonia
	Retrosternal chest pain
	Dental erosion
	Chronic sinusitis
	Anemia
	Weight loss

TABLE 2: Complications of gastroesophageal reflux disease

Esophageal	Extraesophageal
Esophagitis	Laryngitis
Esophageal ulcers	Laryngeal cancer
Peptic stricture	Laryngeal nodules
Barrett's esophagus	Globus
Adenocarcinoma	Chronic bronchitis
	Pulmonary fibrosis
	Pneumonitis

TABLE 3: Diagnostic workup

Test	Utility	When
Endoscopy	Diagnostic	First test in ALL patients
Modified barium swallow	Ancillary *(defines anatomy before surgery)*	ALL patients before surgery
24-hour pH monitoring	Diagnostic	Patients without objective evidence of GERD on endoscopy
Impedance/pH monitoring	Diagnostic	Patients without objective evidence of GERD on endoscopy
Impedance manometry	Ancillary *(rules out motility disorders)*	Patients with chest pain or dysphagia

GERD, Gastroesophageal reflux disease.

Patient Selection and Predictors of Success

Studies within the literature have shown that patient's symptomatic response to preoperative PPI treatment can be directly correlated with resolution of symptoms after fundoplication. Furthermore, patients who have poor compliance with preoperative PPI therapy are likely to have worse outcomes after surgery. Old age should not be considered a contraindication for surgical intervention, as long as the patient is otherwise an acceptable candidate for surgery. Outcomes in patients older than 65 years of age have been shown to be on par with those of younger patients. For patients with GERD and body mass index (BMI) of more than 35 kg/m^2, gastric bypass, not fundoplication, should be the procedure of choice. Not only does fundoplication have a high failure rate in morbidly obese patients, but the procedure does not adequately address the underlying problem (obesity) that causes GERD, nor does it address a number of other medical conditions related to obesity for which there is opportunity for resolution.

TECHNIQUE

The authors' center made a concerted effort to standardize the operating room setup and patient positioning amongst surgeons specializing in these procedures. Perioperative and postoperative care have also been standardized. These changes led to gains in operating room efficiency and improvement in surgical outcomes and rates of readmission.

Positioning

After induction of general anesthesia, the patient is placed in the supine position, with the arms extended and secured to arm boards. A foot board is placed on the bed to allow for significant reverse Trendelenburg's position. A Foley catheter is placed, and the patient is secured to the table. This positioning is less complicated and accomplished more expeditiously than with the use of split leg or stirrup table attachments. The surgeon stands on the patient's right side, and the assistant on the left. A pneumatic camera holder is used for the laparoscope. The clamp for fixating the liver retractor to the bed is placed under the patient's right arm.

Port Placement

Access is gained to the abdomen with an optically viewing trocar, inserted under the left subcostal margin 10 cm from the xiphoid process (Figure 1). The 10-mm camera port is then inserted just to the right of the midline, away from the falciform ligament, 15 cm

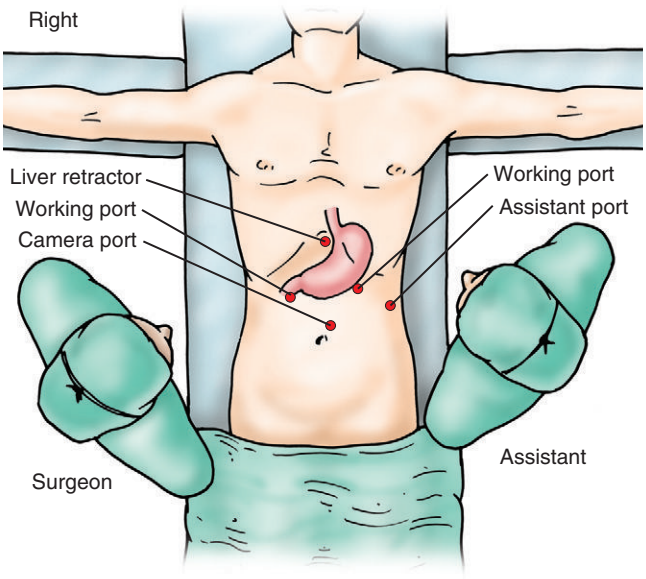

FIGURE 1 Port placement. *(Modified from Townsend CM, editor: Sabiston textbook of surgery, ed 18, Philadelphia, 2007, Saunders Fig. 2-6.)*

from the xiphoid process. Next, the assistant's port is inserted in the left abdomen along the left subcostal margin 10 cm further from the optically placed trocar. A subxiphoid incision is made as closely to the xiphoid process as reasonable for placement of a Nathonson-type liver retractor. The last working 5-mm port, the surgeon's left hand, is then placed for comfortable triangulation with the surgeon's right hand and below the caudal edge of the retracted liver, usually at the base of the falciform ligament. A 10-mm, 30-degree viewing scope is typically used. A 45-degree viewing scope is kept available for cases where the camera port is found to be too low for a good downward viewing angle to the hiatus, or where there is a large amount of visceral fat in lower aspect of the field of view.

The many alternatives to these port placements include the use of single port techniques, which can be used in selected settings but are beyond the scope of this discussion.

Early Gastric Mobilization

The dissection is begun along the greater curve of the stomach with division of the short gastric vessels with a bipolar sealing device (Figure 2). Most often, a posterior veil of the gastrosplenic ligament contains a few additional short gastric vessels near the gastroesophageal (GE) junction; division of this leads into the vessels that make up the most intimate part of the gastrosplenic ligament. Once these vessels are divided, the dissection plane leads to the left crura. If surgeons have difficulty seeing the left crura, they have most likely not completely divided the posterior veil of the gastrosplenic ligament. The peritoneum can now be incised at the angle of His (phrenoesophageal membrane), and the mediastinum entered (Figure 3). Here, the anterior mobilization of the esophagus should be straightforward. The most advantageous maneuver at this point is to complete the dissection of the peritoneum from the base of the left crura completely, mobilizing the esophagus medially. Completion of this now makes for a much easier creation of the retroesophageal window.

Left to Right Crural Dissection and Esophageal Mobilization

The dissection is then continued with the division of the gastrohepatic ligament. This is typically avascular. The only notable structure is the hepatic branch of the vagus nerve; on occasion, a replaced left hepatic artery may be present. These are typically preserved; however, they can be divided if they limit visualization of the hiatal dissection. A replaced left hepatic artery can be divided if needed, but this is usually not necessary. The right crus is dissected in the same manner as the left, with incision of the peritoneum and mobilization of the esophagus. Good tissue handling is critical, and this maneuver can be facilitated by the surgeon's left hand with a blunt grasper placed inside the crura with gentle medial retraction to serve as counter traction (Figure 4). In many cases, the mobilization of the esophagus can be accomplished with gentle blunt sweeps of the right-handed instrument away from this retraction. The dissection is completed to the base of the right crura (posteriorly) first, and this connects to the window that was previously made from the left side. This allows for the passage of a Penrose drain behind the esophagus, through the retroesophageal window, encircling the GE junction. The Penrose is held by the assistant who can now provide counter traction for the rest of the division of the phrenoesophageal membrane and mobilization of the esophagus. The anterior and posterior vagus nerves can be easily identified and preserved. Care must be taken by the assistant not to overly retract to avoid praxia or injury to the vagus nerves. The esophagus is mobilized widely to ensure ample intra-abdominal length, of which there should be a minimum of 3 to 4 cm without traction. This further ensures minimal risk of wrap migration.

Crural Closure

A dilating esophageal balloon is inserted into the esophagus with direct vision before closure of the crura (to minimize risk of esophageal injury proximal to the closure, which can be easily missed). Once

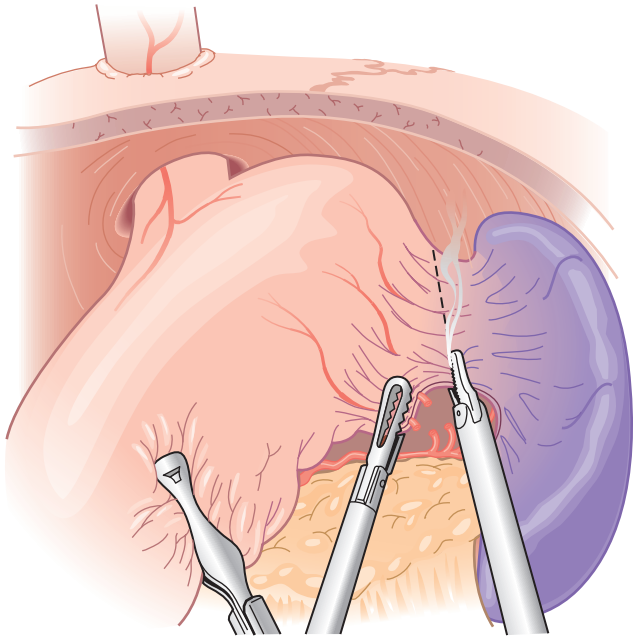

FIGURE 2 Early gastric mobilization. The dissection is begun along the greater curve of the stomach with division of the short gastric vessels with a bipolar sealing device. *(From Townsend CM, editor:* Sabiston textbook of surgery, *ed 18, Philadelphia, 2007, Saunders, Fig. 42-8.)*

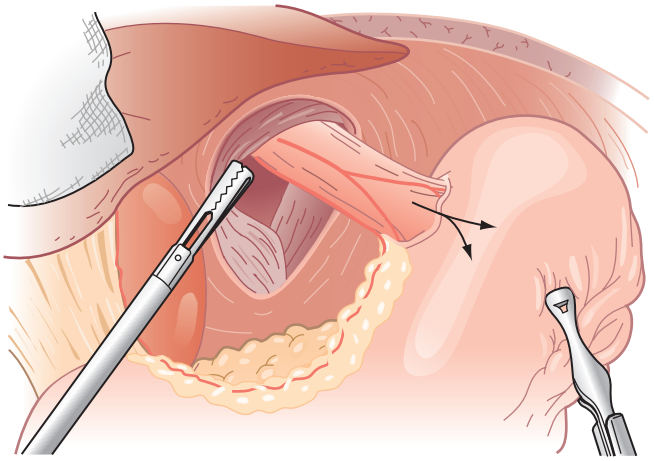

FIGURE 4 Esophageal mobilization. Gentle counter traction with a blunt grasper in the left hand is useful in assisting with dissection and mobilization. *(From Townsend CM, editor:* Sabiston textbook of surgery, *ed 18, Philadelphia, 2007, Saunders, Fig. 42-10.)*

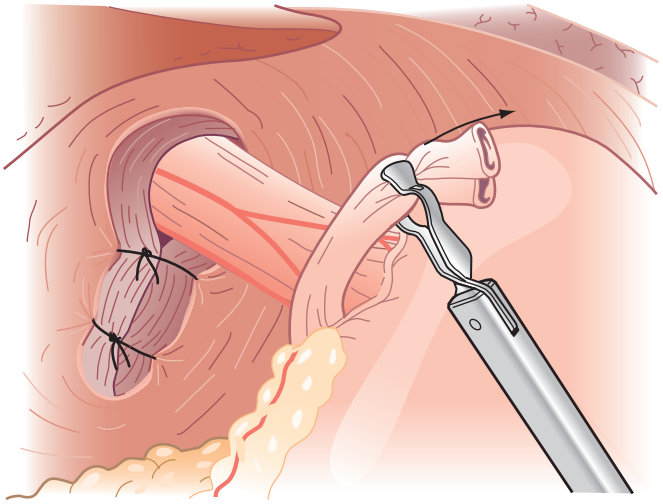

FIGURE 5 Crural closure. A Penrose drain encircles the gastroesophageal junction, and traction is used to provide adequate visualization for crural closure. *(From Townsend CM editor:* Sabiston textbook of surgery, *ed 18, Philadelphia, 2007, Saunders, Fig. 42-11.)*

placed, the crura are closed posteriorly, usually requiring two or three nonabsorbable sutures (Figure 5). Pledgets made of bioabsorbable material can be used to reinforce these sutures if the quality of the crura is deemed poor. However, they are not used routinely. Placement of prosthetic material at the hiatus is not recommended and not usually necessary. This is believed to increase the risk of rare, but potentially catastrophic, complications, such as prosthetic erosion into the esophagus. In most cases done for the indication of GERD in the absence of a hiatal hernia, esophageal length should not be an issue with wide mobilization, and crural closure without tension should be achievable.

Creation of Tension-free Fundoplication

The fundus is then brought through the retroesophageal window and should lie easily without retracting if the mobilization done initially is adequate and complete. Then, the esophageal balloon is inflated to 56F in the lumen of the esophagus. In some cases for large male patients, inflation to 60F is considered. The closure of the hiatus is then reexamined first to ensure that it is snug around the esophagus with the balloon inflated. Care is taken in orienting the fundus for the fundoplication. It is paramount to avoid twisting of the fundoplication, either at rest or functionally during a swallow. A slightly twisted wrap, on occasion, is exacerbated by a swallow, and a twisting action of the GE junction may be seen during endoscopy. This is prevented with three standard maneuvers: (1) ensuring that the posterior short gastric vessels are completely mobilized; (2) using a "shoe shine" technique to ensure the wrap is constructed with the same part of the fundus (Figure 6); and (3) placing sutures at or near the cut edge of the short gastric vessels on both the medial and the lateral sides of the fundoplication.

The fundoplication should be created without tension; this can be checked by the ease of passage of the grasper behind it along the stented esophagus. The wrap should be situated above the z-line and not on the cardia of the stomach to prevent slippage of the fundoplication. Typically, the wrap is created with three sutures placed 1 cm apart, for a total 2 cm length. The longitudinal outer fibers of the esophageal wall are incorporated in the first two sutures to fixate the wrap in the correct position, with care taken not to incorporate the anterior vagus nerve.

Endoscopy is routinely performed to assess the morphology of the fundoplication and to ensure there has been no occult perforation. The wrap should be further assessed with endoscopic

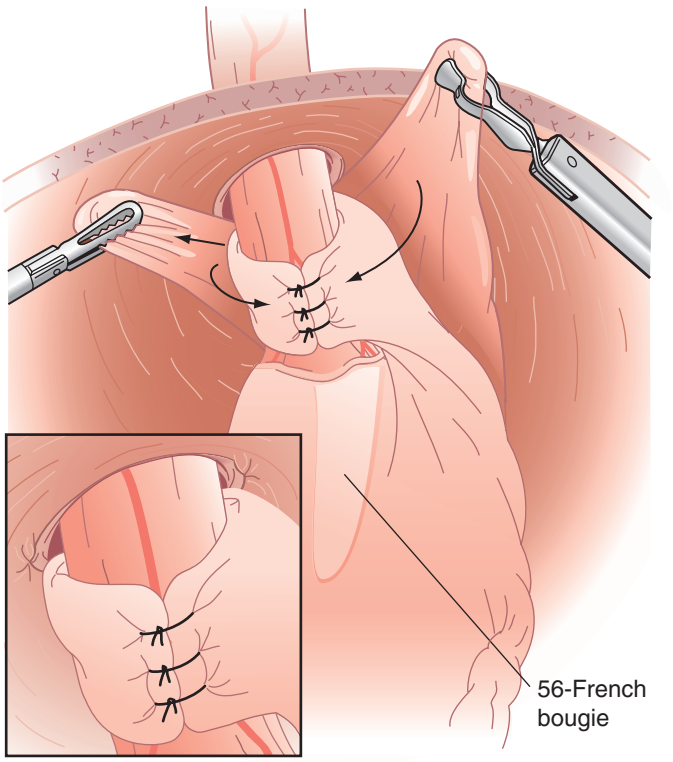

FIGURE 6 Creation of tension-free fundoplication. The "shoe-shine" technique is used to create a wrap with the same portion of fundus. Wrap should be 2 cm in length, with sutures 1 cm apart. *(From Townsend CM editor:* Sabiston textbook of surgery, *ed 18, Philadelphia, 2007, Saunders, Fig. 42-12.)*

insufflation to ensure that the folds of the fundoplication do not twist into the GE junction. The folds should appear as a "stack of coins" going around the scope (Figure 7). Twisting into the GE junction around the scope indicate a malpositioned wrap. A gastropexy of the wrap to the diaphragm or crural closure is not routinely done.

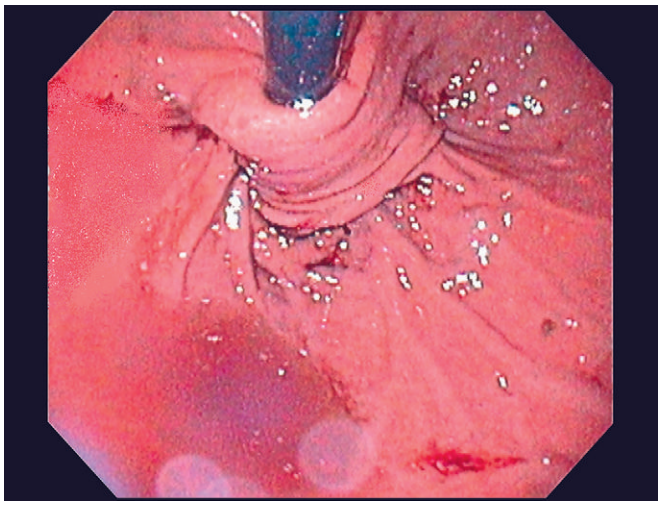

FIGURE 7 Stack of coins view. After completion of the wrap, the endoscope can be retroflexed within the lumen of the stomach to confirm proper wrap formation.

Additional Maneuvers and Controversy

Some recent publications advocate use of synthetic mesh to assist in closing the hiatus, typically as a posterior onlay reinforcement, with the argument that doing so decreases the likelihood of a postoperative hiatal hernia. This decrease in risk, however, can be associated with rare but significant complications, such as dysphagia, stricture, or esophageal erosion, which can necessitate a second operation—one that will be technically challenging because of the presence of incorporated mesh. In many of these cases, a major gastroesophageal resection may be required for remediation. As such, the authors believe the risk of routine mesh placement at the hiatus far outweighs the risk of a second operation for a hiatal hernia repair in which mesh was never placed. They only recommend the use of mesh in hiatal closure when it is impossible to approximate the tissue behind the esophagus or when the character of the crura is obviously poor. In such cases, a biologic material is chosen for buttress.

Similarly, some surgeons opt to secure the fundoplication via pexy to the diaphragm, advocating that anchoring sutures prevent wrap herniation into the chest. The authors advise against this technique for reasons similar to use of mesh at the hiatus. No available evidence shows that this practice decreases the incidence of wrap migration, the most common anatomic failure of this procedure. The authors have observed that revisions done after these sutures have been placed can be much more difficult because of dense scarring between the fundoplication and the diaphragm, and the benefit of these sutures is not clear.

POSTOPERATIVE CARE

This procedure is typically done with a planned overnight observation, although it can also be safely done on an outpatient basis. During this observation, the patient is on a clear liquid diet and is seen and counseled on the recommended dietary instruction by the nutritionist. If the procedure is done on an outpatient basis, this nutritional education can be done before surgery. The diet is then advanced to a full liquid diet on postoperative day 4, with a subsequent progression to a general diet after 3 weeks.

During the early postoperative period, unexpected increases in intra-abdominal pressure from excessive coughing, gagging, vomiting, or belching can predispose patients to early anatomic failure of the newly created fundoplication. Thus, to minimize the risk of wrap failure, patients are recommended to be placed on scheduled antiemetics for the first 24 to 48 hours.

COMPLICATIONS

Early postoperative complications after laparoscopic fundoplication are unusual, and mortality is rare. Conversion from a laparoscopic to an open approach occurs less than 2.4% of the time at high-volume centers. Gastric and esophageal perforation only occurs 0 to 4% of the time, with the highest rates seen in redo fundoplication cases. Aggressive dissection around the hiatus can lead to pneumothorax (0 to 1.5% of cases); however, because the injuries are usually to the pleura and not the lung parenchyma itself, very few are of clinical significance and they resolve without intervention.

Most notable complications from fundoplication occur in the longer term. Wrap migration is the most common form of anatomic recurrence and occurs in approximately 10% of cases. Other forms of anatomic failure include slippage of the wrap onto the cardia of the stomach or twisting of the wrap. Any of these can lead to recurrent symptoms, most notably recurrent reflux symptoms, dysphagia, or chest pain. Atypical symptoms may also occur. Studies show that as many as 60% of patients are again placed on PPIs in the long term, but in most cases, these treatments are not given based on objective evidence of recurrent reflux. In most of these patients, objective testing actually shows that pathologic reflux is not present.

Other symptoms such as post-Nissen syndrome (gas bloat) can occur and can be troublesome to treat. In most cases, these new gastrointestinal symptoms can be treated medically, and quality of life is much improved compared with preoperative measures. Approximately 3% to 4% of patients need revisional surgery to address these issues, and usually some type of anatomic failure is present.

OUTCOMES

Multiple series within the literature report equal efficacy between surgical and medical therapy for GERD, although surgery may in fact result in better symptom control and quality of life for the patient. After fundoplication, 80% to 85% of patients have complete resolution of typical GERD symptoms; atypical symptoms resolve 60% to 75% of the time. Mild dysphasia is not uncommon within the first 30 days of surgery. Only 4% of patients, however, continue to note dysphagia at 90-day follow-up. Most studies within the literature report postoperative use of acid-reducing medications to range from 30% to 60%. Among those patients who resume postoperative PPI therapy, however, only 25% to 30% have documented reflux recurrence on 24-hour pH testing. Long-term (>5 years after surgery) patient satisfaction rates range anywhere from 80% to 96%, with 81% to 95% of patients maintaining they would undergo surgery again.

CONCLUSION

The successful surgical treatment of GERD requires the combination of a meaningful elicitation of the patient's presenting symptoms, with appropriate preoperative workup to understand the underlying esophageal and gastric physiology and function, and practiced surgical technique. The authors' center too often treats patients with complications from surgeries done without adequate preoperative characterization of the disease process or in whom the procedure was not the best surgical choice. The surgeon must have an understanding of the nuances of the preoperative testing that is needed and other esophageal disorders to choose the most appropriate surgical therapy for any given patient.

Laparoscopic Appendectomy

Brian R. Smith, MD, FACS, and Ninh T. Nguyen, MD, FACS

INTRODUCTION

Among the many disease processes and operations in general surgery, appendicitis and appendectomy remain not only the most common but arguably the most impactful form of surgical progress in the last two centuries. Since the mid 1700s, when Amyand performed the first appendectomy for trauma, and the late 1800s, when McBurney published the first series of appendectomy for acute appendicitis, this operation has become the most common operation performed annually worldwide and has saved countless millions of lives. More than 250,000 appendectomies are performed annually in the United States in both adults and children, and the procedure touches nearly 7% of the U.S. population annually.

PATHOPHYSIOLOGY

The pathophysiology of appendicitis is based on lumenal obstruction and visceral blood flow. The inside of the appendix is lined with gut mucosa-associated lymphoid tissue (MALT), which is more active in children and relatively quiescent in adults. In children, this MALT tissue can hypertrophy, causing lumenal obstruction along the length of the appendix. On doing so, ongoing mucous production from the appendiceal mucosa builds up distal to the obstruction, causing visceral distention and initiating visceral-type pain that is colicky, vague, and poorly localized. Along with most small intestinal visceral peritoneal distention, pain is typically periumbilical. As swelling increases distal to the obstruction, venous return from the appendix is initially compromised, followed later by arterial blood flow obstruction with eventual patches of necrosis of the appendiceal wall and subsequent perforation. In adults, firm pieces of stool serve to similarly obstruct the appendiceal lumen in the form of a fecalith. In elderly patients, tumors can occasionally serve a similar obstructive role that follows the same pathophysiology.

DIAGNOSIS

The classic presentation of appendicitis is the starting point from which clinicians should begin their evaluation, and progressive clinical deviation from this presentation warrants further investigation. Patients often present with acute onset of abdominal pain that typically precedes vomiting. Visceral distention usually results in anorexia from the time the pain starts. Pain is described as colicky and vague, initiating in the periumbilical region and difficult to localize initially. As the source of lumenal obstruction of the appendix persists, the localized inflammatory process on the serosal surface of the appendix eventually touches the parietal peritoneum. This causes pain that is well localized to the site of irritation and now migrates typically to the right lower quadrant overlying the inflamed appendix (McBurney's point tenderness). When a right lower quadrant appendicitis is nearby but not adjacent to the abdominal wall, it can be brought in close proximity with pressure or palpation in the left lower quadrant, which can elicit pain in the right lower quadrant (Rovsing's sign). Retrocecal and pelvic appendices may not have access to the parietal peritoneum and hence, may not manifest focal peritoneal symptoms. However, retrocecal appendicitis often approximates the psoas muscle, causing pain with active flexion of the hip (psoas sign). Similarly, pelvic appendicitis more closely approximates the parietal peritoneum when the pelvic space is closed down by passive adduction of the flexed hip (obturator sign). More advanced peritoneal irritation can occur and yield voluntary or involuntary guarding or rebound tenderness to palpation.

Other supportive evidence of appendicitis includes leukocytosis (>10K in 85% of patients), fever (present in 50%), anorexia (present in 75%), and absence of other obvious etiologies. The average appendicitis takes 72 hours to evolve from initial lumenal obstruction to perforation. On perforation, with the associated decompression of the appendiceal lumenal distention distal to the obstruction, patients often feel better transiently before generalized peritonitis sets in from lumenal content spillage. Therefore, patients with significantly longer periods of pain or pain that has failed to progressively worsen over several days should have other diagnoses entertained. In young healthy males, the differential diagnosis is relatively limited to terminal ileitis or colitis or Meckel's diverticulitis. In children, mesenteric adenitis, or diffuse lymph node swelling throughout the intestinal mesentery often as a result of a viral infection, can very closely mimic acute appendicitis and is highest on the differential. In women, pelvic inflammatory disease, adnexal cysts or torsion, and tuboovarian abscesses are all high on the differential and often require a pelvic examination to help delineate. Symptoms of vaginal discharge and a

menstrual and sexual history often help provide insight into these differentials.

The further the clinical picture deviates from the previous classic presentation, the larger the differential diagnosis and hence, the greater the role imaging plays in securing the diagnosis. Right lower quadrant ultrasound scan can be helpful but is highly operator dependent and less sensitive and specific (~90% and 97%, respectively) than computed tomographic (CT) scanning (~95% and 98%, respectively). However, the value of ultrasound scan is high in children and pregnant females in whom radiation exposure from CT scanning is of concern. Indiscriminate use of imaging, particularly CT scanning, has been shown to increase cost and delay diagnosis and management of cases where appendicitis is clinically either obvious or unlikely.

INDICATIONS

For patients who present with acute nonperforated appendicitis, the appropriate treatment is timely appendectomy. Best evidence supports no increase in risk of perforation or postoperative complications if surgery is performed within 24 hours of presentation. Beyond 36 hours from time of symptom onset, the risk of appendiceal perforation goes up by 5% for every 12-hour period of delay, and most evidence supports increased postoperative morbidity beyond this period. Patients should ideally be started on antibiotics once the diagnosis is made and taken to surgery at the first feasible opportunity.

Benign and malignant tumors of the appendix are rare and most often manifest a clinical picture identical to that of acute appendicitis. As a result, preoperative diagnosis of these tumors is rare, and distinction is typically made by a pathologist. This group of tumors is composed of appendiceal carcinoid, adenocarcinoma, and mucocele. For the tumors that are diagnosed either on preoperative CT scan or after appendectomy, right hemicolectomy is indicated for tumors of more than 2 cm or the presence of any lymph node metastases. At the time of laparoscopic appendectomy for presumed appendicitis, obvious tumors larger than 2 cm or with clinically visible lymphadenopathy should be converted to either laparoscopic or open right hemicolectomy depending on surgeon skill level.

TECHNIQUES

The two fundamental and most often debated techniques for appendectomy are laparoscopic versus open. The open technique has been the dominant approach for well over a century. Yet in only the last 20 years, the laparoscopic approach has largely replaced the open approach at most institutions, despite ongoing debate about its true superiority. Regardless of which approach is used, all patients should be counseled about the risks and benefits of each and sign consent for both. Preoperative antibiotic prophylaxis should consist of gram-negative and anaerobic coverage. Patients should be placed under a general anesthetic, and a timeout should be performed by the entire surgical team to verify patient identification, correct operation and site, proper antibiotic prophylaxis, and presence of necessary equipment and review the need for blood products or special equipment. A Foley catheter should be placed for decompression of the bladder. Skin prep should ideally be with chlorhexidine solution, and the patient should be draped to expose the entire abdomen from nipples to the pubis and laterally to the midaxillary line.

For a laparoscopic approach, the patient's left arm should be tucked and arm board removed to facilitate both the camera operator and the surgeon standing on the patient's left side during surgery. The abdomen can be entered with Veress needle or Hassan technique per surgeon preference, and the abdomen is insufflated to 15 mm Hg with carbon dioxide gas. Preincisional infusion of local anesthetic at each trocar site has been shown to decrease postoperative pain. Ideal trocar placement is one 5-mm trocar at the umbilicus to accommodate a 5-mm angled laparoscope and another in the midline just above the pubis under direct vision, with care taken to avoid bladder injury (temporary indwelling urinary catheter and bed positioning in Trendelenburg's position facilitate this; Figure 1). Initial insertion of the laparoscope should visualize the viscera and omentum beneath the entry site to ensure there are no signs of visceral injury during placement of the initial port. In the left lower quadrant (LLQ), centered vertically between the first two trocars and horizontally in the anterior axillary line, a 12-mm trocar is placed with direct vision, with care taken to avoid injury to the sigmoid colon (tilting the bed to the patient's right facilitates this). The bed is then tilted to the patient's left and in modest Trendelenburg's position to facilitate exposure of the right lower quadrant (RLQ) region.

A 5-mm atraumatic grasper is inserted in the suprapubic port and used by the left hand to grasp and retract the appendix. The appendix can always be located by following the tenia of the ascending colon to their termination at the appendiceal base. A Maryland dissector is placed through the 12-mm LLQ port and used by the right hand to dissect a window through the mesoappendix immediately adjacent to the base of the appendix (Figure 2). Care should be taken to stay against the appendiceal base when creating this window, as the appendiceal artery lies at the free (antimesenteric) margin of the mesoappendix and is less likely to be injured. Similarly, care must also be taken when creating this window to avoid injury to the cecum. Once the window is created, the Maryland dissector is replaced by a laparoscopic stapler; the mesoappendix is stapled first, and the

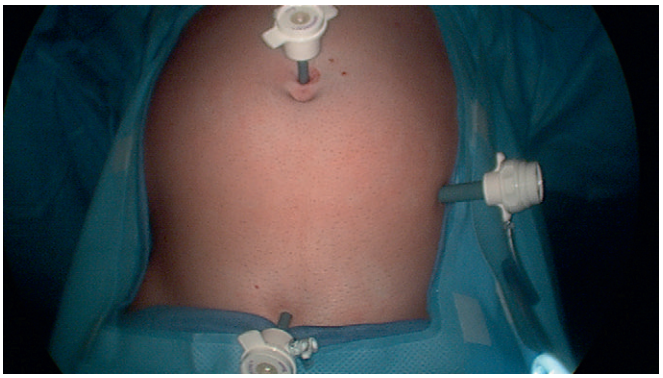

FIGURE 1 Trocar placement for laparoscopic appendectomy. The superior trocar is cephalad to the umbilicus.

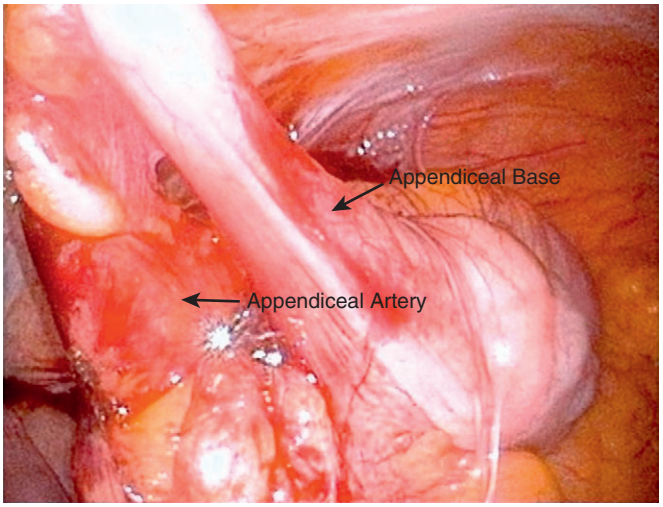

FIGURE 2 Laparoscopic view shows appendiceal artery separated away from appendix.

appendiceal base immediately adjacent to the cecum is stapled after (Figure 3). However, it is important to use a vascular staple load for the mesoappendix and medium bowel staple load for the appendiceal base, with great care taken to ensure all of the appendix is transected to avoid stump appendicitis in the future.

In the rare event that the cecum at the appendiceal base is inflamed or not healthy appearing, stapling in this region should be avoided in consideration of an alternative diagnosis of colitis. Once the appendix and mesoappendix are hemostatically stapled, the appendix should be placed inside of a protective bag and removed through the LLQ 12-mm port. Irrigation can then be undertaken as needed in the RLQ and pelvis until all purulent fluids are aspirated and hemostasis is ensured. Many surgeons prefer to close the 12-mm trocar fascial defect with absorbable suture, and again, bed tilt to the patient's right can minimize proximity of closure efforts to the colon. Skin is then reapproximated with absorbable subcutaneous sutures after irrigation of the port sites.

Open appendectomy is performed with the patient supine and both arms out on arm boards. A 4-cm to 5-cm transverse RLQ (Rocky-Davis) or oblique (McBurney's) incision is made approximately one third the distance from the umbilicus to the anterior superior iliac spine, centered over the midclavicular line. This incision is carried down through Scarpa's fascia to the external oblique, which is also incised transversely. The internal oblique and transversalis muscles are then separated with muscle-splitting and progressive dissection down to the peritoneum, which is opened sharply in a transverse fashion. The appendix is then palpated digitally and finger-dissected free from surrounding structures and delivered out through the wound with a Babcock clamp. A window in the mesoappendix is created, and the base of the mesoappendix ligated. The base of the appendix is then purse-stringed with a 2-0 absorbable suture. The base is then clamped, and the base is transected and specimen passed off the field. The base is then suture ligated and inverted into the cecum before the purse-string suture is tied, effectively inverting the appendiceal stump into the cecum. The surrounding area is then copiously irrigated until clear, and local purulence is removed. The peritoneum is then reapproximated with 3-0 running absorbable suture, followed by reapproximation of the external oblique fascia with a 2-0 absorbable suture. The wound is then copiously irrigated, and skin is closed with either clips or absorbable subcutaneous sutures. Routine drain placement is not indicated after appendectomy unless the presence of a clear abscess cavity may benefit from short-interval drainage.

For patients with nonperforated appendicitis, continuation of prophylactic antibiotics beyond 24 hours after surgery has shown no documented benefit. For patients with perforated appendicitis or more serious intraabdominal sepsis, best evidence supports antibiotic therapy until the patient has been afebrile for 24 hours and with a normalization of leukocytosis. Dietary progression should be guided by overall clinical picture, presence of ileus, severity of intraabdominal sepsis, and patient's desire to eat. Most patients with nonperforated appendicitis can safely start a bland diet immediately after surgery. Like most operations, patients should ambulate as soon as possible after surgery, have their urinary catheter removed by postoperative day 1 unless otherwise indicated, aggressively use their incentive spirometer 10 times per hour every hour that they are awake, and undergo chemoprophylaxis against deep venous thrombosis (DVT) within 24 hours of surgery unless otherwise contraindicated or discharged home. Many patients with nonperforated appendicitis who undergo timely appendectomy can also be discharged the same day or within 24 hours of surgery if they are tolerating diet and are pain-controlled.

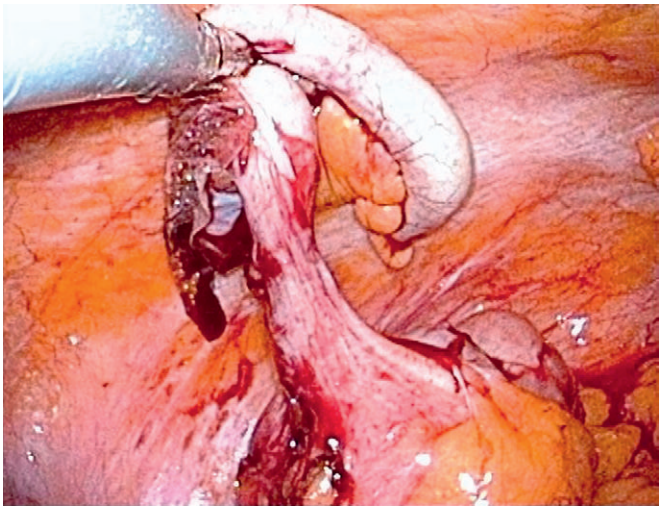

FIGURE 3 Laparoscopic view shows appendiceal vessels already divided with appendiceal base clearly seen.

RESULTS

Despite extensive analysis of the outcomes of laparoscopic versus open appendectomy, very little level I data exist to document the superiority of one approach over the other. In addition, the laparoscopic approach is currently estimated to account for more than 80% (and growing) of all appendectomies done in the United States, which makes the ongoing debate over what may ultimately be small differences increasingly futile. However, some generalizations of the outcomes can be made based on large database analyses of both approaches.

Laparoscopic appendectomy has been definitively shown to be safe in all subgroups of patients, including children, pregnancy, complicated appendicitis, and the elderly. The laparoscopic approach has also been shown to modestly decrease postoperative pain, hospital stay, and recovery time when compared with open appendectomy. Laparoscopic appendectomy most consistently decreases wound complications when compared with the open approach but in many studies has a rate of intraabdominal/organ space infection that is higher than that of open appendectomy. Given the inconsistency in superiority of these two approaches, and true differences being relatively small, the value of the debate has decreasing clinical value.

SPECIAL CONSIDERATIONS

Pregnancy

Pregnant patients pose a considerable diagnostic and therapeutic dilemma. With modern diagnostic techniques and improved critical care, prior concerns about maternal mortality from complicated appendicitis have been largely replaced by concerns for preterm delivery and fetal loss. A study by McGory and colleagues in 2007 evaluated more than 3000 pregnant patients operated on for appendicitis, and found 30% of patients already had complicated appendicitis at presentation. Complicated appendicitis during pregnancy resulted in higher early delivery rates (11% vs 4%) and higher fetal loss rates (6% vs 2%) when compared with patients with uncomplicated appendicitis. Pregnant patients also have higher rates of negative appendectomy compared with nonpregnant counterparts (23% vs 18%, respectively). However, a negative appendectomy during pregnancy still holds rates of early delivery and fetal loss of 10% and 4%, respectively. Given these relatively high rates of early delivery and fetal loss in all groups of pregnant patients operated on for appendicitis, the ideal solution is timely diagnosis and operation for appendicitis before perforation. Use of ultrasound scan has been shown to lower negative appendectomy rates from 54% to 32% with examination alone. CT scanning can further lower negative appendectomy

rates to 8% but must be balanced with the yet unclear detriment of modern CT scanning during pregnancy, particularly during the first trimester. Patients must be counseled about all of these statistics and provided with thorough informed consent.

Incorrect Diagnosis

A negative appendix at laparoscopic evaluation provides a unique opportunity for global abdominal evaluation for an alternative diagnosis. In women, pelvic reproductive organs can be evaluated as they are high on the differential. The gallbladder can be easily evaluated, and a diligent search for a Meckel's diverticulum can also be performed. In addition, the colon and small bowel can be carefully evaluated for signs of inflammatory bowel disease. It is the view of these authors that, given the low morbidity of a completion appendectomy once laparoscopy has been established, a planned appendectomy should be carried out in all cases except when the cecum at the base of the appendix is inflamed, as the risk of postoperative leak from the appendiceal stump increases in this circumstance.

Complicated Appendicitis

Those patients who present with complicated appendicitis pose a much more difficult and debated therapeutic challenge. Traditional approach of surgery for all, regardless of perforation, revealed that patients often had prolonged hospital courses and significant morbidity after appendectomy for perforated appendicitis. This led to an era of antibiotic management without surgery for cases of documented or suspected perforated appendicitis. From these two periods, a complex debate has arisen over optimal management of these patients. To further plague the debate, very little high-quality evidence exists to point the clinician in the optimal direction. A recent meta-analysis that evaluated more than 1500 patients, while conceding overall suboptimal quality of the data, found patients who underwent initial nonoperative management for perforated appendicitis had overall lower rates of complications, particularly wound complications.

Interval Appendectomy After Nonoperative Management

For those patients who undergo initial nonoperative management of complicated appendicitis, indications for and optimal timing of interval appendectomy remain debated. Studies that follow patients for clinical recurrence show an incidence rate of 25% at 6 months from initial perforated episode, concluding little benefit to interval appendectomy in most patients. Others that follow histologic persistence/recurrence after interval appendectomy show a nearly 85% incidence rate of ongoing inflammatory changes seen at interval appendectomy and hence, justify routine performance. Overall, no high-quality data guide the management of patients initially treated nonoperatively, and this decision remains at the discretion of the surgeon. Regardless of the decision towards interval appendectomy, patients should undergo routine colonoscopy approximately 6 weeks after resolution of perforated appendicitis to rule out an oncologic source.

SUMMARY

The centuries-old approach to diagnosis of appendicitis has become simplified with the use of modern imaging. Despite these advances, many patients can still be diagnosed based on history and physical examination alone. The choice of surgical approach to appendectomy remains at the discretion of the surgeon, with numerous small benefits conferred to the laparoscopic approach, which continues to evolve as the clear dominate choice among modern surgeons for every patient group.

Laparoscopic Inguinal Herniorrhaphy

Hien T. Nguyen, MD, FACS

OVERVIEW

Inguinal herniorrhaphy is the most common general surgery procedure performed, with 750,000 cases yearly in the United States. The lifetime risk of developing inguinal hernias is 27% in men and 3% in women, with direct annual costs at $2.5 billion. There are multiple contributing factors that lead to the development of inguinal hernias, including strain, collagen diseases, and hereditary factors. These stressors create a laxity of the muscles within the inguinal region, allowing progressive patency. Indirect hernias occur most commonly and result from the congenital invagination and eventual dilatation of a peritoneal sac running through the internal inguinal ring along the cord structures in men and round ligament in women. Direct hernias are the result of a weakened transversalis fascia lateral to the rectus muscles and above the inguinal ligament. Femoral hernias occur within the femoral canal medial to the femoral vein and are more commonly found in women with a high risk of incarceration.

The definitive treatment for inguinal hernias is surgery. The advantage of the laparoscopic approach is the ability to evaluate the entire myopectineal orifice and address all possible hernias

originating from the inguinal region. The posterior approach of laparoscopic repair allows the lightweight mesh to be placed in an inlay fashion as opposed to the anterior onlay technique of open repair. There is a steeper learning curve for the laparoscopic approach compared to the open repair, as well as potentially longer operative times and higher costs. However, the benefits of the laparoscopic endeavor include less postoperative pain, shorter convalescence, and equivocal or lower recurrence rates compared to the open technique. However, complication rates for the laparoscopic approach may be higher than open until the surgeon performs up to 250 cases. Recurrence rates are lower than 6% and are commonly caused by incomplete reduction of the hernia sac, insufficient overlap of mesh over the defect, or missed small indirect hernias and cord lipomas. A common comment about laparoscopic inguinal herniorrhaphy is higher cost compared to open. The LEVEL-Trial by Langeveld and colleagues comparing laparoscopic and Lichtenstein inguinal hernia repair showed that operative costs were higher for the laparoscopic approach, mainly due to disposables and surgical equipment, but social costs were higher for the Lichtenstein approach due to more sick leave time needed. Overall, total costs were comparable between laparoscopic and Lichtenstein inguinal hernia repair, making the laparoscopic approach a worthwhile investment from the patient and societal perspectives due to decreased postoperative pain and shorter convalescence, allowing earlier return to work.

EVALUATING THE PATIENT

Patients with symptomatic inguinal hernias are candidates for surgical repair unless they have comorbidities that outweigh their risk of strangulation. According to Fitzgibbons and colleagues, minimally symptomatic men should have the option of postponing surgery with minimal risk of acute incarceration, but they have a 23% chance of requiring surgical repair within 2 years, mostly due to pain.

The patient is asked about any pressure or bulging sensation over the inguinal site, which is commonly associated with activities that increase intraabdominal pressure such as lifting or straining. Any acute onset of severe inguinal pain associated with obstructive symptoms such as nausea or vomiting suggests bowel incarceration or strangulation, which may require acute surgical intervention. Patients should also have risk factors for complications addressed such as smoking, chronic cough, constipation, and obesity.

Physical examination includes assessing for the amount of tenderness to palpation, hernia size, reducibility, and for a contralateral defect. The external inguinal ring is palpated by invaginating the scrotum with the index finger toward the pubic tubercle while the patient is standing. A defect descending into the scrotum is likely an indirect hernia, while a bulge at the external inguinal ring is a direct hernia. Femoral hernias are most commonly found in women and can be palpated below the inguinal ligament medial to the femoral vessels. Patients are asked to perform a valsalva maneuver such as coughing to palpate the impulse of a small defect and to evaluate for a subtle contralateral hernia. Griffin and colleagues found that up to 22% of patients with unilateral inguinal hernias may have an occult contralateral defect not detected on physical exam. Therefore, most patients are consented for laparoscopic evaluation for bilateral inguinal hernias.

RELEVANT ANATOMY

The preperitoneum is the space between the peritoneum and the bilaminar transversalis fascia. Both the totally extraperitoneal (TEP) and transabdominal preperitoneal (TAPP) procedures require entering this space. The anterior layer of the trasversalis fascia is attached to the rectus abdominus muscle, while the posterior transversalis fascial layer envelopes the cord structures and the bladder. Dissection of the peritoneal hernia sac off the cord structures should not disrupt the translucent posterior transversalis fascial layer to minimize dissection injury and potential mesh irritation to the cord structures. The retropubic space of Retzius lies anterior to the bladder between the medial umbilical ligaments. The space of Bogros extends laterally from the space of Retzius toward the anterior superior iliac spine (ASIS). These spaces need to be developed to allow adequate room for repair of the inguinal hernia and mesh placement.

The pubic symphysis is the cartilaginous joint between the superior pubic rami and denotes the midline. Cooper's ligament, also known as the pectineal ligament, is a lateral extension of the lacunar ligament and forms the periosteum of the superior pubic rami.

The oval-shaped myopectineal orifice of Fruchaud is the origin of all inguinal hernias. It is bound medially by the edge of the rectus muscle, laterally by the iliopsoas muscle, superiorly by the arch of the transversus abdominus and internal oblique muscles, and inferiorly by Cooper's ligament. The iliopubic tract is a thickened fold of transversalis fascia that extends from the pubic ramus to the ASIS and divides the myopectineal orifice into a superior and inferior portion. Below this tract is the femoral canal medially and external iliac vessels laterally. The Triangle of Doom contains the external iliac artery and vein, and it is bordered medially by the ductus deferens and laterally by the spermatic vessels (Figure 1). The Triangle of Pain contains the lateral femoral cutaneous nerve, the femoral branch of the genitofemoral nerve, and the anterior branch of the femoral nerve. It is bound medially by the spermatic vessels and superolaterally by the iliopubic tract. The lateral femoral cutaneous nerve is most commonly injured and results in pain or numbness in the lateral upper portion of the thigh.

Hesselbach's triangle is bordered superolaterally by the inferior epigastric vessels, medially by the rectus muscles, and inferiorly by Cooper's ligament from the laparoscopic posterior perspective. Direct hernias protrude through Hesselbach's triangle medial to the inferior epigastric vessels, while indirect hernias enter the internal inguinal ring lateral to the epigastric vessels (Figure 2).

The inferior epigastric vessels arise from the external iliac vessels and ascend medially toward the rectus muscle between the two layers of the transversalis fascia. In 20% of patients, a large pubic branch of the inferior epigastric artery courses inferiorly across Cooper's ligament and anastomoses to the obturator artery. This aberrant vessel is called the Corona Mortis, and it can potentially be injured while dissecting areolar tissue laterally on Cooper's ligament toward the femoral canal, leading to brisk bleeding. There is also a network of veins within the lower subinguinal Space of Bogros branching from the exterial iliac, coursing underneath Cooper's ligament and along the lower lateral fibers of the rectus muscles and iliopubic tract that may be injured with dissection. Collectively, this variable deep venous circle is called the circulation of Bendavid and is composed of the suprapubic, retropubic, deep inferior epigastric, and rectusial veins (see Figure 2).

INDICATIONS AND CONTRAINDICATIONS

The laparoscopic approach is ideal for patients who are obese, have recurrence from a prior open approach, have bilateral hernias, or require an operation that may result in a shorter convalescence (Table 1). All laparoscopic inguinal hernia repairs require placing mesh in the preperitoneal space to reinforce the myopectineal orifice. This was initially performed with a TAPP approach requiring initial entry into the abdominal cavity followed by division of the peritoneum and subsequent entry into the preperitoneal space. TAPP is preferred for patients with a large hernia or a prior infraumbilical abdominal incision because the contents of a large hernia can be assessed and reduced from the abdominal cavity, and scar tissue from a prior midline incision makes TEP entry more difficult due to adhesions. However, TAPP requires a transfascial incision into the abdominal

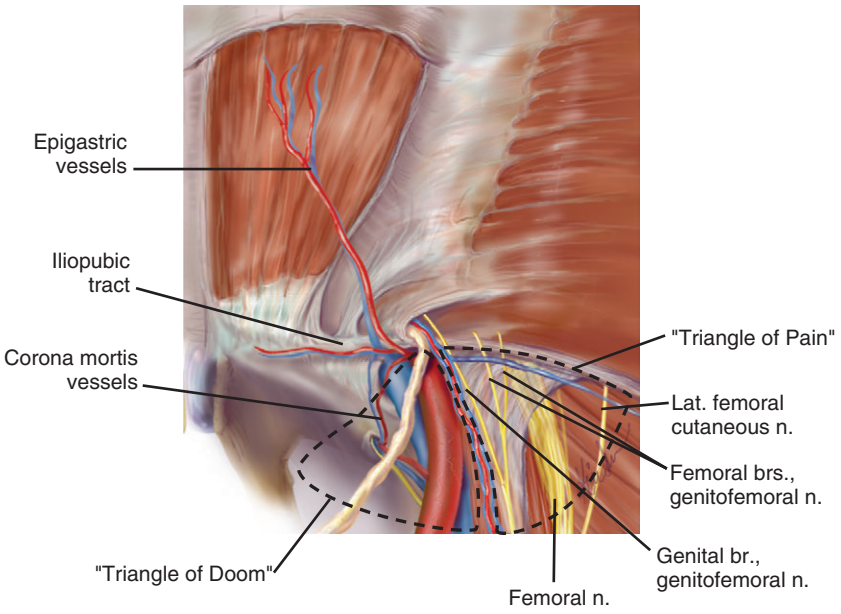

FIGURE 1 Triangle of doom and triangle of pain. *(Courtesy Anne Erickson, CMI.)*

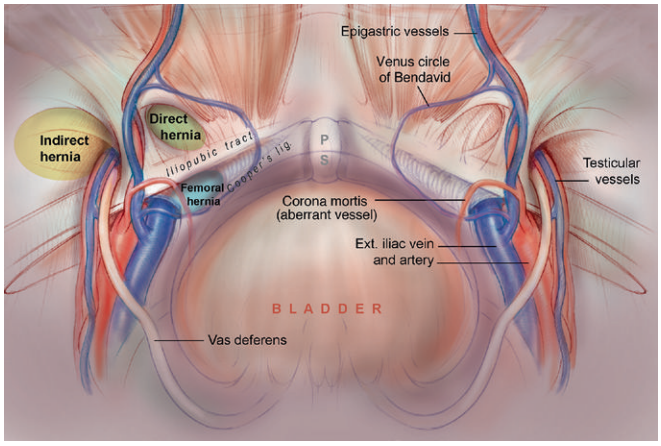

FIGURE 2 Hesselbach's triangle. *(Illustration from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II (in press); used with permission from PMPH-USA, Shelton, CT.)*

cavity, which can lead to port site hernias and intestinal injury. TAPP also requires the divided peritoneum to be reattached to cover the mesh, which adds time to the operation. To address these issues, the TEP approach enters the preperitoneal space directly by staying above the posterior rectus sheath and peritoneal layer and never entering the abdominal cavity. TEP has a longer learning curve than TAPP due to a more limited operative field. However, TEP is associated with shorter operative time, fewer bowel injuries, and port site hernias, making it the preferred approach.

Absolute contraindications include severe illness, coagulopathy, and active severe infection. Acutely incarcerated hernias have a higher risk of bowel injury with laparoscopic manipulation and should undergo open repair. Although there are reports of laparoscopic inguinal herniorrhaphy being performed with spinal anesthesia, patients who cannot tolerate general anesthesia should undergo open repair. Relative contraindications include prior surgery in the retropubic space, sliding hernias, large chronic incarcerated hernias, and ascites.

TABLE 1: Patient assessment for transabdominal preperitoneal versus totally extraperitoneal

Attributes	TAPP	TEP
Typical surgical candidates	Bilateral inguinal hernia Recurrence from prior open inguinal hernia surgery Prior midline abdominal surgery Prior preperitoneal surgery Large, partially reducible defect Morbidly obese patient	Bilateral inguinal hernia Recurrence from prior open inguinal hernia surgery Smaller, fully reducible defect
Common complications	Bowel injury Port site hernia Mesh exposure to bowel	Bleeding from injured epigastric vessels Incomplete hernia reduction Higher risk of recurrence

PREPARING THE PATIENT

The patient is placed supine with video monitors at the feet, and bilateral sequential compression devices are placed on the lower extremities (Figure 3). The effectiveness of antibiotic prophylaxis is not clear. A randomized, double-blind study by Perez and colleagues looking at tension-free herniorrhaphy of 360 patients did not show a marked decrease in infections in the patient population receiving antibiotics.

After general endotracheal anesthesia is performed, the patient is positioned supine with both arms firmly tucked to the patient's side.

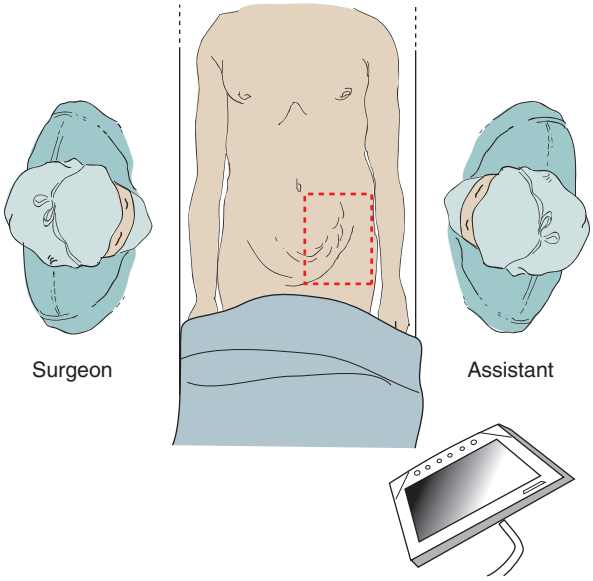

FIGURE 3 Positioning of the patient and surgical team. *(Courtesy Anne Erickson, CMI.)*

A Foley is not placed to minimize the risk of postoperative urinary retention and urinary tract infections unless the patient has had prior inguinal or pelvic surgery. The patient is placed in mild Trendelenburg, and the hernia is manually reduced as much as possible.

The hair on the abdomen and groin are clipped, and the area is widely prepped with a chlorhexidine/isopropyl alcohol solution. The operative field is draped to allow for a TAPP, TEP, or open procedure using an iodophor adhesive sterile drape to keep the synthetic mesh from contacting skin.

TOTALLY EXTRAPERITONEAL

The surgeon stands on the contralateral side of the inguinal hernia. A 1-cm incision is made below the umbilicus, and blunt dissection continues past the thick orange Scarpa's fascia to the fibrous linea alba running between the rectus muscles (Figure 4). The linea alba is pulled up, and a 1-cm horizontal incision is made slightly laterally from the linea alba through the anterior rectus sheath extending toward the side with the hernia. The linea alba at midline is adherent to the peritoneum, so a deep incision will create a fascial defect communicating into the abdominal cavity. If this occurs, the defect is closed and the contralateral side can be incised to reattempt a preperitoneal approach, or a TAPP can be performed. The medial edge of the rectus muscle is visualized, and the fascial incision should be large enough to allow a finger to sweep behind the rectus muscle above the firm posterior rectus sheath (Figure 5). The rectus muscle is retracted laterally to visualize the white posterior rectus sheath. At this point, either the laparoscope or a dissecting balloon is used to bluntly dissect the preperitoneal space of Retzius. The use of the laparoscope as a blunt dissecting instrument begins with placing the scope below the rectus muscle and advancing toward the bony pubic symphysis while staying in the areolar space. Once below the arcuate ligament, the thick posterior rectus sheath is replaced by thin peritoneum. Blunt dissection is performed by moving the scope laterally within the preperitoneal plane to create enough space between the inferior epigastric vessels to allow 5-mm trocars to be placed.

The dissecting balloon can create a similar space in the preperitoneal plane (Figure 6). The balloon is placed below the rectus muscles and directed inferiorly toward the pubic symphysis. The dissecting balloon needs to be advanced with minimal effort, or either the balloon was placed too anteriorly or the incision was too small to accommodate the device. After the tip of the balloon touches the pubic symphysis, a 10-mm angled laparoscope is placed into the lumen of the balloon as it is inflated. Visualization of bowel or omentum means that the peritoneum is torn and the balloon is now in the abdominal cavity. If this happens, the operation can proceed as a TAPP or be converted to an open approach. Next, the inferior epigastric vessels should be seen anteriorly. Use of a dissecting balloon is associated with a higher incidence of vessel injury due to dissection between the inferior epigastric vessels and the rectus muscles. If the balloon was placed too anteriorly, insufflation should stop, and the balloon is repositioned more posteriorly to the epigastric vessels. These vessels may be subtle to visualize in obese patients and are best found by looking toward the internal inguinal ring and finding a purple-white stripe that can be traced superiorly. The

balloon is insufflated until a portion of the white edge of Cooper's ligament is seen. If there is minor bleeding from the dissection, the balloon is kept inflated to allow tamponade of the bleeding. Afterward, the scope and dissecting balloon are removed from this preperitoneal space and a 10-mm trocar is placed with insufflation set at 12 mm Hg to minimize subcutaneous emphysema.

The 5-mm trocars are placed inferiorly to the umbilicus through the linea alba, where space has been created to minimize the risk of tearing the peritoneum. The first 5-mm trocar is placed three fingerbreadths above the pubic symphysis to allow adequate space for mesh placement, and the second trocar is placed at the midpoint between the pubic symphysis and the umbilicus. The patient can be placed in further Trendelenburg to optimize visualization.

Dissection begins by palpating the bony pubic symphysis. The areolar space is bluntly separated to reveal Cooper's ligament as dissection continues laterally toward the femoral canal, looking for the aberrant Corona Mortis. Injury of this vessel can be prevented with gentle blunt dissection of the lateral portion of Cooper's ligament. If injury occurs, the Corona Mortis is grasped quickly to prevent posterior retraction and further bleeding, followed by clipping. Brisk bleeding can quickly obscure the injured vessel, which lies very close to the external iliac vein.

Dissection continues laterally by next identifying the inferior epigastric vessels and bluntly dissecting through the areolar tissue posterior to these vessels, with the intention of creating space toward the transversus abdominus arch and ASIS laterally. After the muscle striations of the transversus abdominus are seen laterally, dissection is continued superiorly past the ASIS to allow adequate space for mesh placement. In creating this space, the anterior-superior portion of the cord structure has been identified.

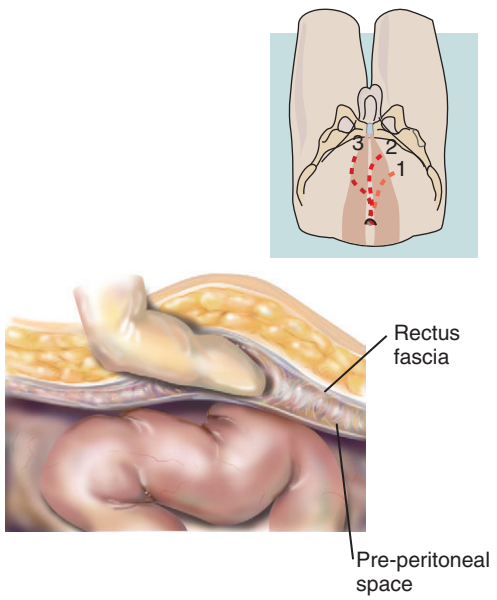
A direct hernia is encountered medially to the inferior epigastric vessels and is reduced by retracting the herniated contents posteriorly until the white edge of the weakened transversalis fascia is seen. The edge of this pseudosac is circumferentially peeled anteriorly as the herniated fatty tissue continues to be pulled posteriorly and reduced completely. The lateral edge of the defect can involve portions of the inferior epigastric vessel. If the direct defect is large, the redundant transversalis fascia can then be pulled into the preperitoneal space and tacked above Cooper's ligament medially to minimize seroma formation.

The cord structure needs to be separated from the iliac vessels to allow adequate space for the safe reduction of the indirect hernia sac. This is done most easily adjacent to the internal inguinal ring, which is identified by following the epigastric vessels inferiorly to the external iliacs. The internal inguinal ring and cord structure is directly lateral to the inferior epigastrics at this point. The cord structure spreads out in a triangular configuration proximally, with the ductus deferens being the medial border of the triangle. Loose fatty tissue overlying the cord is bluntly swept off. Once seen, the ductus is pushed anteriorly and laterally with the rest of the cord structure as gentle blunt dissection allows further separation between the cord structures and iliac vessels. The indirect sac is the thin blue-white peritoneum attached to the cord structure. Dissection adjacent to the internal inguinal ring allows identification and separation of the sac from the cord structures. The sac is often densely adherent to the cord structure and requires steady retraction to separate it from the cord structures. Blunt dissection is used to sweep the adherent tissue off the medial and lateral sides of the sac as the edge is isolated and peeled off the cord structure (Figure 7). Branches of the delicate pampiniform plexus may be adherent to the hernia sac and should be carefully handled to minimize the risk of venous thrombosis leading to testicular ischemia. Once separation between the sac and the cord structure is established, steady retraction and separation of the sac from the cord structure will allow it to be pulled out of the internal inguinal ring until the tip of the distal edge comes into view. The tip of the sac is peeled back to the psoas muscle, allowing mesh placement that will completely exclude the sac. If tearing of the sac occurs, a vessel loop or clipping is used to close the peritoneum to prevent bowel exposure to mesh and to minimize insufflation of the abdominal cavity. If necessary, veress decompression can be performed in the left upper abdominal quadrant. If the sac is large and cannot be completely separated from the cord structure, then a high ligation can be performed. After complete division, the distal sac can be seen retracting into the inguinal canal, and the proximal sac is closed with a vessel loop.

Often a large cord lipoma is identified running lateral to the cord structures into the internal inguinal ring. These lipomas can create a sizeable bulge that is clinically relevant to the patient and must be reduced from the inguinal ring. The fatty composition of the cord lipoma is slightly different from the cord fatty tissue, and the larger fat globules can be easily reduced from the inguinal canal with steady

pressure, making sure that there are no vessels encased in the lipoma. Similar to a hernia sac, the cord lipoma is bluntly separated from the cord structures and reduced back from the internal inguinal ring to allow complete exclusion after the mesh is placed.

If clinically indicated, femoral hernias can be reduced by first identifying the external iliac vessels by tracing the inferior epigastrics caudally. After clearing the fatty tissue medial to the iliac vessels, the femoral canal is found below the iliopubic tract and above Cooper's ligament. The hernia is reduced with circumferential blunt dissection. Lymphatics in the areolar tissue and large adjacent vessels require dissection directly over the hernia sac to minimize injury. If the hernia is too densely adherent or incarcerated, the operation should be converted to open to minimize catastrophic injury to the external iliac vessels.



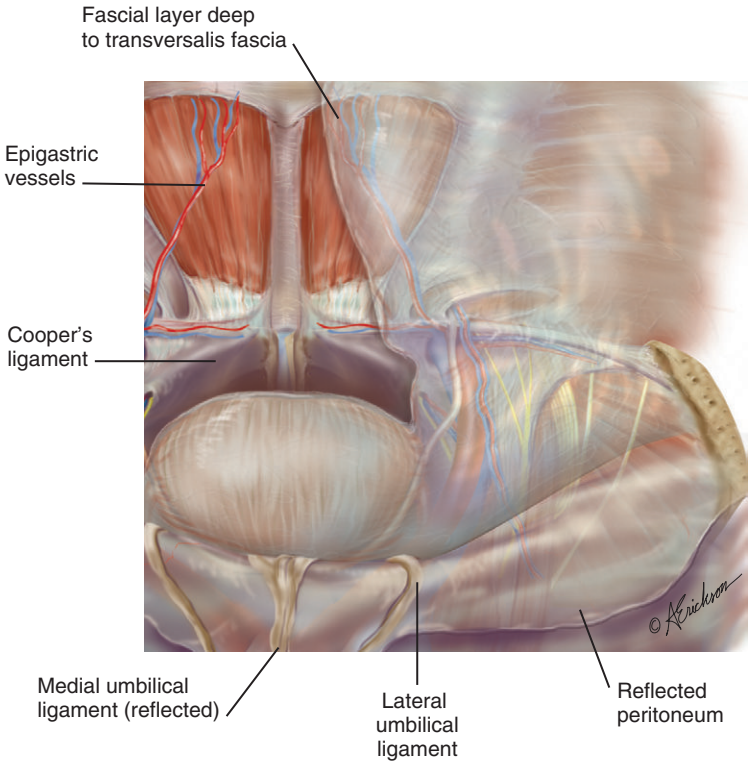


FIGURE 7 Developing the preperitoneal space in the midline. *(Courtesy Anne Erickson, CMI.)*

Intraoperative evaluation of an occult contralateral hernia does not require additional skin incisions and should take less than 15 additional minutes to perform. Easy detection and repair of a contralateral hernia is a known advantage of the minimally invasive approach and saves the patient from a subsequent operation through a larger open incision or through scarred preperitoneal tissue.

After evaluation for a contralateral hernia, the operative field should have ample space from the pubic symphysis to the ASIS bilaterally. A lightweight 10 × 15-cm mesh can adequately cover and reinforce the myopectineal orifice on each side. The corners of the mesh are trimmed to allow ease of placement. Creating a slit in the mesh to allow the cord structures to pass may increase the risk of reherniation or chronic pain and is not done. There is commercially available mesh with a preformed notch to allow placement over the cord structures. The mesh is inserted through the 10-mm trocar and should lie flat, with the medial edge at midline over the pubic symphysis and the lateral edge at the palpable ASIS. The inferior edge of the mesh should extend 3 to 4 cm past Cooper's ligament inferiorly, leaving adequate mesh to cover the potential direct, indirect and femoral defects (Figure 8).

There is a growing body of evidence, such as studies by Messaris and colleagues, that show that hernia repair without mesh fixation does not lead to early recurrence. Furthermore, fibrin glue has also gained popularity as a way to fixate mesh with lower risk of complications from tacking such as inguinodynia. In performing a study evaluation comparing stapling versus fibrin glue fixation, we found that fibrin glue fixation achieves similar recurrence rates compared to staple fixation, but with a decreased incidence of chronic inguinal pain, and may be the preferred fixation technique. If tacking is to be performed, care must be taken to minimize risk of bleeding and bladder and nerve injury. Typically, the mesh is tacked above

FIGURE 8 The extraperitoneal fascial layer. *(Courtesy Anne Erickson, CMI.)*

Cooper's ligament and rectus abdominus medially, avoiding the circulation of Bendavid. The mesh is never tacked below the bony ligaments to prevent injury to the bladder. Laterally, the ASIS is palpated externally with the nondominant hand to ensure the mesh is tacked into the transversus abdominus muscle above the iliopubic tract to minimize injury to the nerves within the Triangle of Pain. A contralateral hernia is fixed similarly with a separate piece of mesh that should slightly overlap at midline.

Afterward, the operative field is evaluated for bleeding or peritoneal tears. At completion, the 5-mm trocars are removed under direct vision to check for port site bleeding. All trocars are then removed, and the preperitoneum is allowed to desufflate. Any persistent abdominal tympany means that the abdominal cavity was inadvertently insufflated due to a peritoneal tear. A Veress needle can be used to decompress the abdominal insufflation. The anterior rectus sheath incision is then closed with 0-gauge absorbable suture. Local anesthesia is injected, and the skin is reapproximated. The scrotum is checked for swelling caused by insufflation as well as a retracted testicle.

TRANSABDOMINAL PREPERITONEAL

Patient position and prepping is the same as TEP. The first incision is infraumbilical, and the abdominal cavity is entered with a Hasson technique and insufflated to 15 mm Hg. After initial laparoscopic evaluation of the abdominal cavity for overt pathology, two 5-mm trocars are then placed, each laterally from the umbilicus at the edge of the rectus muscle (see Figure 4). The patient is placed in further Trendelenberg, and the inferior epigastric vessels are followed caudally toward the external iliacs to identify the internal inguinal ring laterally and Cooper's ligament medially. A deep peritoneal indentation lateral to the inferior epigastrics at this point suggests the presence of an indirect hernia, while a broad indentation medial to the inferior epigastrics suggests a direct hernia. A punctate indentation medial to the external iliac vessels is consistent with a femoral hernia. Herniated tissue through the defect is carefully reduced as adhesions to the pelvic peritoneum are sharply divided. The peritoneum is divided using cauterization starting laterally at the palpable ASIS and continues in an upward arc formation medially with 3 to 4 cm distance from the edge of the hernia past the medial umbilical ligament. The peritoneum is pulled away from the epigastric vessels to minimize risk of injury. The medial umbilical ligament may have a patent umbilical vessel and is clipped and divided to allow adequate access to the preperitoneal space. Once in the preperitoneal plane, blunt dissection proceeds in a manner similar to the TEP technique and continues inferiorly through the alveolar tissue toward the pubic symphysis (Figure 9). Cooper's ligament is then cleared of areolar tissue, extending toward the femoral canal.

Dissection continues laterally toward the transversus abdominus muscle between the inferior epigastric vessels and the cord structures, which are then followed into the internal inguinal ring. The entire myopectineal orifice should be visible. A direct hernia is reduced by peeling the transversalis fascia anteriorly and reducing the herniated fatty tissue back into the preperitoneal space. The transversalis fascia of a large pseudosac can then be tacked to the rectus muscle to minimize postoperative seroma formation. From within the abdominal cavity, the peritoneum of indirect hernia sac can be separated from the cord structures. The ductus deferens and adherent testicular vessels are bluntly separated from the sac, which can be completely reduced back to the psoas. Once separated from the cord structures, the sac can also be ligated if the distal tip is too firmly adherent and cannot be reduced from the inguinal canal. A femoral hernia is bluntly separated from the external iliac vessels and gently reduced. A 10 × 15-cm lightweight mesh is placed transversely in the preperitoneal space to completely reinforce the myopectineal orifice from the ASIS to the pubic symphysis, extending 3 cm inferiorly past Cooper's ligament. The edge of the mesh is cut and tucked anteriorly to the peritoneum, and the divided peritoneal edge is reapproximated to completely cover the mesh. The peritoneum can either be sutured or tacked back together with gaps less than 1 cm to prevent bowel herniation into the gaps (Figure 10). Tacks are placed flush with the

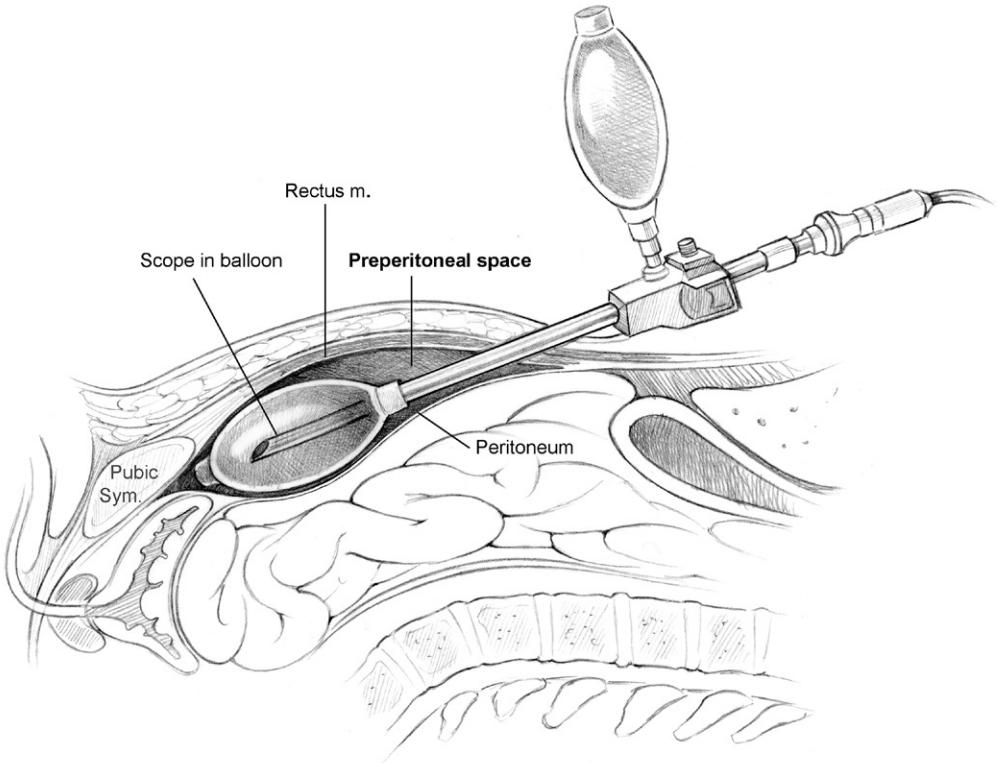

FIGURE 9 Transabdominal Ppreperitoneal (TAPP). *(Illustration from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II [in press]; used with permission from PMPH-USA, Shelton, CT.)*

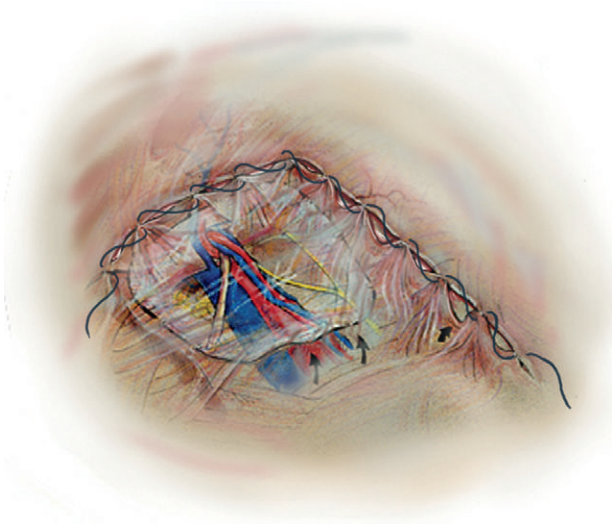

FIGURE 10 Closure of the peritoneal flap. *(Courtesy Anne Erickson, CMI.)*

abdominal wall along the edge of the divided peritoneum. A reduced hernia sac may allow the redundant peritoneum to be more mobile and allow overlap of the edges. Peritoneal tears away from the edge should be closed with vessel loops and not tacked to prevent potential injury of critical preperitoneal structures. Often the omentum can be pulled down to further insulate the operative field from the bowel. After evaluation of the contralateral side for an occult hernia, a final evaluation for bowel injury is performed. The trocars are then removed under direct vision to look for bleeding, and the abdominal cavity is desufflated. The infraumbilical fascial defect is closed with 0-gauge absorbable suture, followed by local anesthesia and skin incision closure. The scrotum and testicles are then checked for swelling and retraction, respectively.

MANAGEMENT OF COMPLICATED HERNIA

Reoperations for recurrent hernias comprise up to 17% of inguinal hernia repairs. They are typically performed laparoscopically if the prior attempt was an open approach to allow dissection within a plane with minimal scarring. Studies such as the ones by Kouhia and colleagues find that laparoscopic repair of recurrent inguinal hernia is superior to open mesh repair in several important clinical aspects, including less incidence of chronic pain and earlier return to work. Both TEP and TAPP approaches are acceptable methods with lower rerecurrence rates as compared to a reattempted repair with an open approach. The presence of prior mesh may cause the hernia sac to be more adherent and difficult to completely reduce and may require high ligation.

With large pantaloon hernias the direct and indirect defects may make dissection difficult in the TEP procedure. A TAPP approach allows more space for evaluation and reduction of the herniated contents and the hernia sac. A large direct component of the pantaloon hernia can sometimes obscure the inferior epigastric vessels. Therefore, it is reduced first to allow space for reduction of the indirect defect. A large patulous internal inguinal ring may be encountered, and the reduction of a cord lipoma first will allow easier identification and reduction of the indirect hernia sac. For large chronic hernias, high ligation may be necessary.

Incarcerated hernias are difficult to repair laparoscopically. The best approach is TAPP, where the herniated contents are visualized and potentially reduced. Placing the patient in steep Trendelenburg and applying taxis to the hernia may aid with reduction of herniated contents back into the abdominal cavity. Herniated omentum can be grasped and reduced with steady pressure, but laparoscopic reduction of incarcerated bowel can easily lead to injury, and the bowel must be inspected carefully.

Inguinal hernias are commonly found concomitantly in patients undergoing prostatectomies. Concerns regarding infection are raised with implantation of prosthetic mesh adjacent to newly formed bladder-urethral anastomosis. However, mesh infections have been shown to be low in studies such as the one published by Allaf and colleagues, prompting more patients to undergo simultaneous laparoscopic prostatectomy and inguinal herniorrhaphies with acceptable outcomes.

Laparoscopic inguinal hernia surgery after prior preperitoneal surgery can lead to a higher rate of bleeding and bladder injury. The dissection balloon of the TEP approach may cause excessive bleeding, so the TAPP approach is used because it allows controlled dissection into the adherent preperitoneal plane. If it is safe to proceed, then blunt dissection is used to find the landmarks discussed above. Mild oozing can be temporized with pressure from the endo-kuttners, and bipolar electrocauterization is judiciously used in the severely adhesed plane. The bladder can be adherent above Cooper's ligament, and a Foley catheter is used to minimize the risk of bladder injury.

AFTER SURGERY

Patients are typically discharged the same day of surgery if they have minimal discomfort, are able to ambulate, and can adequately urinate. Once discharged, patients are encouraged to remain active. Over-the-counter analgesics and compresses prior to prescription medications are encouraged for pain control. A weight restriction of 15 pounds for 1 to 2 weeks is imposed, and patients can return to their normal activities after 2 to 3 weeks. Patients follow up 2 weeks postsurgery.

COMPLICATIONS

Postoperative urinary retention is treated with catheterization. Wound infections are aggressively treated to minimize the risk of mesh infections. Seromas can occur after repair of a large direct hernia and can be clinically differentiated from hernia recurrence by palpation. Typically a recurrent hernia can be partially reduced, while a seroma is a nonreducible, firm, fluid-filled sac that causes minimal discomfort for the patient. Seromas can take 3 to 6 months to completely resolve, and aspiration is seldom required unless the patient is severely symptomatic. If necessary, aspiration is performed with sterile technique to minimize the risk of mesh infection.

According to Ferzli and colleagues, postoperative chronic inguinodynia can range from 9.7% to 34%, and occurs more commonly in obese patients and those with significant preoperative pain (Table 2). Mild postoperative discomfort can be explained by nerve irritation from extensive dissections and should be transient. Antiinflammatory treatment and compresses should provide relief. Severe immediate postoperative pain of the inguinal region is usually due to nerve entrapment by a lateral tack. Use of fibrin glue or positioning of the tacker above the ASIS should minimize nerve injury, but a small percentage of patients have aberrant nerves found above the iliopubic tract that can potentially be injured despite appropriate technique. These patients are taken back to the operating room, and the lateral tacks are removed. Although the risk of testicular infarction is low with laparoscopic inguinal hernia, patients presenting 2 to 3 days after surgery with severe testicular pain and swelling should undergo Doppler sonography to evaluate the testicular blood flow.

Bowel injury should lead to conversion to open, at which time the bowel is thoroughly assessed and repaired. In the setting of contamination, synthetic mesh should not be used due to the high risk of mesh infection. The inguinal hernia can then be repaired with either a biologic mesh or a nonmesh technique such as a Bassini or a McVay procedure. The long-term efficacy with the use of biologic mesh for inguinal herniorrhaphy is not known.

Bleeding from injury to the inferior epigastric vessels can be controlled in many ways, including clipping, ligation with a suture-passer, or use of a 5-mm energy ligation device. The epigastric vessels are fed caudally from the external iliacs, so controlling the caudal side first will slow the bleeding more substantially. Injury to the iliac vessels requires immediate action after recognition. The site of injury to the iliac vessel needs to be grasped, and pressure is held to minimize the bleeding as the case is converted to open. This is done expeditiously because iliac vein injury has the additional risk of air embolism.

TABLE 2: Postherniorrhaphy pain

Types	Examples
Neuropathic factors	Nerve entrapment Nerve irritation due to aggressive dissection Neuroma formation
Postsurgical factors	Osteitis pubis Hernia recurrence Mesh irritation
Visceral factors	Cord irritation Ischemic orchitis

SUMMARY

The laparoscopic inguinal herniorrhaphy can be performed safely and with good outcomes. Advantages include smaller wounds, shorter convalescence, and the ability to assess both sides. Earlier in the learning curve, surgeons should be comfortable with TAPP prior to attempting TEP and have a low threshold for conversion to open. Most of the operation can be performed with blunt dissection (Table 3).

ACKNOWLEDGMENT

The author would like to thank the following people for their help with this chapter: Mike Rosen, Bruce Ramshaw, Michael Schweitzer, Thomas Magnuson, Mark Duncan, Fatima Khambaty, Jenny Hong, Josh Grimm, and James Harris.

Laparoscopic Repair of Recurrent Inguinal Hernias

Amir H. Fathi, MD, and Yuri W. Novitsky, MD

OVERVIEW

The first evidence of operative repair of a groin hernia dates to the first century AD. In the late 1880s, Bassini revolutionized the surgical repair of inguinal hernias with his novel anatomic dissection and low recurrence rates. However, in the 1990s, the tension-free Lichtenstein (anterior) mesh hernioplasty essentially became the operation of choice. Subsequently, technique modifications included the use of cone shape meshes "plugs" for groin hernia repairs. Recently, inguinal hernia repair has undergone another transformation with the advent of laparoscopic surgery. Two main laparoscopic (posterior) approaches have been described: totally extraperitoneal (TEP) and transabdominal preperitoneal (TAPP) repairs. Sixteen randomized, controlled trials and meta-analyses that compared laparoscopic and open techniques demonstrated that laparoscopic repair has a definite and likely beneficial role in modern surgery.

Beyond doubt, the traditional benefits of minimal access are pertinent for laparoscopic inguinal hernia repairs. It has been shown that the laparoscopic approach is associated with less postoperative pain, shorter hospital stays, decreased chronic pain, and increased patient satisfaction. The ultimate measure of success in hernia surgery is the rate of recurrence, regardless of the technique of repair. Although other procedure-related events are important and have been shown to affect health-related quality-of-life parameters, recurrence is one of the most difficult and frustrating issues facing both patients and surgeons. From the surgeon's perspective, repair of a recurrent inguinal hernia is technically more challenging because of prior mesh placement and scar tissue within dissected planes. For the patient, the initial physical and mental investment in the operation has failed, and subsequent operations carry fewer guarantees for success, more risks for serious complications, and the prospect of additional pain and recovery time. Currently, surgical repair of recurrent inguinal hernias account for 8% to 17% of more than 700,000 repairs performed each year in the United States. Although much has been published about primary repair of inguinal hernias, less is known about the best approach to address recurrent inguinal hernias.

INDICATIONS AND CHOICE OF THE REPAIR

The signs and symptoms of a recurrent inguinal hernia are usually similar to the initial herniation. However, only minimal pain and/or bulging is often present. Interestingly, most patients with recurrence are familiar with how their hernia "felt" the first time and will seek medical care if and when their symptoms recur. In fact, in our experience, most patients can even pinpoint the time their recurrence began to develop.

One of the important considerations in evaluating for a recurrent inguinal hernia is a missed femoral hernia, especially in women. In 2005, a large prospective analysis of inguinal hernia repair data from the Swedish Hernia registry showed at the time of reoperation, more than 40% of women previously reported to have inguinal hernias were found to have femoral defects. We found that patients with misdiagnosed femoral hernias will often report persistent discomfort and even bulging following the original operation. High index of suspicion, especially in elderly females, is mandatory to avoid missing a femoral defect when an anterior approach is undertaken.

The choice of repair of a recurrent inguinal hernia depends on a number of patient factors; however, the technique of the original operation is largely the main determinant of the surgical approach to be chosen (Figure 1). Initial repairs can consist of primary (no mesh) tissue-based repairs, such as Bassini, McVay, or Shouldice repairs. If a mesh was used, the plane of mesh placement as well as the type/shape of a prosthetic varies greatly. Primary anterior mesh repair, such as Lichtenstein, employs a flat mesh placed ventral to the floor of the inguinal canal. Posterior repairs, including retromuscular Stoppa and Kugel repairs, as well as the traditional laparoscopic repairs, involve a prosthetic placed dorsal to the floor of the inguinal canal. Finally, repairs with plugs or two-layered meshes (such as the Prolene Hernia System; Ethicon, Inc., Cincinnati, Ohio) violate both anterior and posterior planes, and failures of those repairs may present additional challenges for subsequent herniorrhaphies.

A vigilant review of previous operative reports is paramount in guiding the ensuing repair technique. In addition to patient factors, the choice of the procedure should be adjusted according to the surgeon's personal experience and the degree of laparoscopic skill/expertise. In certain cases, however, a referral to a more experienced surgeon may be warranted to minimize performing a necessary but less familiar operation. Multiple recurrent inguinal hernias with failed both anterior and posterior repairs represent a very formidable challenge, even in experienced hands.

Although we favor the laparoscopic approach to patients with failed open tissue–based repairs, either open anterior or open posterior approach is quite acceptable. However, if the initial anterior repair involved mesh placement, we recommend favoring an approach

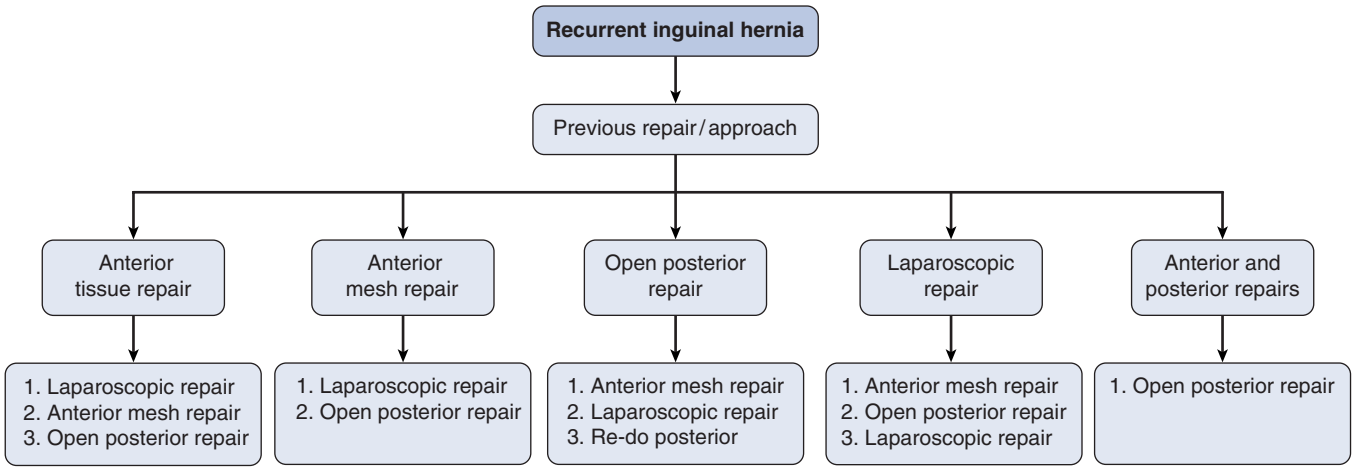

FIGURE 1 Recurrent inguinal hernia surgical repair/approach.

utilizing the space in which the tissue planes have not been violated previously (see Figure 1). A posterior approach including laparoscopic techniques is clearly the best choice after failed anterior repair. In our practice we utilize laparoscopy for failed anterior repairs in all cases except for patients with significant scrotal herniations and those with previous abdominopelvic procedures. The latter group is better served by an open posterior retromuscular or preperitoneal Stoppa repair.

Laparoscopic Repair of Recurrent Inguinal Hernias

Laparoscopic inguinal hernia repair affords the benefit of a panoramic view of the entire myopectineal orifice of Fruchaud. Therefore, all the potential hernia spaces, such as direct and indirect inguinal, femoral, and obturator defects, can be diligently evaluated. The laparoscopic approach for recurrent inguinal hernias after anterior repairs not only provides the technical advantage of operating through unscarred tissue but still carries the added advantages of a minimally invasive procedure. Without a doubt, failed anterior repairs are best approached laparoscopically. We strongly believe that those patients should be referred to centers where laparoscopic expertise is available.

The laparoscopic approach to failed laparoscopic repairs represents a significant technical challenge. In select cases, previously placed mesh may have been undersized or may have shrunk, making a redo laparoscopic repair fairly routine. However, the majority of those patients have extensive scarring of the preperitoneal plane, with the old mesh creating a major impediment to the dissection. Only surgeons with significant expertise in laparoscopy and laparoscopic inguinal hernia repairs should attempt to redo laparoscopic/posterior failures laparoscopically.

TEP Versus TAPP

There is a paucity of reliable data comparing TAPP and TEP, with no prospective randomized trials investigating repair efficacy. Recently, Bittner and colleagues published guidelines for TAPP and TEP repairs of inguinal hernia based on the Cochrane database review. They concluded that there was no statistically significant difference regarding postoperative complications, recurrence rates, and chronic groin pain. We have adopted TAPP as our approach of choice for both routine and recurrent inguinal hernias. We found that our approach allows for a reliable and reproducible dissection of the entire myopectineal orifice and allows for identification of both ipsilateral and contralateral herniations. In addition, surgeons who prefer the TEP approach must still be versed in TAPP to minimize the need for open conversions in cases of significant peritoneal tears.

Operative Considerations

As mentioned above, careful review of the antecedent operative report is of utmost importance, especially in cases of recurrence and associated groin pain. Review of the size, type, and shape of the mesh used, as well as the fixation method employed, is paramount for successful operative planning. If significant discomfort is present, we plan for the old mesh removal during reoperation. Preoperative counseling should include discussion of risks of visceral injuries, bleeding, vas deferens injury, chronic groin pain, and recurrence.

The patient is positioned supine with both arms tucked in the adducted position. The patient should be prepped widely to include the entire abdomen and both groin regions to midthigh. In contrast to our standard laparoscopic approach for initial inguinal hernias, patients with recurrent hernias routinely have a urinary catheter placed. This not only facilitates identification of the bladder by allowing for its distention (if necessary) but also allows for prompt identification of an inadvertent bladder injury during Cooper ligament dissection.

Once safe access to the peritoneal cavity is obtained, we perform a diagnostic laparoscopy to confirm the diagnosis. It is important to point out that the mechanism of recurrence varies depending on the original choice of the repair. Anterior repairs usually fail medially, and posterior recurrences usually occur inferiorly. At times, laparoscopic repairs fail because of inadequately sized mesh or cases of significant prosthetic migration or shrinkage. In those circumstances, the recurrence pattern may mimic the anterior failures.

We initiate our dissection just below the arcuate line. A preperitoneal plane is entered. We try to avoid dissecting in the pretransversalis fascia plane to minimize bleeding from the inferior epigastric vessels and easier dissection of the Cooper's ligament and myopectineal orifice. In cases of failed posterior or plug repairs, previous prosthetic may significantly complicate this dissection. In addition, those meshes often encase the inferior epigastric vessels. In those circumstances, we tend to control inferior epigastric vessels with clips both proximal and distal to the mesh to minimize bleeding. In addition, the meshes in these instances may extend very close to the iliac vessels, and thorough knowledge and understanding of anatomy are critical to avoid major vascular injuries. Similarly, the vas deferens may be closely adherent to the mesh and may need to be sacrificed during this dissection. Furthermore, a portion of the old

mesh could be left behind if its dissection from the iliac vessels is difficult and/or deemed too risky.

Subsequent dissection is carried out to expose the inferior aspect of the myopectineal orifice and distal 2 to 3 cm of the psoas muscle. This extent is necessary to prevent recurrences along the inferior edge of the mesh due to inadequate mesh coverage. Once again, thorough knowledge of anatomic landmarks is critical to avoid neurovascular injuries.

Once the mesh is placed, we utilize tackers to fixate the mesh at Cooper's ligament as well as anterior-medially and anterior-laterally. No tacks are placed below the inguinal ligament or near any areas of neurovascular structures. We favor absorbable tacks, although there is no solid scientific evidence that supports such practice. Often, fibrin glue is used to fixate the inferior aspect of the mesh. Finally, the peritoneum is reclosed with tacks. In cases of significant peritoneal tears due to a difficult dissection or removal of the old mesh, we advocate the use of coated meshes with an antiadhesion barrier while leaving the peritoneal flap open. This approach will minimize the risks of intestinal obstruction in a peritoneal fenestration or avoid bowel exposure to the uncoated synthetic mesh. We advocate against the use of biologic or bioabsorbable meshes during laparoscopic repair of recurrent inguinal hernias.

OUTCOMES

To date, contrary to primary inguinal hernias, there is no ample body of literature comparing laparoscopic approaches to open techniques for recurrent inguinal hernias. The results from large randomized studies have demonstrated that the Lichtenstein repair carries a low recurrence rate. However, a number of meta-analyses that have compared laparoscopic and open hernioplasty techniques have indicated that patients undergoing laparoscopic hernia repair experience less pain in the early postoperative period, have lower analgesic and narcotic requirements, return to their normal activities sooner, and have better cosmetic outcomes (Table 1). Eklund and colleagues from the Swedish Multicenter Trial of Inguinal Hernia Repair by Laparoscopy (SMIL) published a randomized trial and compared TAPP and

TABLE 1: Studies comparing open to laparoscopic recurrent inguinal hernia repair

First author	Type of repair	Type of study	Number of points	Findings

Lichtenstein repairs for recurrent inguinal hernias. They concluded that the short-term advantage for patients undergoing laparoscopic technique is less postoperative pain and shorter convalescence. In the long term, no differences were observed in the chronic pain or recurrence rate. In a recent prospective randomized trial, Sanna and colleagues showed the TEP technique to be superior to the Lichtenstein hernioplasty in treating recurrent inguinal hernias with regards to chronic pain, impaired sensibility in the inguinal region, and accelerated return to normal activity. However, it is important to point out that in our experience, the laparoscopic approach to failed posterior repairs is usually associated with prolonged dissection as well as frequent peritoneal tears. As a result, the major benefit of laparoscopy with regards to decreased pain and fast recovery is typically lost or minimized.

With recent advances in surgical techniques and equipment, increasing numbers of surgeons are using laparoscopic procedures for the management of recurrent inguinal hernias. However, the cost-effectiveness, patient satisfaction, and recurrence rates associated with laparoscopic repair are currently under investigation at our institution.

Laparoscopic Ventral Hernia Repair

Michael J. Rosen, MD, FACS

INTRODUCTION

Ventral hernia repair is one of the most common procedures performed by general surgeons. Ventral hernias can be defined as primary or acquired. Primary hernias include epigastric, umbilical, spigelian (lateral), and rare hypogastric hernias. Acquired hernias can occur after traumatic events but most commonly are related to a prior surgical incision. The incidence rate of incisional hernia formation after a midline laparotomy is estimated at 10% to 20%, depending on the patient population at risk. With almost 2 million laparotomies performed annually, somewhere between 100,000 and 200,000 ventral hernia repairs are performed annually in the United States. Despite the prevalence of this disease, no universally accepted classification system exists. As a result, there is a wide spectrum of patients that development of ventral hernias, and significant variability is found in the complexity of ventral hernia defects. This spectrum includes those patients with small asymptomatic defects up to patients with massive hernias, loss of domain, and concomitant contamination present during repair. As a result of this diversity, no single repair technique is likely to take care of all patients with ventral hernias. Therefore, surgeons repairing abdominal wall defects should be familiar with both laparoscopic and open approaches to ventral hernias to offer the patient the most appropriate repair technique on the basis of unique patient factors and hernia defect characteristics (Table 1).

The laparoscopic approach to ventral/incisional hernia repair has gained widespread acceptance by the surgical community as a safe and effective approach. It borrows from the principles of abdominal wall reconstruction espoused by Rives and Stoppa of placement of a large sublay prosthetic deep to the hernia defect to provide wide coverage. Unlike the open counterpart, the laparoscopic approach requires the mesh to be placed within the peritoneal cavity. This mandates the use of appropriate tissue-separating prosthetics with a visceral side that prevents bowel ingrowth and an abdominal side that promotes tissue integration. The prosthetic should be fixed with full-thickness transfascial fixation sutures and spiral tacks. Given the absence of subcutaneous soft tissue dissection, a predictably lower rate of wound and mesh infections is seen, which is a major advantage of the laparoscopic approach. The laparoscopic repair also allows for full visualization of the entire anterior abdominal wall to avoid missing small Swiss cheese–type defects.

INDICATIONS

The natural history of an asymptomatic ventral/incisional hernia is largely unknown. Because surgical teaching has always suggested that these hernias pose significant risk for bowel incarceration or strangulation, most surgeons advocate repair on diagnosis of an incisional hernia. No large cohort of patients who have undergone nonoperative management is available, so the natural history remains largely unknown. However, given the increases in intraabdominal pressures with activities of daily living, a ventral hernia tends to grow over time, which makes repair increasing difficult once the hernias become very large. Incisional hernias can also result in unsightly bulges that impact quality of life. In addition, the thin skin overlying a large hernia can become ischemic, ulcerate, and even result in an ascitic leak. The three general indications for operation are: (1) a hernia that is symptomatic and causes pain, discomfort, surrounding cutaneous ulcerations, or changes in bowel habits; (2) a hernia that results in an unsightly bulge and affects the patient's quality of life; and (3) a hernia that poses a significant risk of bowel obstruction (e.g., a large hernia with a narrow neck). In consideration of operative intervention, an individualized approach is important, with patient comorbidities, defect characteristics, and the presence of contamination taken into account. Because a wide spectrum of patients develop a variety of hernias, one single technique is not able to address all patients. Few absolute contraindications are found for a laparoscopic ventral hernia repair, other than inability to tolerate general anesthesia or the presence of active contamination. However, several relative contraindications deserve mention. The ability to perform safe adhesiolysis is paramount to a successful laparoscopic ventral hernia repair; therefore, patients at risk for severe adhesions should likely not undergo a laparoscopic approach. Examples include patients

PTFE, Polytetrafluoroethylene.

with multiple reoperative abdomens, in particular with multiple intraperitoneal prosthetic meshes. Patients who have undergone prior intraperitoneal dialysis are at high risk for an obliterated peritoneal cavity. Patients with massive defects and loss of domain can be successfully completed laparoscopically but an advanced laparoscopic skill set is needed, which generally involves multiple pieces of mesh sewn together and a poor functional and cosmetic result. Patients with excessive scars that need revision should undergo an open repair. Patients with inflammatory bowel disease, in particular, Crohn's disease, should likely not have intraperitoneal mesh placed given the likelihood of reoperations and potential fistulas. Patients with larger defects of more than 10 to 12 cm in width are better served with an open formal abdominal wall reconstruction. The ideal candidate for a laparoscopic ventral hernia repair is an obese or elderly patient with a small to medium-sized defect. Thin, active, manual laborer patients are offered a formal abdominal wall reconstruction either laparoscopically with defect closure as described subsequently or open.

PREOPERATIVE WORKUP

A complete history and physical examination is important in ventral hernia cases. These patients often have significant comorbidities, and consideration of optimizing preoperative glucose control, nutritional parameters, smoking cessation, and weight reduction is key to a successful outcome. In addition, particular attention should be paid to the anterior abdominal wall skin for ulcerations or nonhealing wounds that might preclude a laparoscopic approach. Incarcerated hernias that cannot be reduced can be difficult laparoscopically and should be discerned before surgery. Locations of all prior surgical incisions are noted, and all prior operative reports are reviewed. Important information as to the type and location of prior prosthetic mesh and the history of upper quadrant surgery that could alter the initial access port is critical. A computed tomographic (CT) scan of the abdomen is performed in all but the smallest hernias in the author's practice. This image can provide valuable information as to the size of the defect, the contents of the hernia sac, the presence of occult hernias that might not be palpable in an obese patient, and the presence of prior synthetic mesh. In addition, the integrity of the rectus muscles and lateral abdominal wall musculature can be assessed for reconstructive options. Preoperative counseling is also important for patients undergoing laparoscopic ventral hernia repair. Despite the minimally invasive nature of laparoscopic ventral hernia repair, postoperative pain is often similar to the open procedure. Because the hernia sac is often not excised, a postoperative seroma is almost universally present and the patient should be aware. The possibility of an enterotomy and the appropriate management, including the need to convert to an open procedure, should be clarified.

OPERATIVE TECHNIQUE

Patient Positioning

For patients with midline incisional hernias, patients are placed in the supine position with their arms tucked to the sides. Having the arms tucked facilitates the surgeon standing on the same side of the table as the camera operator (Figure 1). An iodine-impregnated adhesive drape is applied to the skin to protect the mesh from skin flora and facilitate marking the patient during mesh placement. A first generation cephalosporin is given, orogastric tube is placed, and a three-way Foley catheter is placed for any defect below the umbilicus to aid in identification of the bladder during dissection. Pneumatic compression devices are applied, and subcutaneous heparin is administered before surgery.

Access of the Reoperative Abdomen and Trocar Positioning

Gaining access to the reoperative abdomen can be the most treacherous step of a laparoscopic ventral hernia repair. Typically, the upper quadrants are free of adhesions, and the tip of the 11th rib provides a good access point. Attention to prior surgical incisions and intraabdominal procedures can provide clues as to the most appropriate side. For instance, patients who have had their splenic flexure mobilized should be approached through the right upper quadrant. Several methods have been described for access, including an open cut down approach, utilization of optical viewing trocars, and the use of a Veress needle. In skilled hands, each of these approaches is safe and effective and can be used. In general, this access point should be

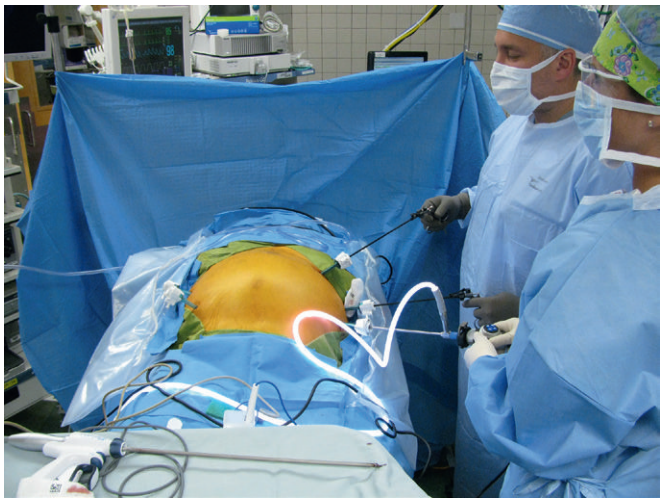

FIGURE 1 Intraoperative view of surgeon and camera operator standing on the same side of patient for adhesiolysis. Patient's arms are abducted and an iodine impregnated drape covers the abdomen.

as far lateral as possible to avoid being covered during mesh placement. Once the abdomen is accessed and insufflated, two additional 5-mm ports are placed ipsilateral to this trocar. This facilitates two-handed technique during adhesiolysis and avoids working in reverse to the camera during dissection. Once the adhesions are completely lysed, at least 1 or 2 additional 5-mm ports are placed on the contralateral side to position and secure the mesh. A 5-mm 30-degree laparoscope is helpful to allow placement through any of the trocars during adhesiolysis, and the angled scope provides superior vision around adhesions and up to the anterior abdominal wall.

Adhesiolysis

The most dangerous part of a laparoscopic ventral hernia repair is safe adhesiolysis. This can be the most time-consuming portion of the case and requires patience and meticulous technique. In general, no electrocautery should be used during adhesiolysis. In particular, vessel-sealing devices such as the ultrasonic dissector or Ligasure (Covidien, Boulder, Colo) should be avoided because they can create a sealed full-thickness injury to the bowel wall that does not leak for several days. If bleeding occurs, liberal use of 5-mm clips is warranted, or the surgeon should convert to an open approach. If prior intraperitoneal mesh is present, avoid blunt sweeping movements because the bowel will likely give way before the mesh. In cases in which the mesh is densely adherent to the intestines, the surgeon can perform a small incision and complete the adhesiolysis open and place the mesh laparoscopically, or rarely remove the mesh off the abdominal wall and leave some adherent to the bowel if no obstruction or fistula was present before surgery. In cases of serve adhesions to mesh, an open bowel resection can be necessary. In obese patients with incarcerated hernias, bimanual palpation of the abdominal wall can help identify the dissection plane during adhesiolysis. It is imperative to clear the entire anterior abdominal wall of adhesions all the way to the pericolic gutters. This avoids missing occult Swiss cheese–type defects and allows a large prosthetic mesh to be placed. Hernias above the umbilicus often require division of the falciform ligament to adequately adhere the mesh to the abdominal wall.

Sizing the Hernia Defect

An accurate measurement of the hernia defect is critical to appropriately size the mesh for adequate overlap and position the mesh for

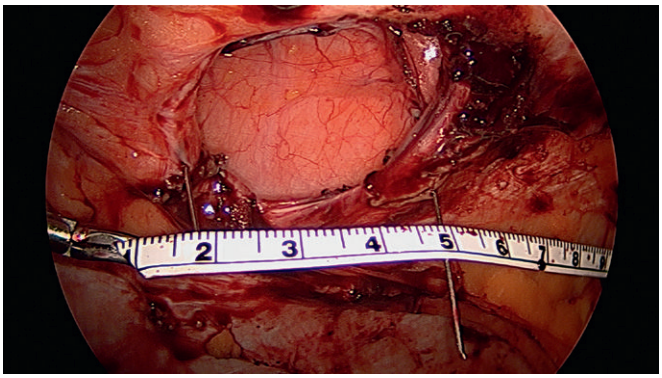

FIGURE 2 Intraperitoneal view of spinal needles placed at the edge of the defect and measured with a 15-cm plastic ruler.

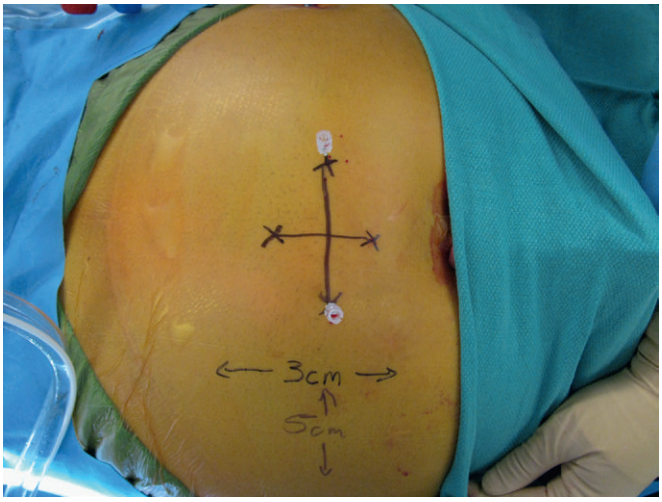

FIGURE 3 External lines mark maximal width and length of hernia defect measured internally with spinal needles.

maximal coverage of the defect. Oversizing of the mesh can result in significant technical challenges in accurate positioning of the prosthetic without buckling. In obese patients, external palpation of the hernia defects can be difficult and inaccurate. The author prefers to use a 3.5-inch, 20-gauge spinal needle to appropriate localize the hernia defect. Intracorporeal measurement of the defect is important because that is the location of the mesh. In obese patients with excessive subcutaneous tissue, a significant discrepancy between internal and external measurement can result in oversizing the hernia defect.

Two spinal needles are placed at the cranial and caudal limits of the hernia (Figure 2). In Swiss cheese defects, the maximal distance is used. A 15-cm plastic ruler is placed intracorporeally, and the distance between the spinal needles is recorded. The location of the spinal needles is also marked externally with a line. Next, the maximal width of the hernia defect is localized with spinal needles and measured internally and marked externally (Figure 3). Once the maximal width and length are calculated, 8 cm (4 cm of overlap on each side) is added to appropriately size the prosthetic material. Multiple different prosthetics are available for intraperitoneal placement. However, the author does advocate use of a tissue-separating mesh of some type.

Because all hernias are not perfect circles, identification of the center of the hernia is important to adequately center the mesh. The center point of the hernia can be identified externally. The surgeon measures the distance of the prior lines marked on the patient that indicate the length of the hernia. A transverse line is drawn across

the patient at this point to indicate the x axis. Next, the middle of the line marking the maximal width of the hernia is measured, and a longitudinal line is drawn across the patient's abdomen to indicate the y axis. Where these two lines intersect is the center point of the hernia (Figure 4). In preparation of the mesh, the prosthetic is folded in half lengthwise, and a line is drawn, and in half along the width as well. Transfascial sutures are secured to the mesh at the edge of each of these lines. If done correctly, these sutures are retrieved on the labeled x axis and y axis on the patient to appropriately center the mesh (Figure 5).

Mesh Positioning

The four cardinal sutures are tucked into the mesh, and it is rolled tightly to fit through a trocar. Larger sheets of mesh sometimes require removal of the trocar. This can be facilitated by passing a 5-mm grasper across the abdomen, out the larger trocar; the trocar is removed, and the mesh is grasped and pulled into the abdomen.

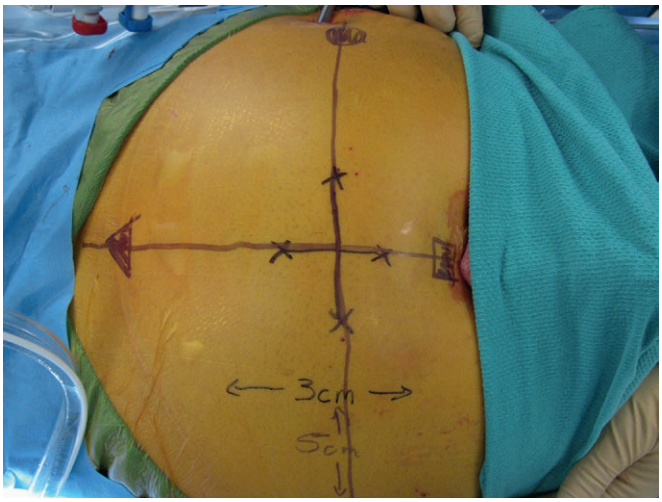

FIGURE 4 Center point of the lines marked externally is measured, which correlates to the center point of the hernia defect.

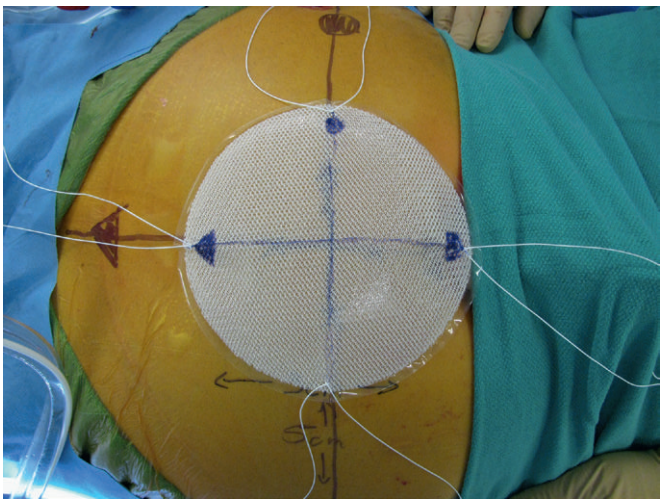

FIGURE 5 Center point of the mesh is identified, and four transfascial sutures are placed on these lines that correlate with the external center point lines previously measured.

Once inside the abdomen, the mesh is unfurled and the sutures are identified.

The initial cardinal suture should be brought up at the site with the least amount of potential coverage. This might be near the xiphoid or above the pubis. Regardless of how the mesh is measured, some excess mesh is common; to keep the mesh taut, more overlap might be necessary. The area at the edge of the hernia defect is localized on the prior y axis line drawn on the patient with a spinal needle. With a grasper used for measurements, the next spinal needle is placed on the y axis line 4 cm past the original spinal needle (Figure 6). A small incision is made, and a suture passer is used to retrieve each tail through separate fascial punctures. These sutures are tagged and left untied.

The lateral suture furthest from the camera is retrieved next. Again, a spinal needle is placed at the edge of the hernia defect on the prior externally marked x axis. With use of a grasper, 4 cm is measured, and another spinal needle is placed. Another stab incision is made, and the two tails are retrieved (Figure 7). In laparoscopic ventral hernia repair, the mesh is placed under insufflation, and it is important to be taut. If the mesh is not taut, the prosthetic buckles once the abdomen is desufflated and prolapses into the hernia sac. To avoid this problem, the two sutures that were placed before are pulled tightly by an assistant, while the surgeon grasps the mesh with a Maryland grasper near the remaining longitudinal knot and pulls

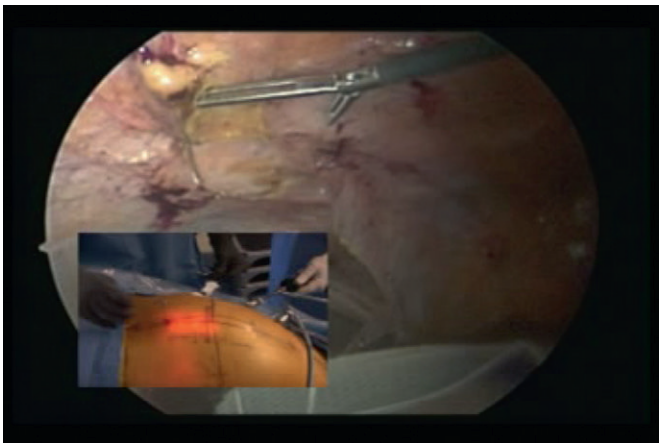

FIGURE 6 A spinal needle is placed at the edge of the defect on the external center line, and a 4-cm grasper is used to measure the overlap of the mesh and marked with another spinal needle. The skin is incised, and the transfascial suture retrieved at this site.

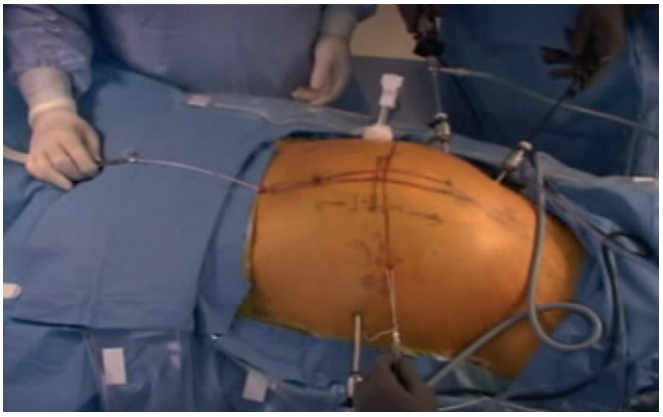

FIGURE 7 Cephalad and lateral suture retrieved through prior center point lines drawn externally on patient's abdomen.

the mesh along the externally marked y axis. Once the mesh is taut, the point on the y axis is marked with a spinal needle. A skin incision is made, and the tails are retrieved. The three sutures are then secured. The final transfascial suture is then pulled taut, the point on the x axis is identified with a spinal needle, and the tails are retrieved. The four sutures are secured, and the mesh is then secured to the remainder of the peritoneum with a tacking device (Figure 8). Multiple varieties of tacking devices are available, of both a permanent and an absorbable variety. No data are found to suggest the superiority of one tacking device over another at this time. These tacks do not provide strength to the repair. However, they do prevent bowel from slipping above the mesh for the first few weeks until the mesh is reperitonealized. The integrity of the repair is maintained by the transfascial sutures. The exact number of transfascial sutures required for a durable repair is unknown. The author uses an individualized approach. In patients with small defects or Swiss cheese–type defects, a large mesh with four sutures is sufficient. However, in obese patients, or those with large defects, 12 transfascial sutures are typically used. All ports over 5-mm should have the fascia closed particularly in hernia cases.

POSTOPERATIVE CARE

In highly selected cases, laparoscopic ventral hernia repair can be performed on an outpatient basis. However, postoperative discomfort can be significant, and most patients benefit from at least overnight observation and a patient-controlled analgesic device. Routine administration of ketorolac or muscle relaxants can also be helpful. Patients who need extensive adhesiolysis are kept on nothing by mouth (NPO) status until flatus. Routine hospital admission can also aid in detection of a missed enterotomy. This can be a life-threatening complication if diagnosis is delayed. Although radiographic evaluation can occasionally be helpful in the early postoperative period, if unexplained tachycardia or signs of sepsis persist, the patient should return to the operating room for a diagnostic laparoscopy.

SPECIAL CIRCUMSTANCES

Subxiphoid Hernia

Subxiphoid hernias are common after median sternotomies. They present particular challenges because the close proximity of body structures (ribs, costal margin) and major vascular structures (heart, aorta) can limit mesh fixation options. The procedure is carried out similar to a standard laparoscopic ventral hernia repair, although the falciform ligament must be taken down completely. The defect is measured as previously described, and the mesh is sized appropriately. However, the most cranial suture is backed off at least 4 to 5 cm from the edge of the mesh. This suture can be retrieved at the xiphoid process, and the mesh is allowed to drape over the diaphragm and pericardium. To prevent buckling, the mesh can be fixated to the diaphragm with fibrin sealant. Tacking devices should not be used above the costal margin or xiphoid process to avoid injury to the pericardium.

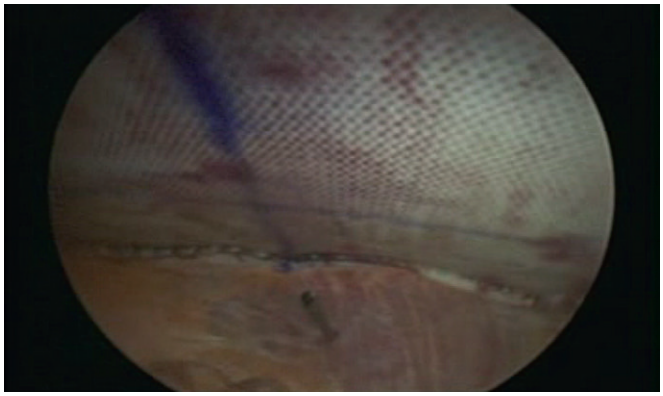

FIGURE 8 Final view of mesh taut across the abdominal cavity with tacks and transfascial sutures in place.

Suprapubic Hernia

Suprapubic hernias pose challenges in obtaining adequate overlap while avoiding the bladder and major neurovascular structures. In reoperative cases, accurate identification of the superior extent of the bladder can be difficult. To facilitate identification, a three-way Foley catheter is helpful. After fully mobilizing the intraabdominal adhesions, the Foley catheter is clamped and 300 mL of normal saline solution is instilled through the irrigation port. With the bladder clearly visible, it is mobilized to expose the pubis and space of Retzius. The inferior sutures are backed off the edge of the mesh for several centimeters. These sutures can be retrieved at the pubis or Cooper's ligament, and the tail of the mesh can be tucked into the space of Retzius to maximize overlap. With placement of tacks to secure the periphery of the mesh, the tip of the tacker must be palpated externally. Like a laparoscopic inguinal hernia repair, if the tacker is below the iliopubic tract, major vascular and neurologic injuries can occur.

Defect Closure

With renewed interest in creation of a functional dynamic abdominal wall, some surgeons advocate closure of defects laparoscopically. The theoretic advantage of closing the defect is that it restores the abdominal wall integrity, may equalize pressure across the abdominal wall and mesh, reduces seroma rates, and might refunctionalize the abdominal wall. Several techniques have been described. The basic approach involves the use of a suture passing device, placed through a small stab incision over the hernia defect. A suture is brought into the abdomen through one side of the fascia, and the device is then placed through the opposite fascia and the suture retrieved through the same skin incision. This can be repeated to form a figure of 8 suture. This is the same technique used to close laparoscopic port sites. Once these sutures are placed, they can be tied, and the mesh is secured in a similar fashion. The mesh must be sized as if the defect were open, so if the midline repair were to break down, the hernia would not recur. Although this approach has an intuitive advantage, no comparative data at this time suggest it results in a superior outcome to a standard laparoscopic ventral hernia repair. In addition, it should be limited to defects less than 8 to 10 cm in maximal width because excessive tension can result.

COMPLICATIONS

Nearly all patients who undergo laparoscopic ventral hernia repair have development of a seroma. These seromas are mostly clinically insignificant and resolve without interventions. Patients must be counseled as to the likelihood of having an early persistent bulge, so as to avoid confusing it with a recurrence. Indications for aspiration are limited and include significant symptoms, impending skin ischemia, and failure to resolve after 6 months. The risk of contaminating the mesh must be weighed against the advantage of removing the fluid.

An enterotomy during laparoscopic ventral hernia repair is a serious potentially life-threatening complication if not dealt with appropriately. No steadfast rule exists for management of an enterotomy during laparoscopic ventral hernia repair, but some basic

surgery principles can be applied. Most importantly, this complication must be recognized when it occurs. If surgeons identify an enterotomy, they must realize that this has the potential to be life threatening. Although several authors have described unique approaches to laparoscopic repair of the enterotomy and fixing the hernia with a biologic graft, or returning to the operating room in 3 to 5 days, this approach is not advocated by the author's group. Instead, if this complication occurs, at a minimum, the segment of bowel is exteriorized through a small incision and adequate repair is confirmed. At that time, the hernia can be left alone, with a return several months later for another attempt at repair. Alternatively, the procedure can be converted to open, with either primary closure of the defect or use of a biologic mesh to repair the hernia. Regardless of which approach is chosen, one should not let being a minimally invasive surgeon get in the way of the right operation for the patient. All patients should clearly understand what will happen if an enterotomy is encountered and that they may wake up with their hernia.

Unlike most laparoscopic procedures, laparoscopic ventral hernia can result in significant postoperative discomfort. The exact etiology of postoperative discomfort is likely multifactorial and includes peritoneal irritation from tacks, mesh, and transfascial sutures. Persistent pain beyond 6 weeks is rare and is often related to a transfascial sutures. These can be successfully managed with percutaneous injection of 30 mL of bupivacaine in most cases. Rarely, the offending suture must be removed.

The major advantage of a laparoscopic ventral hernia repair is that mesh infections are extremely rare. In fact, if the surgeon suspects a mesh infection after a laparoscopic ventral hernia repair, serious consideration should be given to an unrecognized bowel injury. Occasionally, laparoscopic mesh can become contaminated with skin flora during introduction into the abdomen. These patients present with erythema overlying the seroma cavity. The seroma should be aspirated and cultured. Rare cases of mesh salvage with percutaneous drainage, antibiotic irrigation, and lifetime suppression with antibiotics have been described. However, most patients need excision of the mesh and reconstruction.

OUTCOMES

Laparoscopic ventral hernia repair has gained widespread acceptance. Several prospective randomized trials have shown the safety and efficacy of laparoscopic ventral hernia repair when compared with open ventral hernia repair. The one common finding of all series is a significant reduction in wound-related morbidity associated with the laparoscopic repair. Most of these series have included a highly selected group of patients with relatively small defects, and whether the laparoscopic approach is appropriate for larger more complex hernias is unclear. In summary, the laparoscopic repair of ventral hernias is a valuable approach for the repair of abdominal wall defects. In skilled hands, performed appropriately with safe adhesiolysis and adequate mesh placement, excellent long-term results are possible.

Laparoscopic Repair of Peristomal Hernias

David E. Beck, MD, FACS, FASCRS

BACKGROUND

Approximately 100,000 enterostomies are created each year, with an estimated 40% being permanent. The artificial defect created in the abdominal wall fascia produces a weakness that contributes to hernia formation. Previous experience suggests that some degree of herniation around stomas is inevitable. However, little prospective data are available. Factors thought to contribute to hernia formation include age, chronic obstructive pulmonary disease, obesity, malnutrition, steroid use, malignancy, infection, and emergency surgery.

Most hernias occur within the first 2 years following stomal creation, but the risk of herniation continues throughout the life of the patient. Previous results of parastomal hernia repair have been unsatisfactory, and many providers avoid repairs until complications occur.

INDICATIONS AND CONTRAINDICATIONS

Indications for repair include bowel obstruction, incarceration, or enlargement of the hernia to the point where it interferes with appliance wear or the hernia is unsightly. Laparoscopic repair is suitable when the patient's stoma is appropriately sited, the patient lacks a history of extensive adhesions, and the hernia is not too large. Excessive large peristomal hernias are often more appropriately repaired with an open technique. Obtaining good results with underlay mesh usually requires a mesh with at least a 3-cm to 5-cm overlap of the mesh beyond the edges of the hernia. This is difficult to accomplish laparoscopically with large hernias. Another relative contraindication is the need for an associated open procedure. Both ileostomies and colostomies are suitable for laparoscopic procedures, and several techniques of repair have been described. These include various underlay techniques. One type of repair is similar to an open technique described by Sugarbaker in 1980. A second option is a "keyhole" technique of mesh placement. Other variations also include primary closure of the hernia defect with mesh reinforcement or repair with mesh alone.

PREOPERATIVE PLANNING

Preoperative Preparation

Standard bowel preparation is not mandatory. However, because the empty colon handles better than a stool-filled colon, it is the author's preference to have patients who can tolerate a preparation ingest a limited isotonic lavage prep (e.g., one fourth to one half gallon of a polyethylene glycol solution). Patients are instructed to take only clear liquids the day prior to surgery. Oral antibiotics are not prescribed, but standard intravenous broad-spectrum antibiotics are given within 1 hour of skin incision. Deep-vein prophylaxis is also ordered. Informed consent should include the potential for conversion to an open procedure.

SURGERY

Patient Positioning and Preparation

After induction of general anesthesia, an orogastric tube and indwelling urinary bladder catheter are placed. The patient is then placed in modified lithotomy position with the thighs even with the hips and pressure points appropriately padded. One or both arms may be tucked to facilitate securing the patient for the extremes of positioning used during laparoscopy. If only one arm is tucked, it should be on the side opposite the side of the hernia and stoma. The patient is then secured to the table, usually with tape. If one or both arms are kept out, the tape is placed in a "cross your heart" manner. The skin is prepped with antiseptic solution, and draping is done in a fashion to provide for lateral exposure for ports, especially on the side opposite the hernia and stoma. One author has suggested covering the abdominal wall with an adhesive drape to limit potential contamination of the mesh.

Instrument/Monitor Positioning

The primary surgeon will usually stand on the patient's side opposite the stoma or between the patient's legs (Figure 1). The primary monitor is placed on the patient's side that contains the stoma near the level of the patient's hip. A secondary monitor can be placed at the patient's shoulder or at an alternate site viewable by the assistant or surgical technician. Insufflation tubing, suction tubing, cautery power cord, laparoscopy camera wiring, and a laparoscope light cord are brought off the patient's side. A 10-mm laparoscope with a 30-degree lens is preferred.

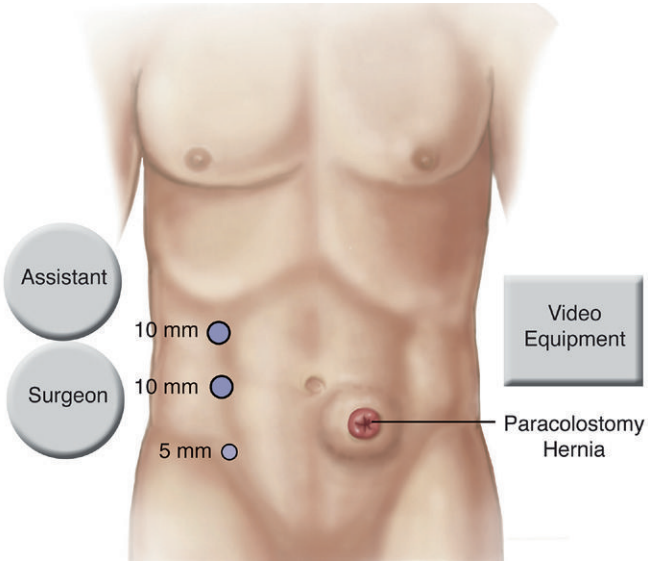

FIGURE 1 Positioning and port placement for laparoscopic assisted colostomy.

Port Selection and Placement

A 10/11-mm port with a balloon is placed using an open (modified Hasson) technique in the lateral abdomen on the side opposite the ostomy and hernia. A vertical skin incision with a scalpel is followed by dissection down to the fascia. If a balloon trocar is not used, a purse-string of 2-0 polyglycolic acid suture is placed, and the fascia is incised inside this suture. Muscles are split, and the peritoneum is opened sharply. Once entry into the peritoneal cavity is obtained, a 10/11 trocar is inserted, and the purse-string is tightened. Laparoscopic inspection of the peritoneal cavity rules out unsuspected pathology and identifies the patient with dense extensive adhesions that would make a laparoscopic approach problematic. If the abdomen is suitable, additional ports are placed under laparoscopic visualization at the locations described in Figure 1. Unless a quality 5-mm camera and mesh fixation device (tacker) are available, one of the other ports needs to be at least 10 mm in diameter. The remaining ports can be 5-mm trocars. The exact location will vary depending on adhesions and the location and size of the hernia. In general they are placed a hand's width apart and on the side of the abdomen opposite the hernia (see Figure 1, left-sided stoma). If the stoma is located on the right side of the abdomen, the trocar placement locations are reversed.

OPERATIVE TECHNIQUE

Division of Adhesions and Reduction of Hernia

Adhesions to the anterior abdominal wall are divided with sharp dissection and traction. This can often be tedious and has the potential for bowel injury. This is especially true if previous repairs have used mesh. Extensive dense adhesions may require conversion to an open technique. Bowel loops are gently reduced from the hernia using traction and careful division of adhesions. Alternate energy sources, such as Enseal (Ethicon Endosurgery, Cincinnati, Ohio), may be helpful for some vascular adhesions, but they are not a substitute for careful dissection. When all of the bowel has been reduced, the bowel leading to the stoma will remain. The peritoneal sac is left in place. The underlay techniques require that the bowel have adequate laxity to allow the bowel to track between the mesh and the abdominal wall. Reduction of the hernia will usually provide adequate laxity. If that does not, additional mobilization of the bowel may be necessary to allow adequate lateralization of the bowel. The ostomy bowel is pulled intra-abdominally to reduce any prolapse. The ostomy bowel is then pulled to the lateral or superior edge of the hernia defect. Some surgeons will then suture the ostomy bowel serosa to the peritoneum with absorbable sutures at the edge of the defect. The abdominal wall is also inspected for additional hernias that need repair.

A piece of mesh is selected that will cover the hernia defect with a 5-cm overlap. It is often helpful to compare the mesh on the abdominal wall, but to minimize the risk of contamination, the mesh should not touch the stoma itself, and contact with the skin should be avoided. Several types of mesh have been used, including nonabsorbable, absorbable, partly absorbable, and acellular collagen matrix meshes. Early authors used a polypropylene mesh. Subsequently, composite meshes were used, and more recent authors have expressed a preference for biologic meshes. Whatever mesh is chosen, it must

be thin enough to allow tacking of the mesh to the posterior abdominal wall.

If peripheral tacking sutures will be used, they are placed at the edges of the mesh. The mesh is then tightly rolled and inserted through one of the larger trocars into the abdomen. Here it is unrolled and moved toward the stoma and hernia and oriented. After orienting the mesh, the traction sutures are extracted with a "suture passer" technique through small separate skin incisions. The sutures are tied down to the anterior abdominal fascia, creating transabdominal fixation. Authors have used a variable number of these traction/fixation sutures, ranging from a suture every 5 cm to just 4 sutures. As tacking devices have improved, the number of traction/fixation sutures has been reduced or eliminated. The author currently uses four sutures. After the traction/fixation sutures are secured, further fixation is done with a mechanical fixation device (e.g., SorbaFix or ProTack) at the margin of the mesh and along the bowel tract and edge of the fascial defect. Care is taken to produce appropriate tension on the mesh and to avoid putting the tackers into the ostomy bowel or mesentary and to allow enough laxity for the ostomy bowel to exit the mesh. After mesh fixation, the bowel is again inspected to exclude any unsuspected injury or bowel compression.

Another technique uses a keyhole piece of mesh. Mesh of appropriate size is cut with a central or slightly offcenter opening and a slit (Figure 2). The size of the mesh and location of the "central" opening should again allow a 5-cm overlap from the edges of the hernia. The central opening should be large enough to accommodate the bowel. If nonbiologic mesh is used, most authors have made the opening large enough that the mesh edges are not in direct contact with the bowel wall. With this technique, less laxity of the bowel leading to the stoma is required. After cutting the mesh, it is inserted into the abdomen as described previously and maneuvered into place. The four traction sutures are placed through the abdominal wall and secured. The edges of the mesh are tacked to the fascia as described previously (Figure 3). The fascia of larger trocar sites is closed with absorbable sutures, and the sites are infiltrated with local anesthetic (bupivacaine or bupivacaine liposome injectable suspension).

POSTOPERATIVE MANAGEMENT

The orogastric tube is removed prior to extubation, and the Foley catheter is removed later in the day or the next morning. Patients are supported with intravenous fluids and offered liquids when they are hungry. Solid food is started when flatus is expressed from the stoma. Pain management is usually provided by patient-controlled analgesia supplemented with acetaminophen, ibuprofen, or ketorolac. The patient is switched to oral pain medication when he or she is taking fluids and early ambulation is encouraged. Patients are ready for discharge when they can care for their stoma, are tolerating a diet, and have evidence of bowel function. Because the bowel is not detached from its skin attachment and stomal education is not required, recovery is usually rapid.

COMPLICATIONS

Early complications include unsuspected bowel injury, infection, or obstruction of the colon. Longer-term complications include hernia recurrence, bowel erosion, and, rarely, pain.

RESULTS

A number of small series have been published with short follow-up. Pooling four nonrandomized studies resulted in 7 recurrences out of 72 repairs. A laparoscopic technique is not feasible in all patients, and in one study, 15% of 55 patients had to be converted to an open procedure. Craft and colleagues described 27 consecutive patients repaired with a nonslit ePTFE mesh (Sugarbaker technique). There were a number of complications but no conversions, and mean length of stay was 6 days (ranging from 2 to 14 days). With a mean follow-up of 32 months, there was a 5% recurrence rate. In two studies of 59 patients, bowel injury occurred in 22% of patients. In another study of 47 patients in which ePTFE mesh was used, 9% had to have the mesh removed due to infection.

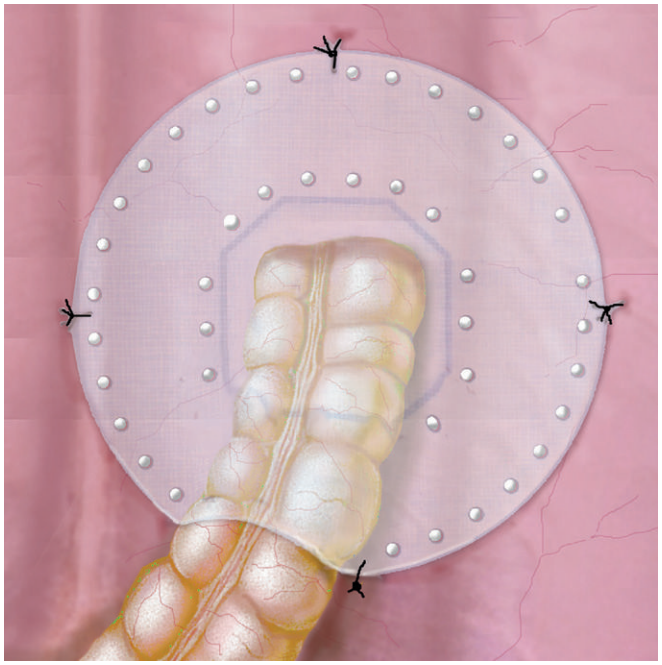

FIGURE 2 Fixation of mesh in a laparoscopic hernia repair.

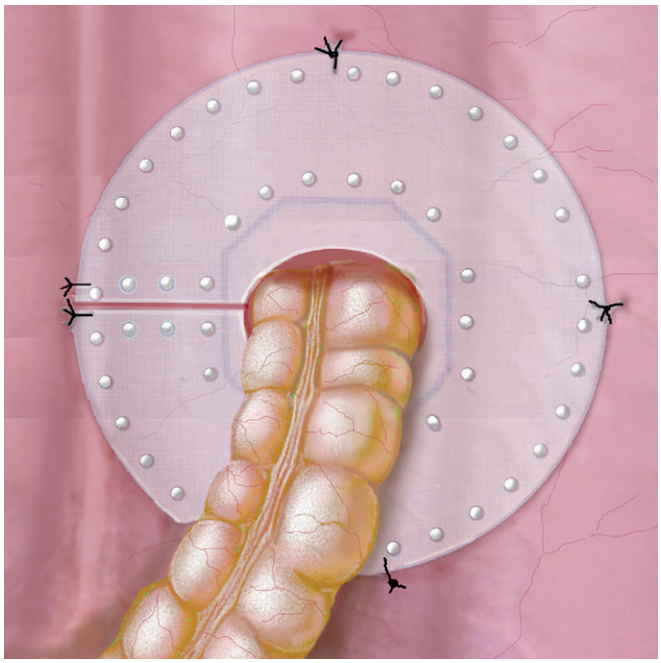

FIGURE 3 Keyhole mesh.

Most authors have not directly closed the hernia defect. This can leave a small bulge at the hernia site that can be displeasing to some patients.

CONCLUSIONS

Parastomal hernia repair is feasible as well as safe. Increasing experience and randomized prospective studies will be needed to define the optimal technique of repair. Until such information is available, laparoscopic repair with an underlay technique is a viable option in selected patients.

LAPAROSCOPIC SPLENECTOMY

Michael J. Lee, MD, and
Edward H. Phillips, MD, FACS

OVERVIEW

Perhaps the earliest reference to splenectomy is an anecdotal description by C. Pliny (23-79 AD) in which incising the body to remove the spleen was believed to remove what hindered a man's running ability. As the spleen's function and the consequences of its removal became further elucidated, surgeons developed effective techniques for safe removal. Just as the laparoscopic approach has gained popularity for most abdominal surgical procedures, laparoscopic splenectomy has become the preferred method for elective splenectomy compared with conventional splenectomy because of the advantages that include decreased postoperative pain, shorter hospitalization, earlier return to normal activity, and improved cosmesis.

INDICATIONS AND CONTRAINDICATIONS

Laparoscopy is generally reserved for elective splenectomy for hematologic disorders, storage diseases, infiltrative disorders, and other benign disorders that benefit from splenectomy. Idiopathic thrombocytopenic purpura (ITP) is the most frequent indication for elective laparoscopic splenectomy. Depending on the surgeon's skill and experience, malignancy, splenomegaly, portal hypertension, pregnancy, and morbid obesity are not absolute contraindications for the laparoscopic approach. A hand-assisted port may even be useful for patients with splenomegaly and for cases that are difficult because of body habitus or inflammation from splenic infarction.

Laparoscopy is, however, contraindicated in emergent situations, such as splenic trauma or rupture with hemorrhagic shock, because of the impracticality of setting up laparoscopic equipment and the inability to pack the abdomen for vascular control if necessary. The inability to tolerate pneumoperitoneum is another absolute contraindication.

PREOPERATIVE PREPARATION

All patients must give informed consent, and the possibility of conversion to an open approach should be explained. In addition, the risk of overwhelming postsplenectomy sepsis should always be explained, with preoperative vaccination against meningococcus, pneumococcus, and *Haemophilus influenza* at least 2 weeks before. Postoperative vaccinations are administered generally on the last day of admission if not given before surgery. Prophylactic antibiotics covering skin flora administered within 30 minutes of incision should be strongly considered for patients with diabetes, morbid obesity, and immunocompromise. If available, preoperative imaging should be reviewed for accessory spleens.

Additional preoperative preparation is specific to the disease being treated. In ITP, intravenous immune globulin (IVIG) or plasmapheresis may help to elevate the platelet count and may benefit the patient with spontaneous bleeding or ecchymosis. Platelets should be available for transfusion after ligation of the splenic artery. Preoperative chemotherapy for splenomegaly from chronic myeloid leukemia may result in a 20% to 50% reduction in size within weeks of treatment. Portal or splenic vein thrombosis is also associated with splenomegaly but rarely with normal-sized spleens.

For patients with massive splenomegaly below the level of the iliac crest, splenic artery embolization on the morning of surgery followed by laparoscopic splenectomy may help to reduce the size of the spleen with manageable pain and ischemic complications. To ensure adequate hemostasis, the surgeon must be aware of the metal coils and avoid them during stapling of vasculature.

TECHNIQUES

Laparoscopic splenectomy has become the preferred approach for idiopathic thrombocytopenic purpura and other diseases with normal-sized spleens. The right lateral decubitus approach, also known as the "hanging spleen" technique, has become the preferred method for most surgeons because of availability of natural ligaments and gravity to lower the viscera to help maintain exposure.

The supine position was once used originally and may be necessary in combined cases but has fallen out of favor because of the easier exposure provided with a right lateral approach.

Regardless of the approach, the basic principles of achieving exposure, dividing the ligamentous attachments, and controlling the vascular supply, remain essential. Regard for anatomic relationships is always critical, and the surgeon should be aware of the attachments and the relationship of the spleen to the stomach, pancreas, left kidney, colon, and diaphragm. The two main attachments include the gastrosplenic and the splenorenal ligaments, which contain the short gastric and gastroepiploic vessels, respectively. The remaining ligaments, including the splenocolic and splenophrenic, are avascular, unless diseased from portal hypertension or myeloid metaplasia. Prior splenic infarction may result in dense inflammation in the splenophrenic ligament, necessitating a hand port, open conversion, or chest tube placement if the diaphragm is injured during dissection. The surgeon should also be aware that the vasculature of the spleen is variable with distributive and magistral patterns (Figures 1 and 2). Also important is awareness that the tail of the pancreas is usually within a centimeter of the splenic hilum and can also be in direct contact with the spleen in one third of all patients.

RIGHT LATERAL APPROACH

After the endotracheal tube is secured, an orogastric tube is placed, and a Foley catheter is placed at the discretion of the surgeon. Bilateral sequential compression devices should be applied to the lower extremities in the preoperative holding area. The patient is then positioned and padded on a taped beanbag in the right lateral position. Positioning should allow the point between the iliac crest and the lateral costal margin to rest at the central break of the table. The left arm is positioned in a semiflexed position on a pillow. An axillary gel foam roll is used, and the hips and legs are gently flexed and padded between pillows and secured to the bed with wide silk tape. The patient is also placed at a 45-degree tilt to maximize exposure exploited by the natural ligaments and gravity (Figure 3). This also facilitates exploration in the abdomen in search for accessory spleens. Lateral positional beams attached to the rails may add to the lateral stability and help to reinforce the beanbag to maintain the 45-degree tilt. Egg crate foam pads should be generously used and added to the surface area to prevent slipping. Once meticulous positioning is complete, the table is then fully tilted in all practical directions to ensure that the patient can safely tolerate it during the operation because proper positional manipulation is key to this approach. The patient is then widely prepped from the nipple line to the hips for possible hand port placement, chest tube placement, or open conversion. The monitor should be placed at the head of the table at an ergonomic height and angle. Suction should be available and ready for use, as should a hook electrocautery device. An ultrasonic dissector should be available as well.

The surgeon stands on the patient's right side and directs the assistant (also standing on the patient's right side) who can drive the camera with the left and assist with the right hand. The patient is tilted to left side up to perform the operation but is tilted left side down such as in a supine position to provide for initial entry of trocars (Figure 4). Because of close proximity to the colon and necessity for specimen extraction, an initial 12-mm Hasson's trocar is the preferred technique in the anterior axillary line opposite the 11th or 12th rib. Once pneumoperitoneum is obtained, a 5-mm port is placed in the subxiphoid location for the surgeon's left hand. A 5-mm port is placed midway between the subxiphoid trocar and the Hasson's port. The most lateral trocar is a 12-mm one placed in the left axillary line between the costal margin and the iliac crest, with care taken to "open" the hip so an endovascular cutter can be inserted (Figure 5).

Initial inspection should begin with a search for accessory spleens in the splenic hilum, the splenic ligaments, the omentum, the small bowel mesentery, and the pelvis. Careful inspection at the start of the case avoids staining from dissection and disrupting small blood vessels and allows for better visualization.

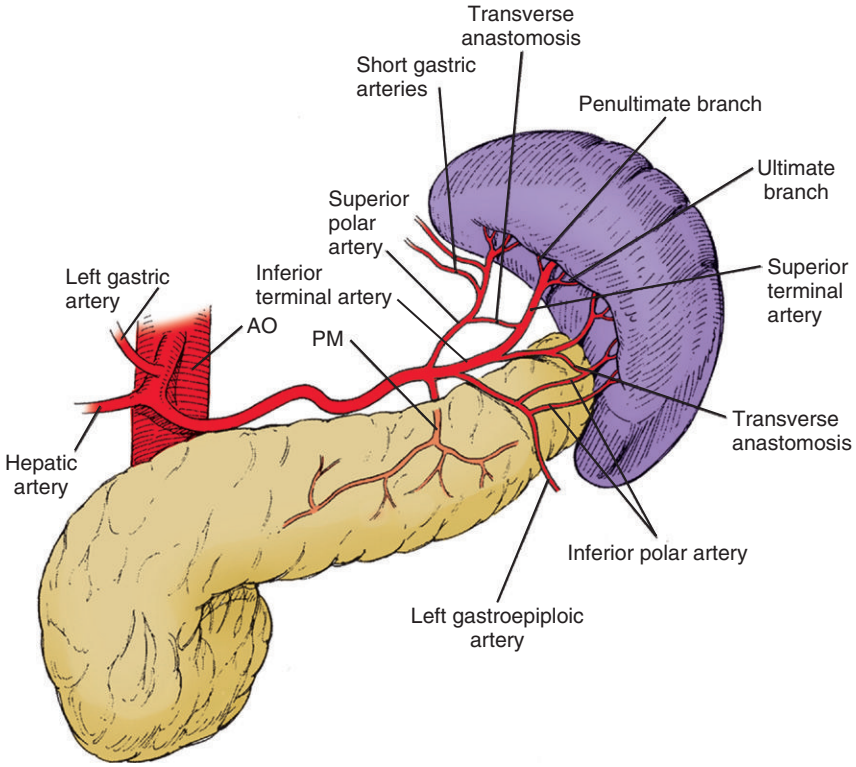

FIGURE 1 Distributed vascularization. By definition, the splenic trunk is short, and many long branches (6 to 12) enter over three fourths of the medial surface of the spleen. The branches originate between 3 to 13 cm from the hilum. Outside the spleen, the arteries also present frequent transverse anastomoses with each other, which according to Testud arise at a right angle between the involved arteries, as with most collaterals. Thus, the application of hemostatic clips or the embolization of coils occluding a branch of the splenic artery before such an anastomosis may fail to devascularize the corresponding splenic segment. *AO,* Aorta; *PM,* pancreatic magna. *(From Poulin EC, Thibault C: The anatomical basis for laparoscopic splenectomy,* Can J Surg *36[5]:485-488, 1993.)*

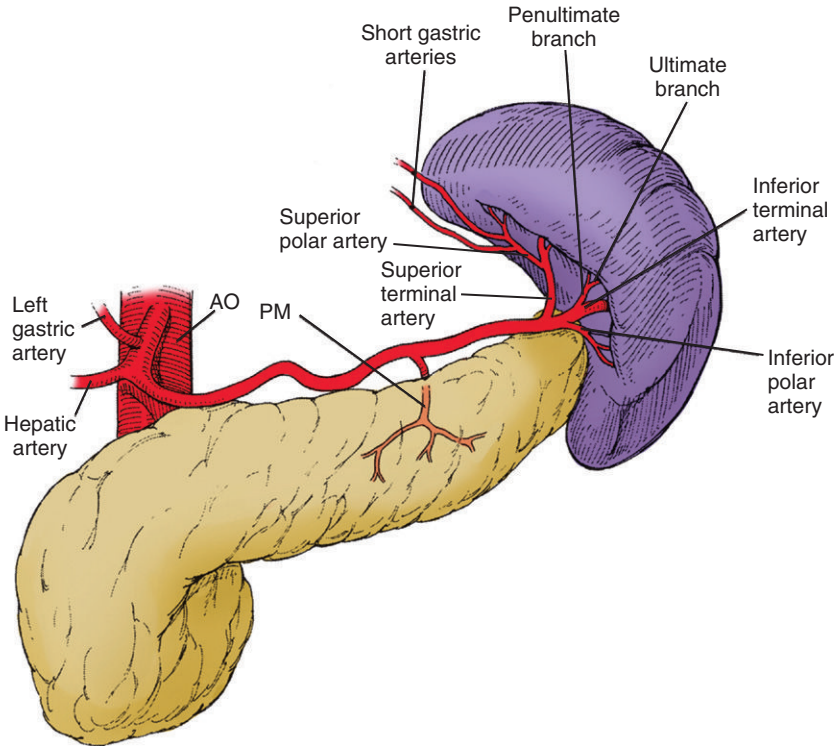

FIGURE 2 Bundled (magistral) vascularization. The bundle type is characterized by the presence of a long main splenic artery that divides into short terminal branches near the hilum. In this type, the splenic branches enter over only a fourth to a third of the medial surface of the spleen. These branches are large, few (3 to 4), originate 3.5 cm on average from the spleen, and reach the center of the organ as a compact bundle. *AO,* Aorta, *PM,* pancreatic magna. *(From Poulin EC, Thibault C: The anatomical basis for laparoscopic splenectomy,* Can J Surg *36[5]:485-488, 1993.)*

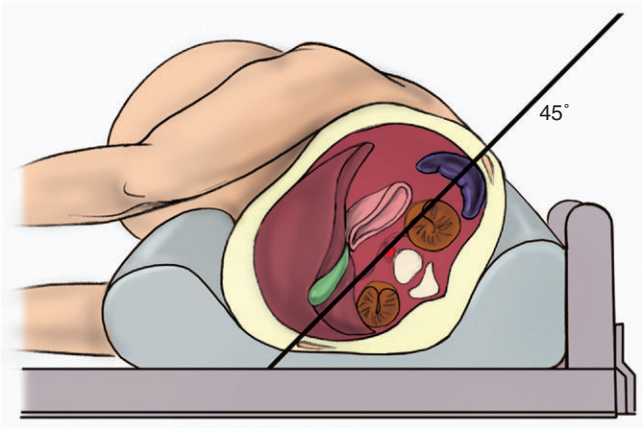

FIGURE 3 The "leaning spleen" technique requires a 45-degree tilt with a beanbag or jelly roll positioning pad. *(Reprinted with permission from Hunter JG, editor:* The atlas of minimally invasive surgical operations, *New York, McGraw-Hill.)*

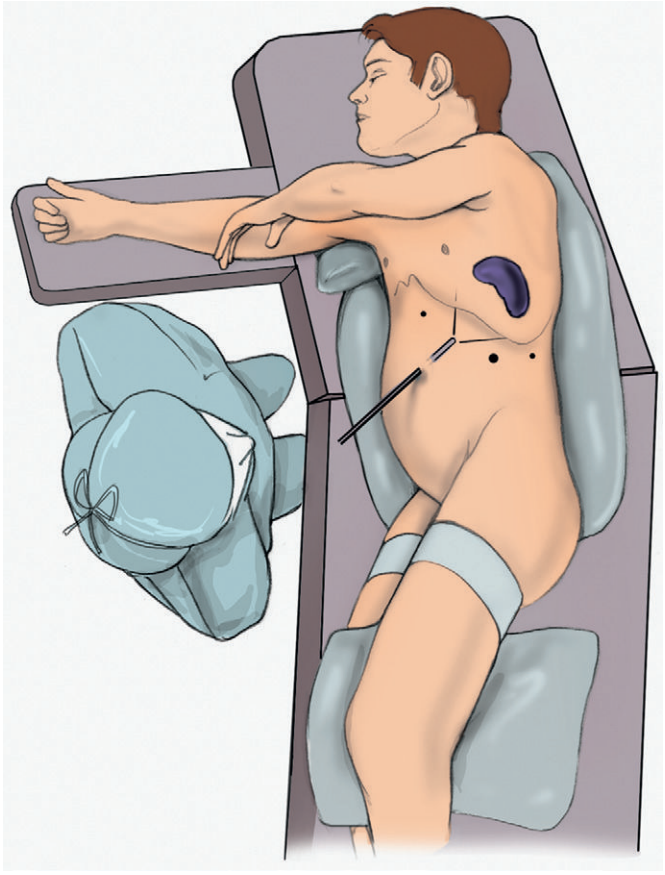

FIGURE 4 Patient, port, and laparoscope positions for the "leaning spleen" technique. *(Reprinted with permission from Hunter JG, editor:* The atlas of minimally invasive surgical operations, *New York, McGraw-Hill.)*

The safest course to approach splenectomy in cases of splenomegaly consists of ligating the splenic artery in the lesser sac because hemorrhage during hilar dissection can possibly occur. The lesser sac is entered through the gastrocolic ligament, and the pancreas is identified and retracted posteriorly and inferiorly to visualize the splenic artery or its pulsation slightly superior to the pancreas. The visceral peritoneum should be dissected with scissors, and clips should occlude the artery without dividing it. The clips should be carefully placed in a low position to later accommodate the linear cutting stapler.

The table should then be tilted to the right to facilitate division of the splenocolic ligament. The hook electrocautery or ultrasonic dissector is used to divide the ligament so that the inferior pole is

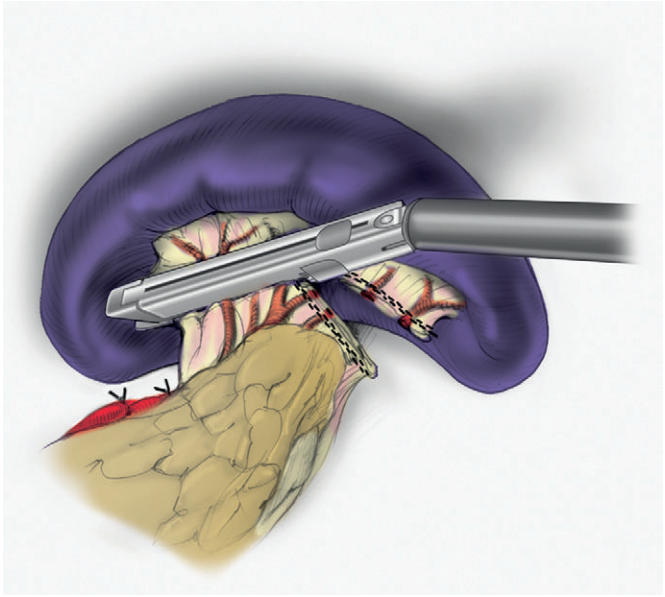

FIGURE 5 The splenic blood supply is controlled in the splenic hilum with a linear cutting stapler. *(Reprinted with permission from Hunter JG, editor:* The atlas of minimally invasive surgical operations, *New York, McGraw-Hill.)*

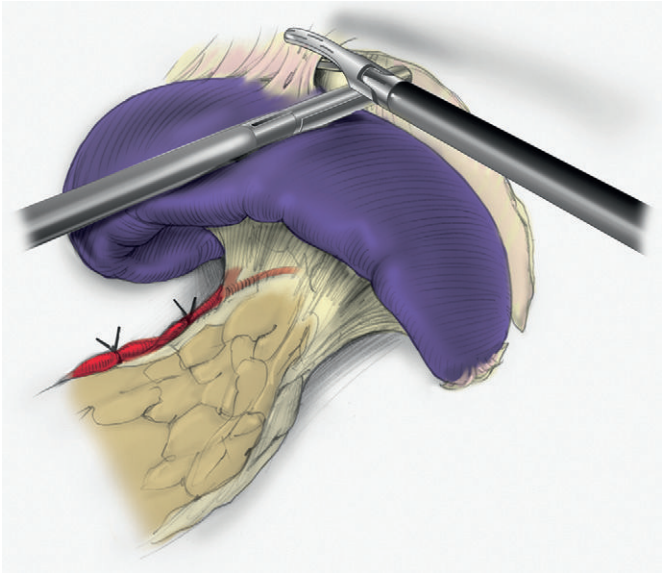

FIGURE 6 The spleen is released by dividing the peritoneal reflection with the Harmonic scalpel (Johnson & Johnson Gateway, Piscataway, NJ). *(Reprinted with permission from Hunter JG, editor:* The atlas of minimally invasive surgical operations, *New York, McGraw-Hill.)*

completely visible. The small tributaries of the left gastroepiploic vein are divided. The splenorenal ligament is then divided, and the dissection proceeds from the inferior pole cephalad to reach the splenophrenic ligament (Figure 6). The short gastric vessels are also divided, and the vascular pattern supplying the spleen should now be apparent. The distributed pattern is most common and present in 70% and is characterized by a short splenic trunk with many long branches (see Figure 1). The magistral type is characterized by a long dominant splenic artery with short terminal branches that enter the medial surface of the spleen (see Figure 2). The hilum should be widely exposed and searched again for accessory spleens. The endoscopic linear cutting stapler can be used to safely and efficiently divide the large vessels at the hilum, offsetting cost by the time savings.

Once the spleen is detached, the inferior pole peritoneal attachment may be grasped and pointed toward the diaphragm and held at three points (6, 10, and 12 o'clock) and then placed in a sturdy bag for extraction through the 12-mm fascial defect of the Hasson's working port. Alternatively, a sterile heavy duty commercial freezer bag may be useful for very large spleens. The bag is then grasped and partially removed into the wound. The spleen is morcellated to allow for extraction with ring forceps while avoiding spilling fragments, which may result in splenosis and recurrent disease. If concern exists that the diagnosis cannot be obtained from a morcellated specimen, direct communication with the pathologist before the procedure is important to decide whether to add a hand port or make a lower midline incision for specimen extraction. Traction provided by the assistant upwards on the specimen bag during morcellation can help avoid spilling of spleen fragments. A 19F closed suction drain is placed if concern exists for injury of the pancreas. All fascial defects greater than 10 mm are closed.

ANTERIOR APPROACH

The anterior approach has been largely replaced by the right lateral technique, but it should be considered in certain cases when the spleen size is normal and patients are undergoing concomitant procedures, such as laparoscopic cholecystectomy or laparoscopic distal pancreatectomy. In the anterior approach, the surgeon stands between the legs, which are placed in low lithotomy, or alternatively on the patient's right side with the patient supine. The dissection is carried similarly in the manner as the right lateral approach.

LAPAROSCOPIC HAND-ASSISTED

As mentioned previously, a hand port may help in cases with massive spleens or in cases with dense scar tissue between the diaphragm and spleen. In addition, if the specimen needs to be removed intact to aid in pathologic diagnosis, a hand port can be very helpful to avoid traumatizing the specimen.

POSTOPERATIVE CARE

After laparoscopic splenectomy, the postoperative care is routine. In addition, the surgeon should also be aware that if the patient was receiving steroids, a taper with oral steroids may be necessary. Patients are usually discharged home the next day when criteria are met.

COMPLICATIONS

Although rare in incidence (3.2%), overwhelming postsplenectomy sepsis carries an extremely high mortality rate reported up to 50%. Patients have the highest risk in the first 2 years after splenectomy but also carry a lifetime increase in risk; vaccination against meningococcus, pneumococcus, and *H. influenza* type B is important.

Portal or splenic vein thrombosis may occur in patients with hypercoagulable myeloproliferative disorders, hematologic malignancy, and massive splenomegaly.

Because of the close proximity, the tail of the pancreas is at risk for injury during dissection at the splenic hilum. If injured, any major duct should be repaired; a 19F closed suction drain should be placed in the vicinity and checked for amylase, and the patient should be placed on a low-fat diet.

RESULTS

No prospective randomized trial has compared laparoscopic with open splenectomy. Similar to the results for other laparoscopic approaches, the results of two meta-analyses show improvement in overall complication rates (9% to 15% vs 12% to 26%), mortality rates (0.2% to 0.6% vs 1.0% to 1.1%), and length of stay (3.6 vs 7.2 days), but at the expense of more than an hour of additional operative time (180 vs 114 minutes) with the laparoscopic approach. Operative times were significantly reduced by an average of 40 minutes (135 vs 177 minutes) by the addition of a hand-assisted port in patients with large spleens greater than 700 g in a comparative analysis of 56 patients.

SUMMARY

Laparoscopic splenectomy should be considered in the stable elective case. In certain situations, a hand port may facilitate dissection and specimen extraction for massive spleens and decrease operative time. The right lateral approach maximizes exposure with natural attachments for retraction and gravity to lower the viscera. Careful meticulous positioning and intraoperative manipulation in table positioning greatly helps. The laparoscopic advantages include lower complication rates, lower mortality rates, shorter hospitalization, and improved cosmesis.

Laparoscopic Gastric Surgery

Han-Kwang Yang, MD, PhD, FACS, and Sebastianus Kwon, MBBS, FRACS

OVERVIEW

Laparoscopic surgery is now considered the standard of care in the surgical management of a number of benign esophagogastric conditions, such as acid reflux, as well as in bariatric surgery. However, application of laparoscopy in the treatment of early gastric cancer is still relatively new and its practice is not standardized around the world. This chapter will focus on laparoscopic surgery for gastric cancer: its rationale, indications, and technical aspects.

In the past two decades, there has been a rapid increase in the application of laparoscopic or laparoscopic-assisted gastrectomy for the treatment of gastric adenocarcinoma in Asia, particularly Japan and Korea, where currently, more than half of all gastrectomies are being performed laparoscopically at many leading centers. The move toward minimally invasive surgery is a result of multiple factors, not the least of which is the high incidence of gastric cancer and the high proportion of early gastric cancer—confined to the mucosa (T1a) or submucosa (T1b)—in Japan and Korea. Also, there is now a growing body of evidence suggesting oncologic feasibility of laparoscopic-assisted gastrectomy in early gastric cancers. In addition, surgeons have made concerted efforts to standardize surgical procedures and enable reproducibility of results. In comparison, in the West, gastric cancer is much less common and rarely diagnosed at an early stage. As such, the clinical application of laparoscopic-assisted gastrectomy has remained limited to a handful of referral centers and has included locally advanced gastric cancers. Clinical trials from the West are similarly limited in number, have small sample sizes, and include tumors of all stages.

INDICATIONS AND RATIONALE FOR LAPAROSCOPIC GASTRECTOMY

There is ample evidence supporting the technical feasibility and various short-term benefits of laparoscopic gastrectomy compared with conventional open surgery. A meta-analysis of randomized controlled trials (RCTs), conducted by Kodera and colleagues (2010), showed a reduction in overall morbidity rates among patients who underwent laparoscopic-assisted distal gastrectomy (LADG), compared with patients who underwent open surgery, but equivalent mortality rates across groups. A significant reduction in estimated blood loss was also observed in the LADG group at the expense of longer operating time. However, Level I evidence supporting the oncologic safety of laparoscopic gastrectomy is still lacking. To date, the evidence is limited to one small Western RCT by Huscher and colleagues (2005; $n = 59$), and numerous retrospective and phase II trials, mainly from Japan and Korea. At present, two notable RCTs assessing long-term outcomes of LADG for clinical stage I disease are in progress, namely the KLASS-01 study by the Korean Laparoscopic Gastrointestinal Surgery Study (KLASS) Group and the JCOG0912 study by the Japanese Clinical Oncology Group. The former study completed its targeted accrual of 1415 patients in 2010 and its 5-year survival data are expected to provide the first Level I evidence on oncologic safety of LADG for clinical stage I disease. For now, other than in the setting of clinical trials, the majority of surgeons in the East restrict laparoscopic gastrectomy to clinical T1N0 disease that falls outside of indications for endoscopic resection, although some centers have expanded their indication to more advanced stages. Another trial by KLASS group, the KLASS-02 study, which is aimed at assessing technical feasibility and oncologic safety of LADG for advanced gastric cancer, is currently in the recruitment phase. Similar studies are ongoing in Japan by groups led by Kitano. Until there are

robust data to support its clinical use, laparoscopic gastrectomy for cancer ought to be considered investigational treatment.

Even greater caution is advised when considering the application of a laparoscopic approach for total gastrectomy, as the lymph node (LN) dissection, and particularly the reconstruction for a laparoscopic total gastrectomy (LTG), are technically more demanding compared with an LADG, and an anastomotic leakage is more consequential. To address this issue, the KLASS group has just commenced the KLASS-03 study, a phase II study, aimed at assessment of technical safety of various reconstructive techniques after total gastrectomy.

CONTRAINDICATIONS

The consideration of contraindications to laparoscopic gastric surgery should take into account the individual surgeon's experience in advanced laparoscopic surgery, stage of the disease, the patient's ability to tolerate prolonged pneumoperitoneum, and patient history of previous abdominal surgery.

PREOPERATIVE WORKUP AND PREPARATION

Accurate preoperative staging by means of endoscopy, endoscopic ultrasound, and abdominopelvic computed tomographic (CT) scan is critical in deciding on the optimal treatment modality (endoscopic or surgery) and the preferred surgical approach. Vascular anomalies, particularly an accessory or replaced left hepatic artery arising from the left gastric artery and a common or right hepatic artery arising from the superior mesenteric artery, should be actively sought on the arterial phase of the CT scan. Preoperative understanding of any variations in the course of the splenic artery can be helpful during LN dissection around it. Also, a three-dimensional arterial phase reconstruction can provide more intuitive information. Positron emission tomography (PET)-CT scan is performed selectively to exclude distant metastatic disease when suspected. In addition to guiding preoperative decisions on the extent of gastrectomy (distal or total, or pylorus-preserving gastrectomy), precise endoscopic localization of the tumor is critical to ensure negative resection margins, particularly for early or nonpalpable cancers. Endoscopic clips placed proximal and distal to the lesion preoperatively are used for this purpose. Other important preoperative considerations include the method of reconstruction (Billroth I, Billroth II, or Roux-en-Y) and its approach (extracorporeally through a mini-laparotomy or intracorporeally).

SURGICAL PRINCIPLES FOR LAPAROSCOPIC GASTRECTOMY

The principles of a laparoscopic gastrectomy for potentially curable disease are identical to those of an open gastrectomy: offering the best chance of cure by a R0 resection and adequate LN dissection, and minimizing surgical insult and complications. A thorough understanding of the anatomy of the LN stations (Figure 1) is a necessity, and the extent of the dissection should be identical to that of an open procedure. Also, the surgical team should be mindful of the risk of cancer cell dissemination from direct handling of tumor, spillage of intragastric content, and disruption of lymphatic vessels or metastatic LNs themselves.

In addition, the following surgical principles are considered essential in minimizing intraoperative complications during a laparoscopic gastrectomy. Setting up optimal exposure of the dissection field prior to dissection at each step is crucial. The importance of identifying and staying in the correct surgical plane cannot be overemphasized. Also, safe techniques for using energy devices such as ultrasonic coagulating shears (UCS) should be adopted. For example, it is recommended that the active blade of UCS be kept visible during and immediately after its activation. Use of the insulated or inactive blade, which has a thinner tip profile, is recommended for blunt dissection and finding the correct tissue plane prior to instrument activation. Finally, surgeons should have a low threshold for converting to an open procedure or extending a mini-laparotomy until they have gained sufficient experience performing laparoscopic gastrectomies.

PITFALLS DURING A LAPAROSCOPIC GASTRECTOMY

A laparoscopic gastrectomy for cancer is a technically challenging procedure with a steep learning curve reported to extend to approximately 50 cases. Gastrectomy requires a large extent of LN dissection, much of it in the immediate vicinity of major blood vessels that need to be preserved. As such, many of intraoperative pitfalls relate to injury to either major blood vessels or bleeding from their branches or tributaries that impair vision and subsequently lead to other major complications. During the early phase of introduction of laparoscopic gastrectomy, there were reports of delayed rupture of a splenic artery pseudoaneurysm, which is unusual in the open setting. Blind attempts to control bleeding immediately after it occurs can invite more serious injury. Most minor bleeding will stop spontaneously with application of gauze alone. Other pitfalls relate to thermal injury to adjacent organs, particularly to the transverse colon, pancreas, duodenum, and esophagus, and steps of reconstruction, which is more difficult by the minimally invasive approach.

EXTENT OF LYMPHADENECTOMY

D2 dissection has long been the standard of care in Japan and Korea, and survival advantage of D2 dissection over D1 dissection has only recently been shown using Western data for the first time. The third English version of *Japanese Gastric Cancer Treatment Guidelines* (2010) recommends a D2 dissection for clinical T2-4b tumor or T1 tumor with suspicion of nodal involvement (Figure 2). Most gastric surgeons in Japan and Korea accept D1+ dissection as a safe alternative in cT1N0 disease. Oncologic safety of laparoscopic D2 dissection remains a topic of debate, as mentioned earlier. The extent of lymphadenectomy is now defined according to the type of gastrectomy indicated and not the location of the lesion (Figure 3).

OMENTECTOMY AND BURSECTOMY

Although there is lack of conclusive evidence regarding the optimal extent of omentectomy in gastrectomy, a partial omentectomy is generally performed for cT1 disease and a total omentectomy for cT2 or above. Results of RCTs in progress to assess the role of bursectomy, albeit in the open setting, are being awaited.

TECHNIQUE OF LAPAROSCOPIC GASTRECTOMY

The authors' standard technique for a LADG with partial omentectomy for an extracorporeal Billroth I anastomosis using a circular stapler is described in this section.

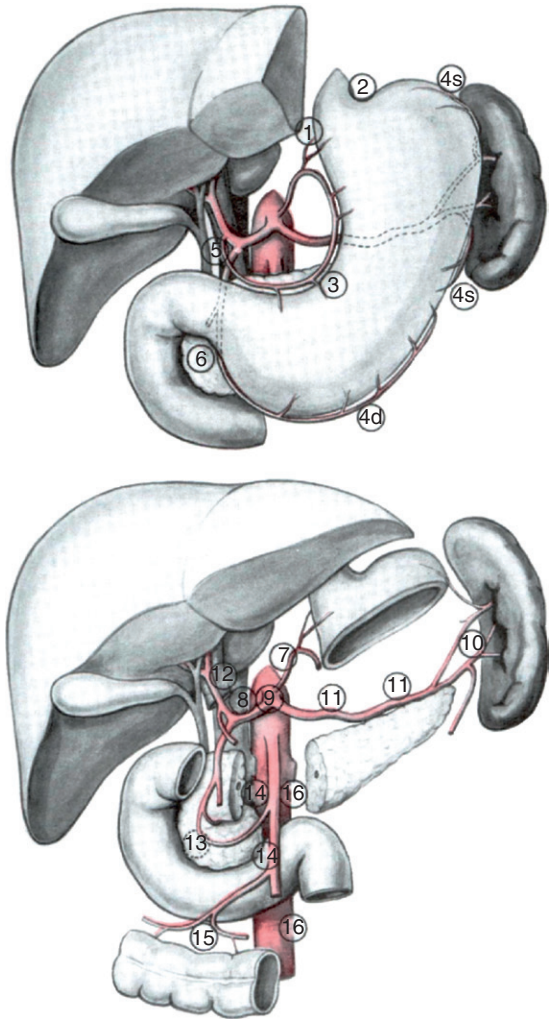

FIGURE 1 Lymph node stations surrounding the stomach. *1,* right cardial nodes; *2,* left cardial nodes; *3,* nodes along the lesser curvature; *4,* nodes along the greater curvature; *5,* suprapyloric nodes; *6,* infrapyloric nodes; *7,* nodes along the left gastric artery; *8,* nodes along the common hepatic artery; *9,* nodes around the coeliac axis; *10,* nodes at the splenic hilus; *11,* nodes along the splenic artery; *12,* nodes in the hepatoduodenal ligament; *13,* nodes at the posterior aspect of the pancreas head; *14,* nodes at the root of the mesenterium; *15,* nodes in the mesocolon of the tranverse colon; *4s,* nodes along the short gastric and left gastroepiploic vessels; *4d,* nodes along the right gastroepiploic vessels; *16,* para-aortic nodes. *(From Peeters KC, van de Velde CJ: Quality assurance of surgery in gastric and rectal cancer,* Crit Rev Oncol Hematol *51(2):105–119, Fig 1, 2004.)*

Room Setup and Patient Position

The patient is placed supine with arms extended out. A nasogastric tube and an in-dwelling urinary catheter are placed after general anesthesia. The patient is secured onto the bed using leg and arm straps. The operator sits or stands on the right side of the patient and the assistant on the left side throughout the procedure. The scopist sits or stands on the right side, next to the operator. A video monitor is placed above each of the patient's shoulders (Figure 4).

Placement of Ports

An infraumbilical 11-mm port is placed using open technique through which a 30-degree angled scope is introduced and pneumoperitoneum to 12 mm Hg established. The peritoneal cavity is inspected for any evidence of tumor spread (Figure 6, *A*). The table is tilted 20 degrees in reverse Trendelenburg position. Three 5-mm ports and one 12-mm port are then placed under direct vision (Figure 5). The right subcostal port is placed aimed at the first part of the duodenum. Correct placement of the 12-mm port is critical. Placed roughly equidistant between the subcostal and the umbilical ports but the outside linea semilunaris, it should be low enough to allow adequate working space for the right side of the greater curvature mobilization and infrapyloric dissection but high and medial enough to allow safe access for the suprapancreatic LN dissection, particularly the proximal splenic artery (No. 11p) LN dissection. The two left-sided ports for the assistant roughly mirror those on the right.

Dissection of Greater Omentum and Left Gastroepiploic Vessels (Nos. 4d and 4sb Lymph Nodes)

Key points: Entry into the lesser sac, dissection between gastroepiploic arcade and transverse colon, ligation of the root of left gastroepiploic vessels.

Potential pitfalls: Injury to middle colic vessels, thermal injury to transverse colon, hemorrhage from left gastroepiploic vessels, capsular tear of the spleen, inadvertent division of short gastric vessels (resulting in delayed infarction of remnant stomach), omental infarction (rare).

The greater omentum is lifted up anteriorly against gravity and spread out by grasping it just inside the gastroepiploic arcade (Figure 6, *B*). The gastrocolic ligament is divided with UCS, staying 3 to 4 cm outside of the arcade, and the lesser sac is laid open. Anteromedial retraction of the posterior wall of the stomach with the assistant's right-hand instrument facilitates the latter part of the dissection. Toward the lower pole of the spleen, the transverse colon is more closely related to the gastroepiploic arcade, and thermal injury to the colon is avoided by checking both sides of the gastrocolic and splenocolic ligaments for its location (Figure 6, *C*). The endpoint of station 4sb dissection is division of left gastroepiploic vessels, as close to their origin as safely possible. The origin can be difficult to find, particularly in obese individuals. The key to obtaining good exposure is to apply adequate traction along the gastrosplenic ligament. This ligament connects the hilum of the spleen and the tail of the pancreas to the greater curvature of the stomach and carries the left gastroepiploic and short gastric vessels. The vascular origins can be found between the tail of the pancreas and the lower pole of the spleen. The vessels are double-clipped and then divided with UCS, just distal to the main omental branch although this is often difficult to directly visualize (Figure 6, *D–F*). The dissection then is carried directly onto the greater curvature of the stomach to avoid inadvertent division of the short gastric vessels, which will be the sole blood supply to the remnant stomach. Finally a portion of the greater curvature of the stomach is prepared for later transection (Figure 6, *G,H*).

Dissection of Greater Omentum and Right Gastroepiploic Arcade (No. 4d Lymph Nodes)

Key points: Completion of mobilization of transverse colon with exposure of second part of duodenum and head of pancreas.

Potential pitfalls: Inadvertent division of transverse mesocolon, injury to superior mesenteric vein, thermal injury to duodenum or head of pancreas.

First, the right side ports are pulled as far back as possible to maximize the working space. Then, the previous line of dissection in

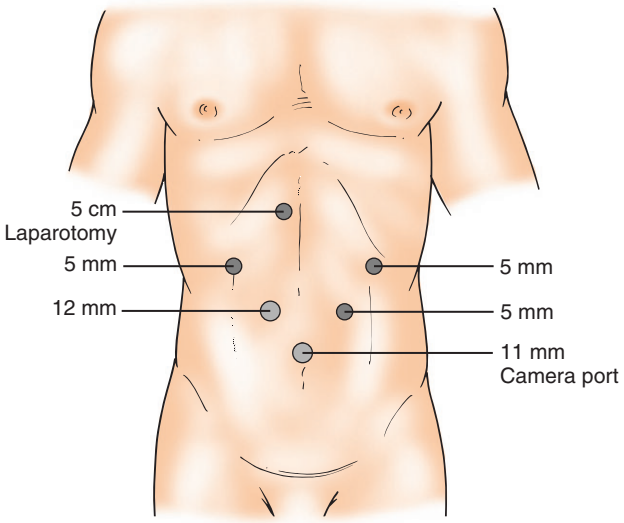

FIGURE 5 Port positions. The position of the right lower (12-mm) port is critical for lymph node dissection. Another 12-mm port for a liver retractor is placed at the medial end of where a 5-cm mini-laparotomy is planned (just to the right of the midline and overlying the pylorus).

the gastrocolic ligament is followed to the hepatic flexure, aiming for the gallbladder, and the dissection is deepened along the embryologic plane between the gastrocolic ligament and the anterior sheath of the transverse mesocolon, staying just anterior to transverse mesocolic vessels (Figure 7, *A–D*). Superior traction on the posterior wall of the antrum with the assistant's right-hand instrument and downward traction on the transverse mesocolon with the assistant's left-hand instrument facilitate this dissection. The endpoint of this dissection is exposure of the second part of the duodenum and the head of the pancreas.

Infrapyloric Dissection (No. 6 Lymph Nodes)

Key points: Division of origins of right gastroepiploic vein (RGEV), then right gastroepiploic artery (RGEA), clearing of first part of duodenum for a gastroduodenostomy.

Pitfalls: Bleeding (frequent), devascularization or perforation of the duodenum from excessive dissection.

The anterosuperior pancreaticoduodenal vein (ASPDV) runs across the anterior surface of the head of the pancreas and is a key landmark during this dissection and also marks the inferior border of LN station 6. It joins the RGEV at the level of the inferior border of the body of the pancreas. Within 1 to 2 cm of this confluence, the RGEV joins the accessory middle colic vein or, less frequently, the middle colic vein to form the gastrocolic trunk of Henle, which in turn drains into the superior mesenteric vein (SMV). The gastroduodenal artery (GDA) divides into two terminal branches—the RGEA and the anterosuperior pancreaticoduodenal artery (ASPDA)—at a significantly higher level compared with its venous counterpart, which divides closer to the superior border of the body of the pancreas.

Dissection is continued carefully along the same embryologic plane to reveal the origins of RGEV and ASPDV, and the gastrocolic trunk of Henle. During this dissection, downward traction on the transverse mesocolon is best achieved with a piece of gauze in the assistant's left-hand instrument, which helps to spread tension and prevent slippage. Further deeper dissection reveals the SMV; however, dissection of SMV (No. 14v) LNs is considered optional. The RGEV and ASPDV are dissected further and RGEV clipped and divided across its root. Then, LN tissues lying on the anterior surface of the head of the pancreas are carefully dissected until the dissection meets the lateral aspect of RGEA. On the opposite side of this vessel, the posterior wall of the antrum and the first part of the duodenum are dissected free from the neck of the pancreas, and the RGEA can be seen as a continuation of GDA. After confirming that the ASPDA has not been inadvertently elevated, the RGEA is double-clipped and divided on the surface of the pancreas. The infrapyloric dissection is completed by division of small branches of GDA to the first part of the duodenum and clearing the duodenum of any attached greater omentum in preparation for the gastroduodenostomy. At this point, perforation of the duodenal wall is a potential hazard.

Suprapyloric Dissection of Right Gastric Artery and Proper Hepatic Artery (Nos. 5 and 12a Lymph Nodes)

Key points: Sufficient infraduodenal dissection, fenestration of hepatoduodenal ligament, division of root of right gastric artery (RGA).

Pitfalls: Bleeding during suprapyloric fenestration, inadvertent injury to major vessels or common bile duct during dissection of hepatoduodenal ligament.

The RGA usually originates from the anteromedial aspect of the hepatic artery proper (HAP) midway up the hepatoduodenal ligament or, less frequently, from the GDA. The RGA gives rise to one or more suprapyloric branches. Suprapyloric branches and the supraduodenal artery from the GDA supply the pylorus and adjacent parts of the stomach and the duodenum.

Suprapyloric dissection is carried out in two portions: infraduodenal and supraduodenal. Adequate infraduodenal dissection makes the supraduodenal portion much safer. The infraduodenal portion of the dissection is a continuation of the infrapyloric dissection. Dissection is continued along the GDA with division of infrapyloric branches to the duodenum and antrum, to expose the junction between the GDA, common hepatic artery (CHA), and HAP (Figure 8, *A*). The CHA is partially dissected at this stage and its associated lymphatic tissues elevated. These are separated from the suprapyloric (No. 5) LNs using UCS, which helps to elevate the hepatoduodenal ligament away from the CHA and GDA for a safer supraduodenal dissection. Similarly, the left side of HAP can also be dissected and sometimes the origin of RGA itself visualized from below. Lastly, a piece of gauze is packed in the space created between the GDA and RGA to widen the space between the RGA and the first portion of the duodenum and to protect underlying vessels from injury during the fenestration of the gastroduodenal ligament (Figure 8, *B–E*).

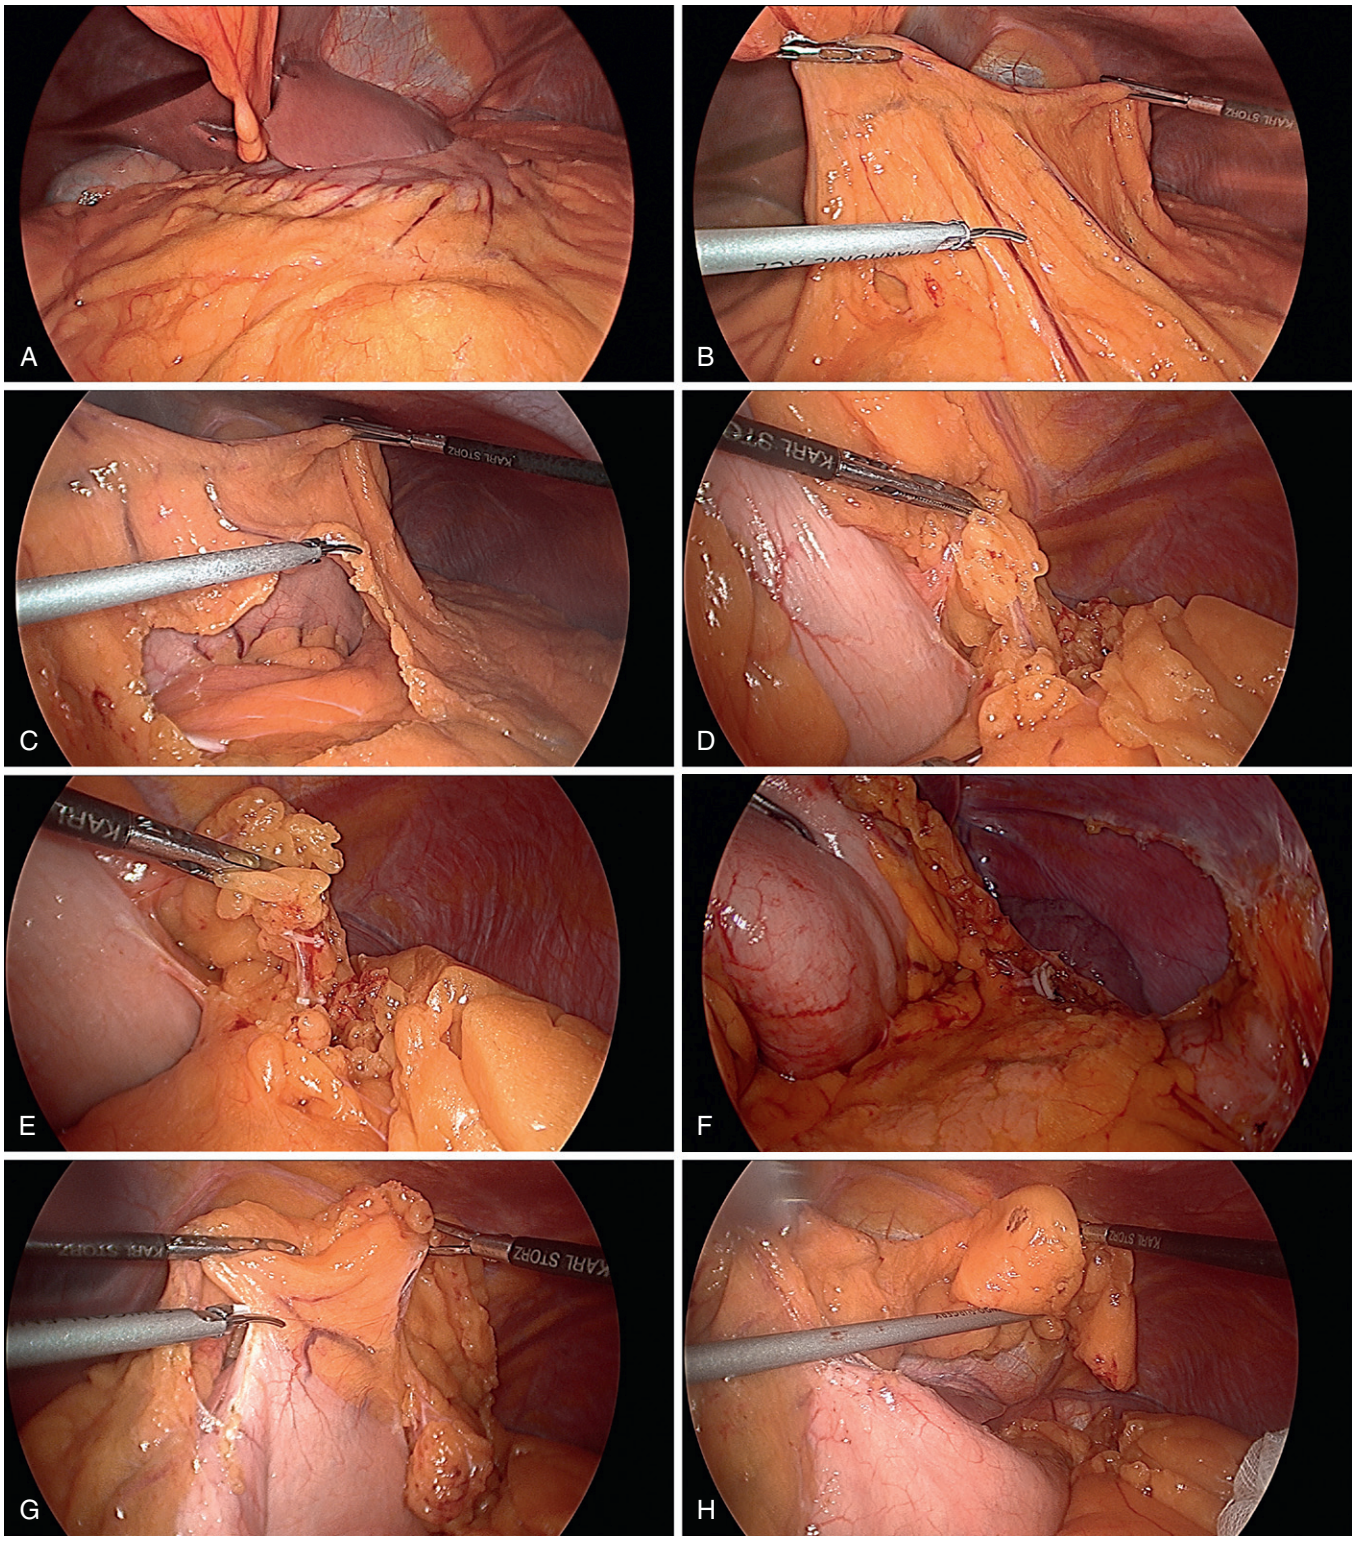

FIGURE 6 Dissection of greater omentum and left gastroepiploic vessels. **A–D,** Partial omentectomy; gastrocolic ligament is divided 3 to 4 cm outside the gastroepiploic arcade. For the supraduodenal dissection, the left lobe of the liver is first retracted. The authors' preferred technique involves using a fan retractor introduced through a 12-mm port placed where a 5-cm long transverse mini-laparotomy is planned (see Figure 5). The mini-laparotomy will be placed to the right of the midline and directly overlying the duodenum. The fan retractor is secured in position with two nylon tapes around the ports to mimic a self-retaining retractor. The dissection starts with fenestration of gastroduodenal ligament. The optimal operative field is set up by splaying out the hepatoduodenal ligament between the surgeon's left-hand instrument and the assistant's right-hand instrument, and rolling down the pylorus with the assistant's left-hand instrument (Figure 8, *B*). Once a small window is created onto the gauze strip placed from below, the dissection is carried along the superior border of the antrum (about 1 cm) and duodenum (about 2 cm; Figure 8, *C–E*). Then the dissection is continued along the hepatoduodenal ligament in line with HAP and the root of RGA is identified, clipped, and divided, together with the right gastric vein (Figure 8, *F,G*). Dissection of HAP lymph nodes along the hepatoduodenal ligament (No. 12a LN) is included in a D2 dissection and involves dissection further cephalad along the hepatoduodenal ligament and more posteriorly onto the left border of the portal vein (Figure 9, *A,B*). Finally, the lesser omentum is divided close to its attachment to the left lobe of the liver until the dissection meets the apex of the right diaphragmatic crus. (The hepatic branch of anterior vagal trunk is preserved if a pylorus-preserving gastrectomy is planned.)

Suprapancreatic Dissection of Left Gastric, Common Hepatic, Celiac Trunk, and Proximal Splenic Artery Lymph Nodes (Nos. 7, 8a, 9, and 11p Lymph Nodes)

Key points: Rolling down of pancreas to obtain adequate exposure, entry into the retroperitoneal space at the superior border of the pancreas, division of left gastric artery (LGA) and coronary vein at their origins.

Pitfalls: Injury to the splenic artery and vein (may necessitate a conversion to a total gastrectomy), injury to the pancreas (leading to pancreatitis or pancreatic fistula) or the aorta.

The celiac trunk and its branches are partially covered by the superior border of the pancreas, particularly so when viewed with a laparoscope through the umbilicus. The pancreaticogastric fold connects the retroperitoneum to the lesser curvature of the stomach and carries the LGA and the coronary vein. The coronary vein usually runs behind and perpendicular to the superior border of the pancreas to drain into the splenic vein; however, when it drains into the portal vein, it is found running down obliquely further onto the right. The tortuosity of the splenic artery and its close relationship to the splenic vein (immediately posterior to it) makes station 11p dissection particularly hazardous. The posterior gastric artery originates from the midpoint of the splenic artery in close proximity to the posterior fundic wall. It is present in only half of all individuals.

The suprapancreatic dissection is one of the most technically challenging and hazardous steps during a laparoscopic gastrectomy. Maintaining an adequate exposure is critical. This can be achieved by applying upward traction on the pancreaticogastric fold (left gastric vessels) with the assistant's right-hand grasper while continually rolling down the superior border of the pancreas with a piece of gauze in the assistant's left-hand grasper as the dissection progresses (see Figure 8, *H*). The suprapancreatic dissection can be approached either with the stomach retracted superiorly (providing a wide view of the lesser sac) or with it resting down (more convenient for dissection to the right of the LGA). The first step of the suprapancreatic dissection is division of the pancreatic capsule along its superior border, from right to left. Then, en bloc dissection is performed, first along the already partly dissected CHA onto its root and then along the splenic artery. The coronary vein lies superficial to the LGA in the pancreaticogastric ligament in this approach, and it is divided between clips, close to the superior border of the pancreas. The proximal splenic artery (No. 11p) LN station is bounded laterally by the posterior gastric artery, which is preserved. Complete 11p dissection is recommended in a LADG for cT2 or greater tumors and in a total gastrectomy. Surgeons tend to include a portion of 11p dissection in all distal gastrectomies, even for early gastric cancer, as this ensures exposure of the origins of the splenic artery and the LGA. After confirming the origins of all three branches of the celiac trunk, the LGA is double-clipped and divided across its root. Then both sides of the celiac trunk are dissected and the diaphragmatic crura exposed to complete station 9 and 11p dissection. Extreme caution is advised, particularly for the lateral extent of station 11p dissection to avoid injury to the splenic artery or vein (Figure 9, *C–F*).

Dissection Along Lesser Curvature of Stomach (Nos. 1 and 3 Lymph Nodes)

Key points: Splaying out and alignment of the stomach wall parallel to the energy device.

Pitfalls: Injury to the fundus of the stomach during station 1 dissection or to the lesser curvature of the stomach during station 3 LN dissection; inadequate dissection, especially on the posterior wall of the lesser curvature.

The right paracardial (No. 1) LN station includes LNs in the pericardial fat pad to the right of the longitudinal axis of the esophagus as well as LNs along the first branch of the ascending limb of the LGA (Figure 9, *G,H*). The lesser curvature (No. 3) LN station includes LNs along the LGA as well as those along the RGA from its second branch.

In preparation of this dissection, the lymphatic tissue attached to the lesser curvature is dissected completely free from the diaphragmatic crura up to the esophagogastric junction. The dissection starts at the top and is progressed distally. The authors' preferred direction of station 3 LN dissection is from the posterior gastric wall to the anterior wall. The key to a safe dissection here is to splay out and orient the gastric wall parallel to the blades of the UCS by applying adequate longitudinal traction along the lesser curvature with the assistant's left-hand instrument while continually rolling out the lesser curvature soft tissues toward the left upper quadrant with the assistant's right hand. Since the correct dissection plane lies just outside of the muscularis propria, a large area of muscle fibers along the lesser curvature will be exposed at the end of this dissection (Figure 9, *I*). When there is a replacing left hepatic artery originated from left gastric artery, we can preserve that replacing left hepatic artery during the dissection of station 7 LN for early gastric cancer (Figure 9, *J*). Lesser curvature dissection is continued distal to the proposed line of gastric transection. This completes the LN dissection for an LADG.

TECHNIQUES OF RECONSTRUCTION

The Billroth I anastomosis (gastroduodenostomy) is a favored method of reconstruction following a distal gastrectomy for cancer at many centers in Japan and Korea. This is in stark contrast to the West, where either Billroth II or Roux-en-Y reconstructions are being used almost exclusively. This section discusses the techniques and pitfalls of three commonly used approaches for a Billroth I reconstruction. Aspects of Billroth II and Roux-en-Y reconstructions that are relevant to laparoscopic distal gastrectomies are also briefly discussed.

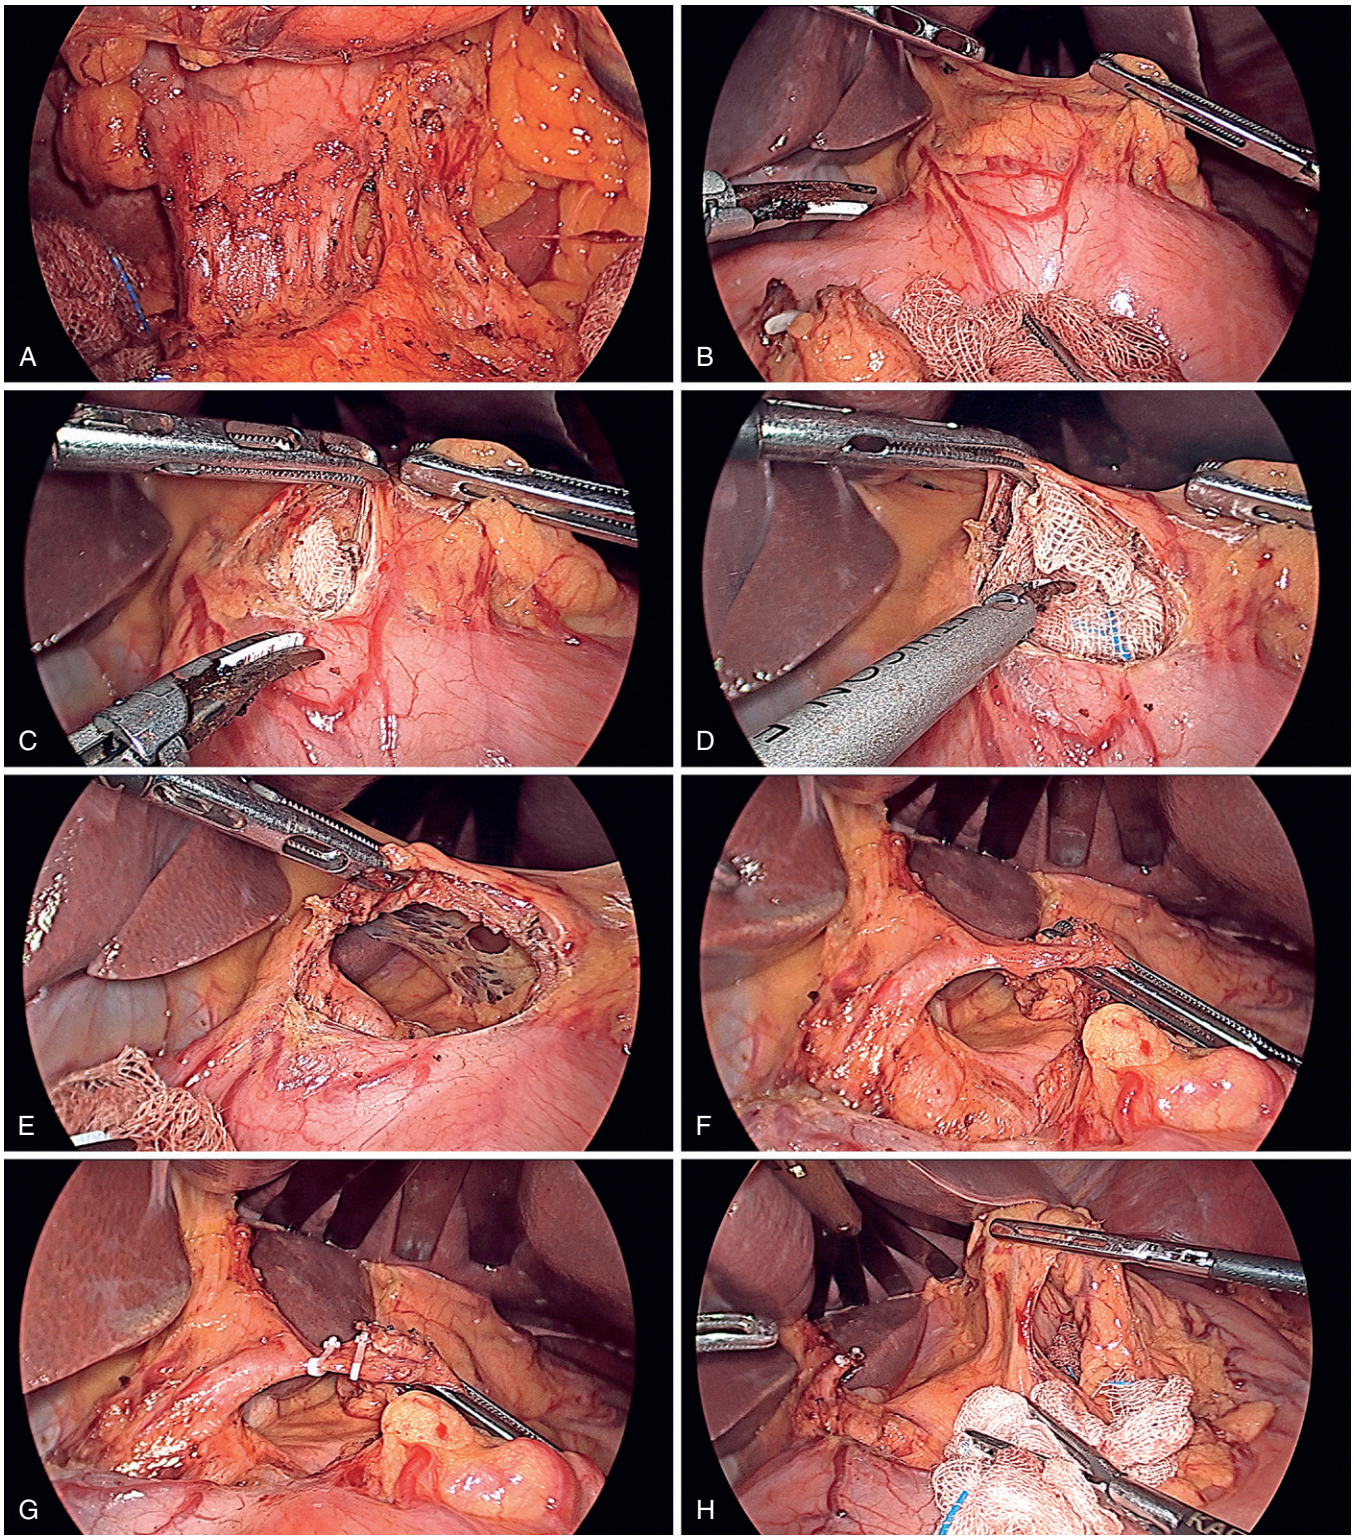

FIGURE 8 Dissection along GDA. **A,** Setup for suprapyloric dissection. **B,** Correct dissection. **C–E,** Opening space between RGA and duodenum. **F,G,** RGA dissected and ligated. **H,** set up for suprapancreatic dissection. *GDA,* Gastroduodenal artery; *RGA,* right gastric artery.

Techniques of Billroth I Anastomosis

An extracorporeal Billroth I anastomosis is commonly performed in one of two ways: modified double-stapled circular anastomosis (favored by the authors) and a side-to-end circular anastomosis through the posterior gastric wall.

Extracorporeal Modified Double-Stapled Circular End-to-End Gastroduodenostomy

A 5-cm transverse mini-laparotomy in the epigastrium is used to perform an extracorporeal anastomosis and to remove the specimen (see Figure 5). The distal stomach and proximal duodenum, as well as dissected LN stations, are first retrieved from the abdomen (Figure 10, *B*). A size 0 Prolene (Ethicon, Somerville, NJ) purse-string suture is applied to the proximal duodenum with a purse-string clamp, and the duodenum is transected just distal to the pylorus (Figure 10, *C*). The anvil of a 28-mm or 31-mm circular stapler is secured into the duodenal stump (Figure 10, *D*). The proximal resection line is determined by palpating the clips or sometimes the tumor itself. A gastrotomy is made, on the specimen side, between two stay sutures on the side opposite to the tumor; direct visualization of the clips or tumor confirms its location (Figure 10, *E*). The stomach is then partially transected, beginning at the greater curvature (Figure 10, *F*). During this first firing of a 60-mm linear stapler, it is imperative that the line of transection be as perpendicular to the greater curvature as possible and that enough of a gap is left medially for passage of the circular stapler. The circular stapler is introduced through the gastrotomy and into the proximal stomach (Figure 10, *G* and Figure 11, *A*). The stapler shaft and the distal stomach are rotated 180 degrees clockwise, and the trocar is advanced so as to penetrate the very corner of the staple line at the greater curvature of the remnant stomach, which is the longest part of the remnant stomach Figure 10, *H-J* and Figure 10, *B*. Rotation and downward angulation of the stapler then allows engagement of the trocar to the previously secured anvil (Figure 10, *K*). Prior to firing of the stapler, the linear staple line should be maneuvered to a 9 o'clock position, forming the new lesser curvature (Figure 10, *L*). Finally, using a 100-mm linear stapler, the

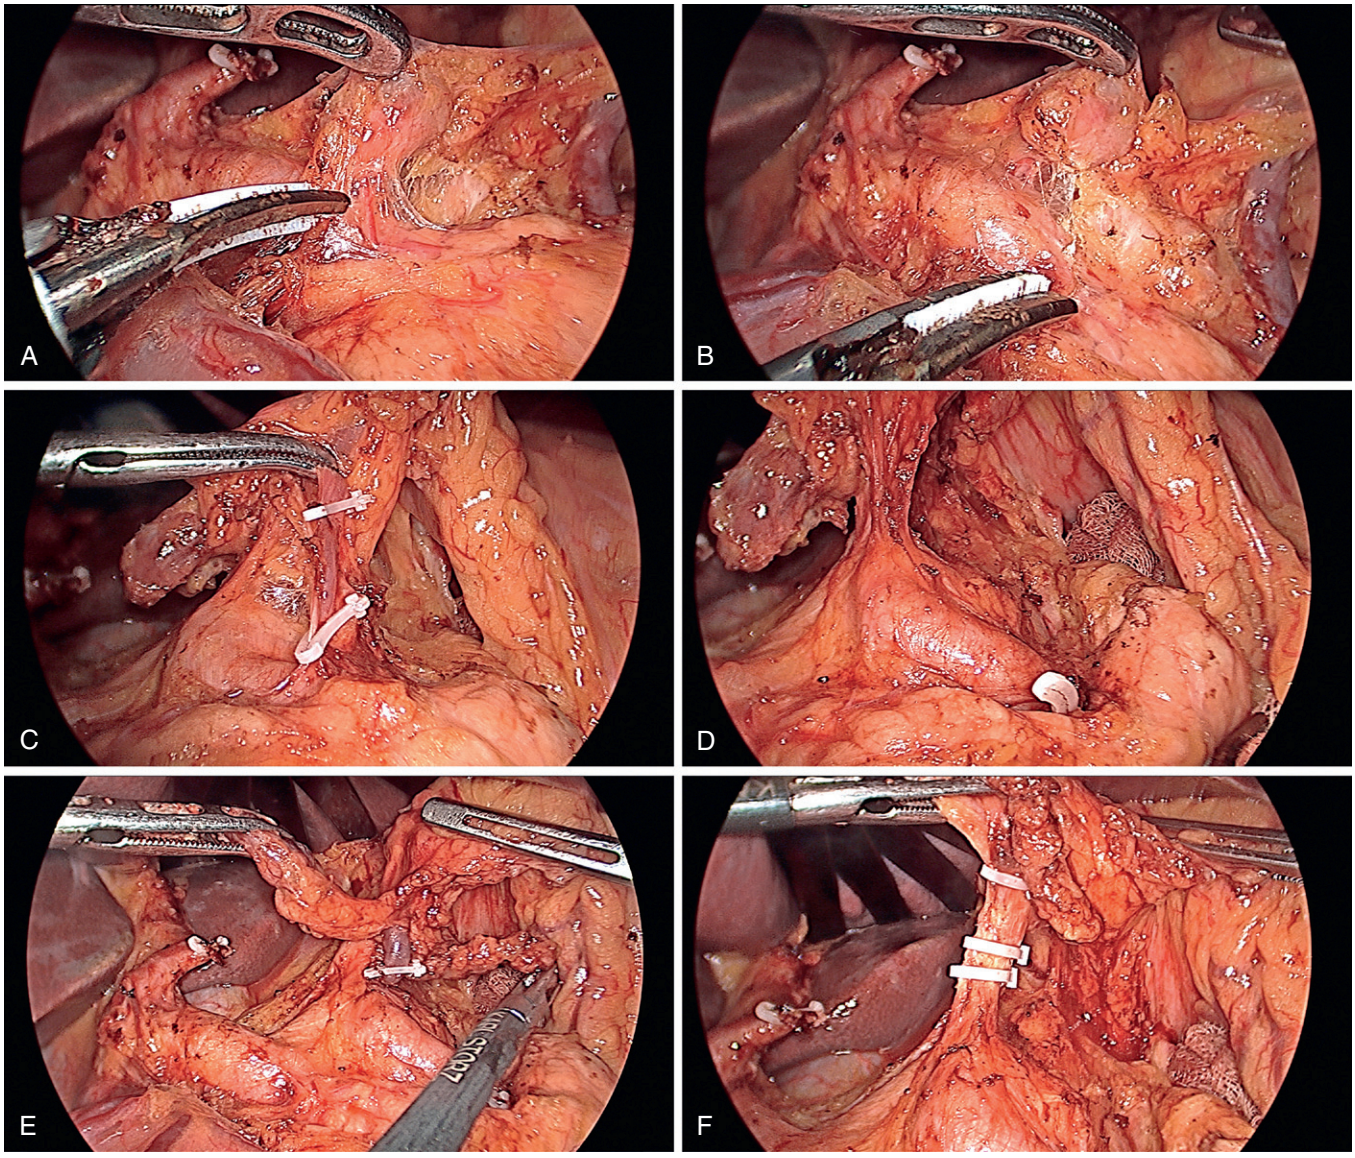

FIGURE 9 **A, B,** Correct dissection plane along CHA. Note the parallel approach of ultrasonic shears along CHA. **C–D,** Coronary vein and proximal part of splenic artery. **E,** Lifted lymph nodes from CHA and SA. **F,** Ligated LGA.

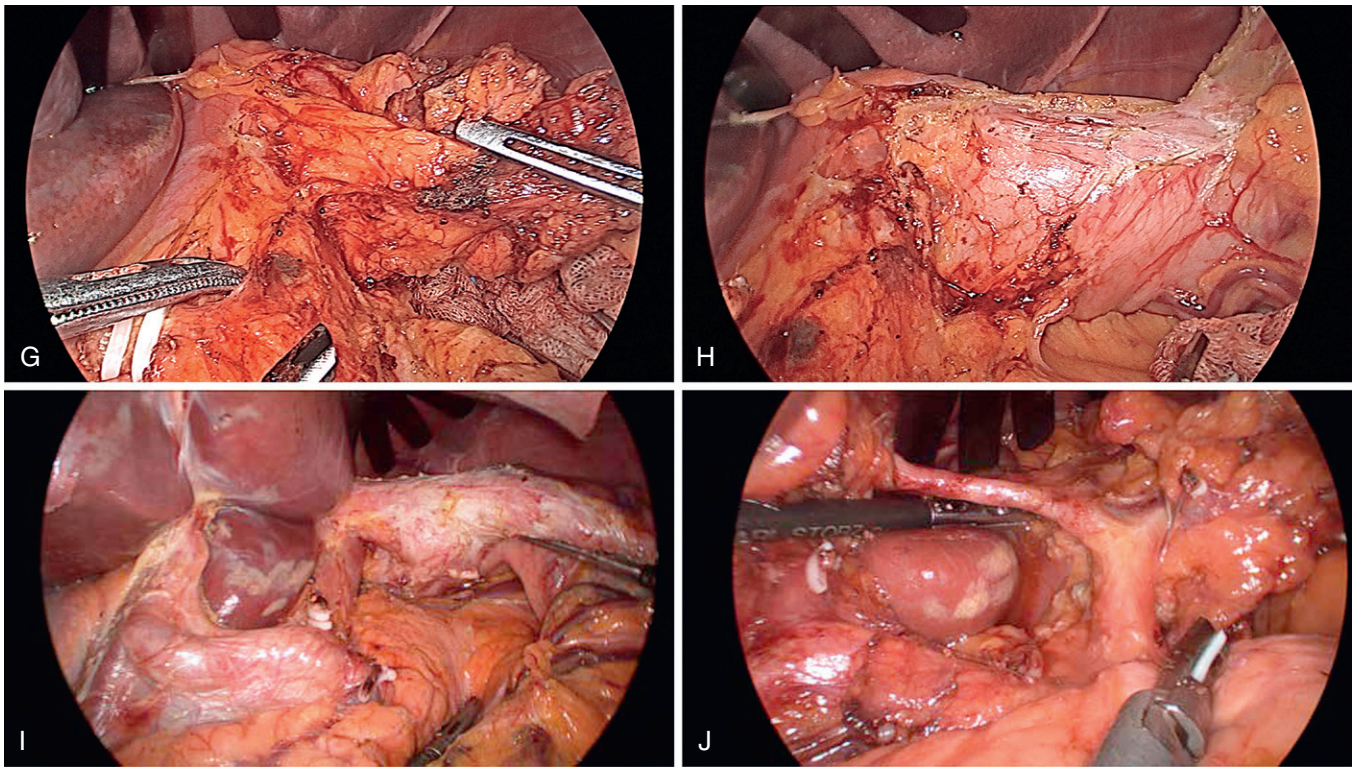

FIGURE 9, cont'd **G,H,** Along the cardia and lesser curvature. **I,** Completed LN dissection. **J,** Preserved replacing left hepatic artery originating from LGA. *CHA,* Common hepatic artery; *SA,* splenic artery; *LGA,* left gastric artery.

lesser curvature side of the proximal stomach is transected toward the gastroesophageal junction with inclusion of the apex of the initial linear staple line into the specimen (Figure 10, *M* and Figure 11, *C* and *D*). The specimen is processed on a back table to assess resection margins. Margins are sent for frozen section routinely. Pneumoperitoneum is reestablished with a glove over a wound protector. After hemostasis has been established, the peritoneal cavity is irrigated and a closed suction drain is placed prior to closure (Figure 10, *N*).

Extracorporeal Side-to-End Circular Gastroduodenostomy

In this method, the duodenal stump is prepared in the same way as it is in the extracorporeal modified double-stapled method. The stomach is then partially transected from the greater curvature side between two clamps, and the transection is completed on the medial side of the stomach with a linear stapler, leaving a transverse gastrotomy laterally. The specimen is checked for adequacy of resection margins on a back table. The circular stapler is then introduced through the gastrotomy and a side-to-end gastroduodenostomy created between the posterior wall of the stomach and the duodenum. The anastomosis should be located close to the greater curvature to reduce tension as much as possible. A gap of around 1 to 2 cm between the two staple lines is ensured to avoid an ischemic bridge of stomach wall. The initial gastrotomy is closed with a linear stapler. This technique is simpler to perform; however, it has greater potential for creating tension in the anastomosis, as the anastomosis is naturally placed slightly more proximally.

Intracorporeal Delta-Shaped Gastroduodenostomy

The stated advantages of an intracorporeal anastomosis include less pain (no upper abdominal mini-laparotomy), improved exposure during the anastomosis (especially in obese individuals), and better cosmesis. However, it is technically more challenging, with numerous potential pitfalls, and requires more firings of the stapler (at least six). Because of the absence of a mini-laparotomy, intraoperative tumor localization poses another challenge. Therefore, this modality is usually limited to distal antral lesions unless an alternative method of intraoperative localization (such as intraoperative gastroscope or intraoperative simple abdomen with metal clips applied near the preoperative clips at the margin of the tumor) is employed. There is also greater potential for uncontrolled spillage of intragastric fluid in a totally laparoscopic approach. The authors' study demonstrated that intragastric luminal cytology was positive even in early gastric cancer and that this positivity increased after surgical maneuver.

For this technique, the duodenum and the stomach are transected with 60-mm linear staplers introduced through a 12-mm assistant's left-hand port. The specimen is removed, with a large plastic bag, through an extended umbilical incision. There are two key points in avoiding anastomosis-related complications. One is to transect the duodenum from the posterior wall to the anterior wall, instead of in the usual craniocaudal direction. This is important in preserving the vascularity of the duodenal stump as well as adequate duodenal cuff for the anastomosis. The other key point is to ensure wide-enough angles between staple lines when performing the gastroduodenostomy (with a 45-mm stapler) by everting the first two staple lines. A safe fallback option in the event of a major intraoperative mishap is conversion to either a Billroth II or a Roux-en-Y gastrojejunostomy.

Billroth II Reconstruction

There are several aspects to be considered when performing a gastrojejunostomy in an LADG. It can be performed extracorporeally (via an upper midline mini-laparotomy) or intracorporeally. An extracorporeal anastomosis may be sutured or stapled with a linear stapler. The antecolic route is easier and generally recommended. The

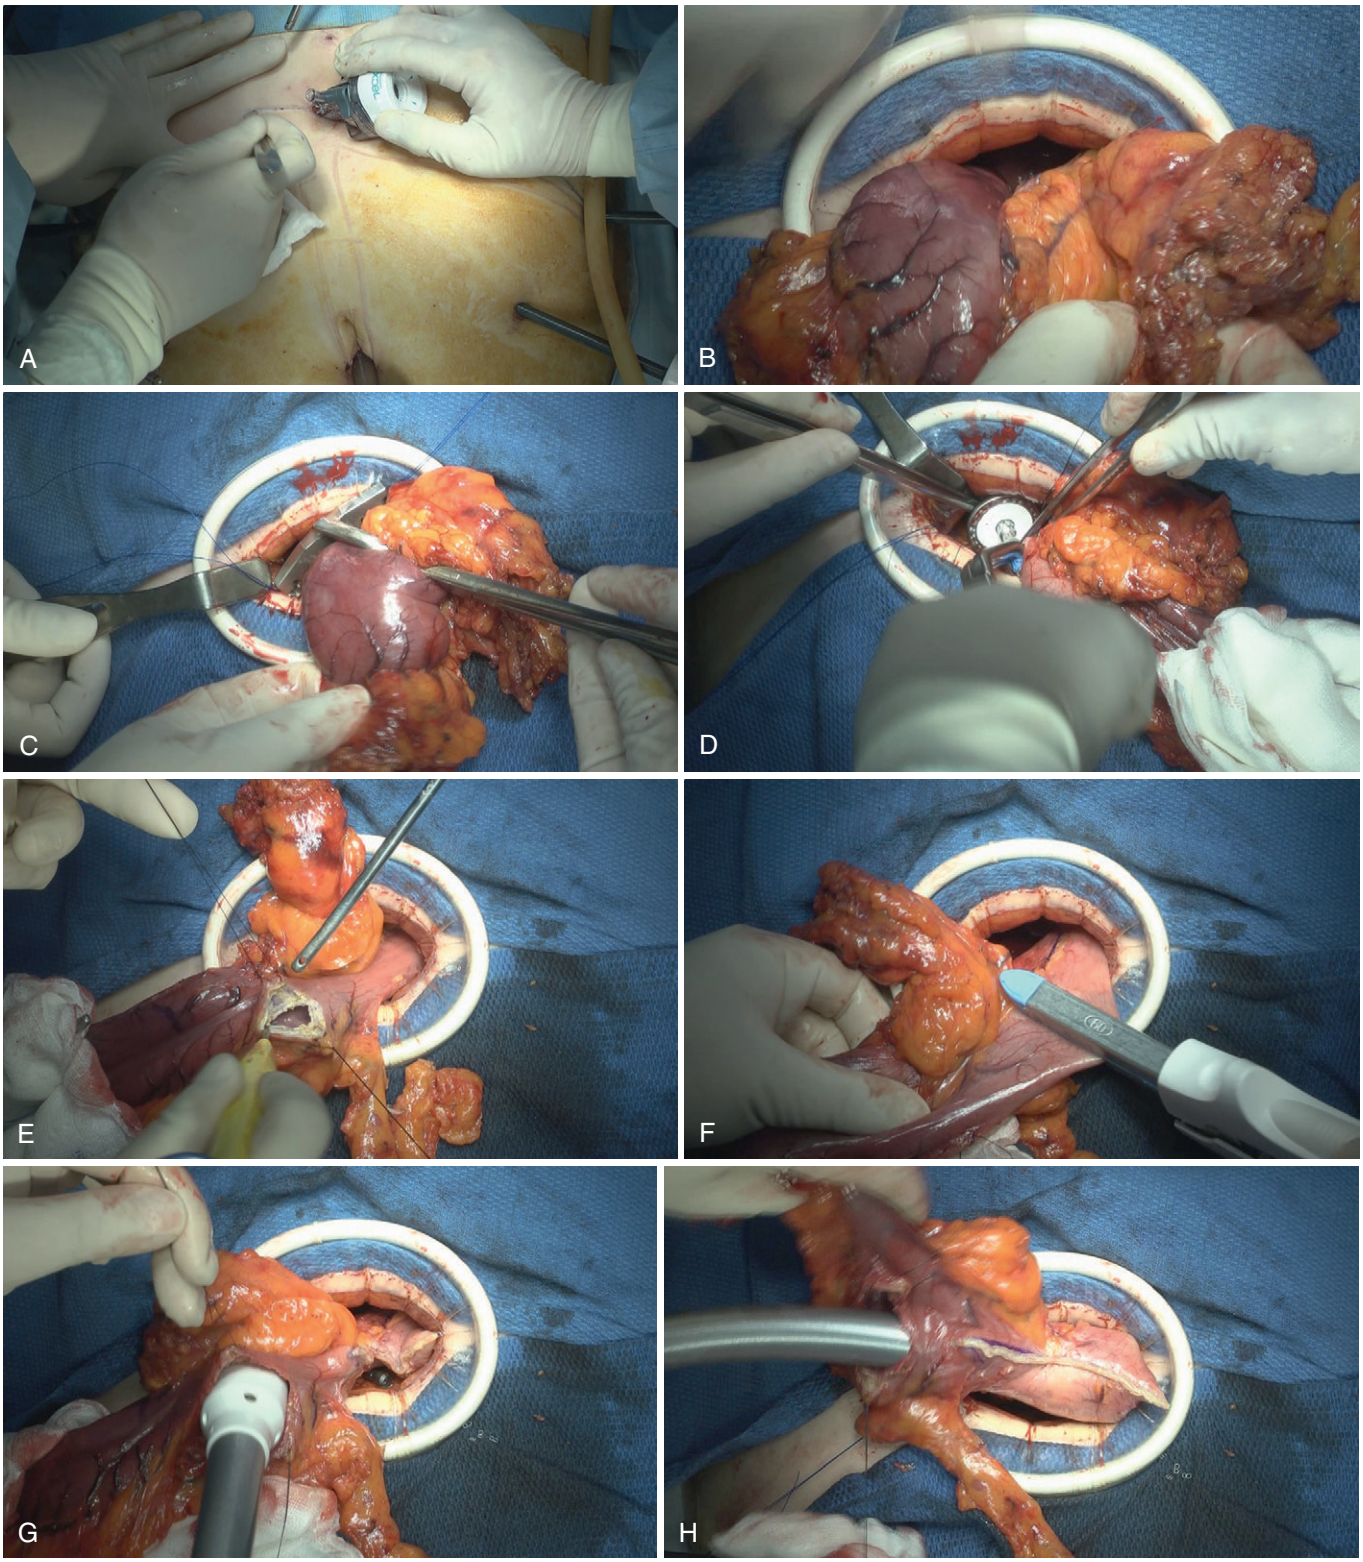

FIGURE 10 Extracorporeal modified double-stapled Billroth I anastomosis.

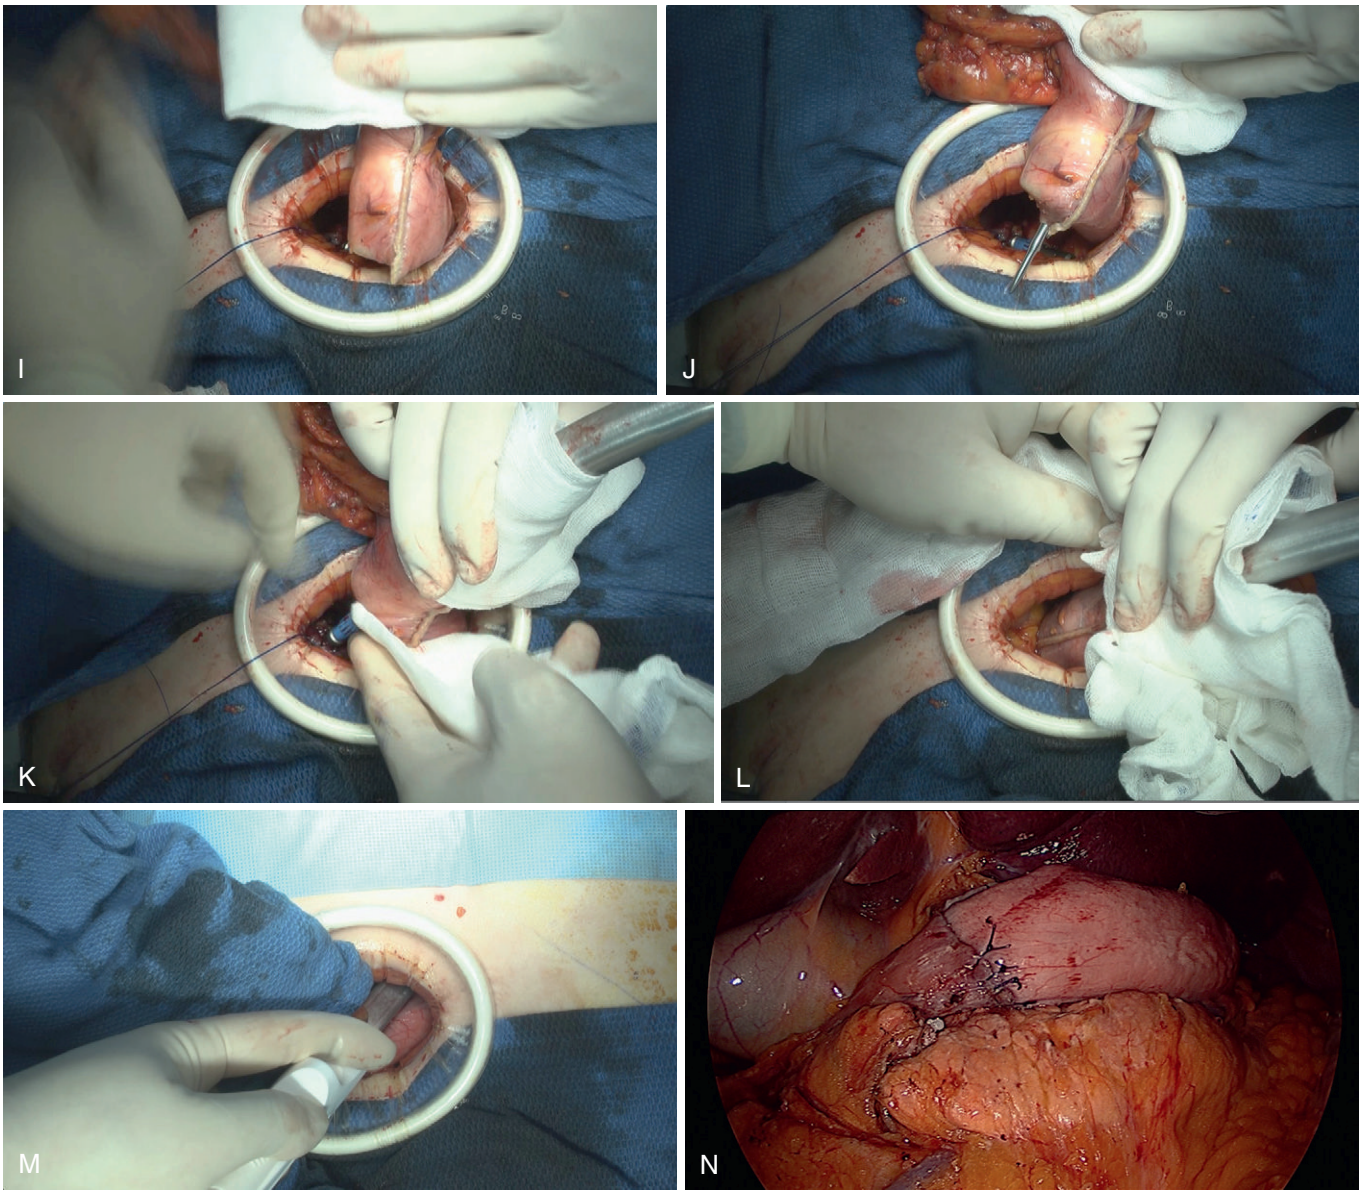

FIGURE 10, cont'd

posterior gastric wall adjacent to the greater curvature is the authors' preferred site for a stapled anastomosis. The jejunal loop can be aligned in either an isoperistaltic or an antiperistaltic manner. If the remnant stomach is small, a Braun anastomosis (a side-to-side jejunojejunostomy connecting the afferent and efferent limbs) can be added to decrease the incidence of bile reflux gastritis.

With a stapler to close the common entry hole in a stapled isoperistaltic anastomosis, the efferent limb can potentially be narrowed, especially if the staple is fired in a longitudinal manner. To avoid this problem, the initial enterotomy should be made as small as possible and the common entry should preferably be sutured close or else stapled in a transverse manner. Minor narrowing of the afferent limb in an antiperistaltic reconstruction may be inconsequential; however, significant narrowing can lead to a duodenal stump leak. If the remnant stomach is very small, a Roux-en-Y reconstruction is preferred, as this minimizes tension at the anastomosis and reduces the incidence of bile reflux esophagitis.

Roux-en-Y Reconstruction

Many of the discussions for a Billroth II reconstruction also apply to the Roux-en-Y reconstruction. For example, a Roux-en-Y reconstruction may be performed entirely laparoscopically or via a mini-laparotomy (upper midline or a left upper quadrant transverse), and the gastrojejunostomy can be similarly stapled or sutured, usually in an antecolic and isoperistaltic manner. Additional considerations include length of the Roux limb (25 to 30 cm is considered ideal for a distal gastrectomy to minimize both bile reflux and Roux limb stasis syndrome); potential to mistake the alimentary limb for the biliopancreatic limb; and potential for future internal herniation.

A Roux-en-Y reconstruction via a mini-laparotomy is described briefly, covering salient points. As in a Billroth II reconstruction, the duodenum is divided prior to the suprapancreatic dissection, which significantly improves the exposure. Following completion of LN dissection, in a Trendelenburg position, the proximal jejunum is

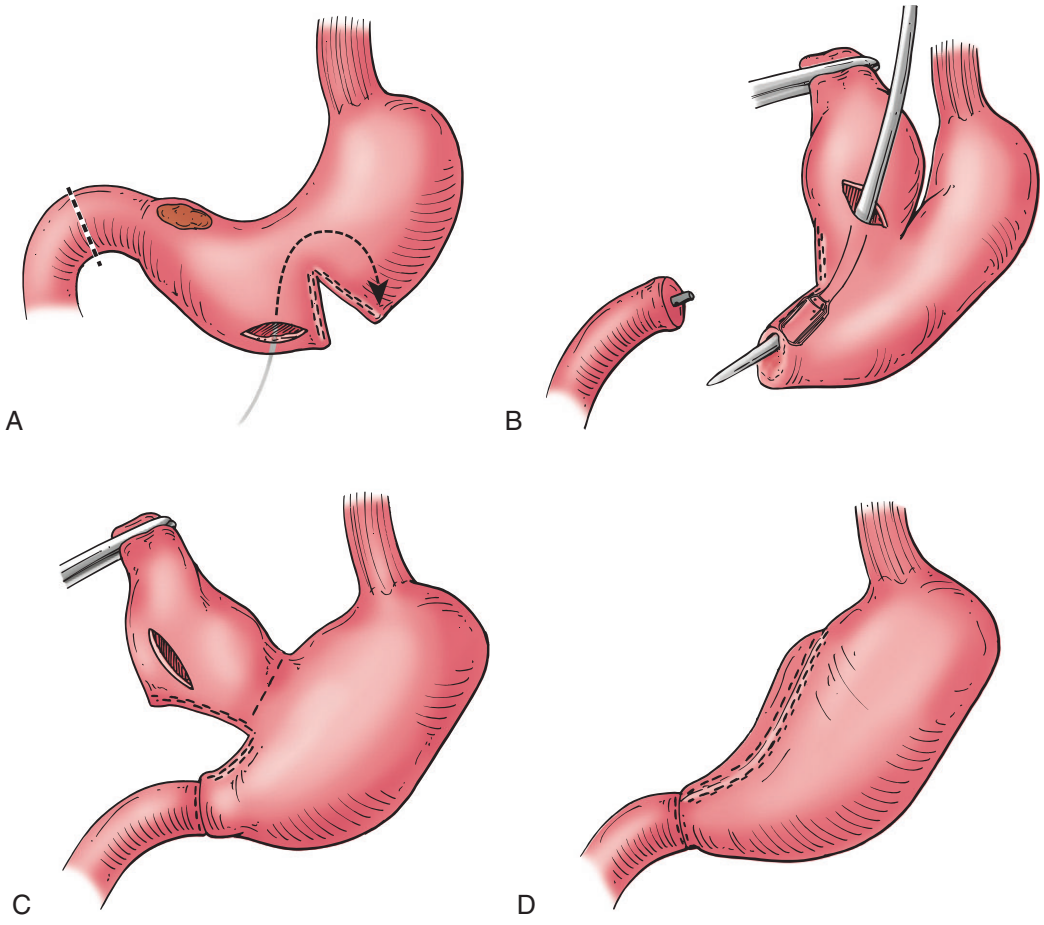

FIGURE 11 Schematic diagram of modified double-stapled Billroth I anastomosis. *(From Yang HK, et al: Safety of modified double-stapled end-to-end gastroduodenostomy in distal subtotal gastrectomy.* J Surg Oncol *96:624–629, 2007).*

oriented with respect to the ligament of Treitz, and a loop with adequate mesenteric length to reach the remnant stomach is selected. Following orientation marking of the jejunal loop with either ink or a suture and with the loop held between two graspers by the assistant, an upper midline mini-laparotomy is made. The jejunal loop is delivered and stay sutures placed. The stomach is divided with adequate proximal margin, which is confirmed by frozen section. The jejunum is then divided with a linear stapler. A formal mesenteric division is usually not necessary in a distal gastrectomy and is difficult to achieve safely through the mini-laparotomy. A side-to-side jejunojejunostomy is created, either hand-sewn or stapled, and the mesenteric defect is closed. A stapled side-to-side gastrojejunostomy, again using the posterior gastric wall close to the greater curvature, with preservation of the short gastric vessels, completes the reconstruction. Closure of Peterson's space is recommended and is best achieved laparoscopically following reestablishment of pneumoperitoneum.

SPECIAL CONSIDERATIONS

Laparoscopic Total Gastrectomy

Currently, the authors' clinical indications for a LTG include early gastric cancer located in or extending into proximal stomach where a distal or subtotal gastrectomy is not possible. Compared to laparoscopic distal gastrectomy (LDG), data on the feasibility and oncologic safety of LTG are so far lacking. A LTG is technically more demanding—particularly the reconstruction, which has not been standardized.

Many reconstructive methods for esophagojejunostomy are used, including end-to-side circular stapler and linear side-to-side (overlap) methods. One of the main difficulties of the circular stapling method is how to apply purse-string sutures for esophageal stump with anvil. Different laparoscopic purse-string suture clamps are being developed; transorally inserted anvil, OrVil (Covidien, Mansfield, Mass) is another option. Because of high morbidity after laparoscopic esophagojejunostomy, a phase II study (KLASS-03) has started in South Korea.

Total Omentectomy

Total omentectomy is indicated in advanced gastric cancer but is time consuming and technically difficult. Care must be taken to avoid thermal injury to the transverse colon, especially when diverticular disease is suspected. Tilting the table in the Trendelenburg position can help in cephalad retraction of the greater omentum during its dissection. After omentectomy, it is difficult to lift the stomach with the omentum. The hanging method, that is, pulling the stomach with wrapped gauzes around the antrum and the lower body, including the omentum, is effective.

Robot-Assisted Gastrectomy

Despite initial enthusiasm and widespread use, robot-assisted gastrectomy has not been shown to have significant additional benefit when compared with standard laparoscopic gastrectomy in terms of patient outcomes or cost-effectiveness. Articulating energy devices may provide benefit compared with a standard laparoscopic approach.

Laparoscopic Management of Crohn's Disease

Alessandro Fichera, MD, FACS, FASCRS, and Konstantin Umanskiy, MD, FACS

OVERVIEW

Despite significant advances in medical management of Crohn's disease (CD) with the introduction of immunomodulators and biologic agents in the late 1990s, patients with CD are still frequently referred for surgery; the lifelong need for surgery has been reported to be as prevalent as 82%. Patients with CD have traditionally been considered poor laparoscopic candidates because of the panintestinal nature of the disease, with "skip" lesions, inflammatory complications, and the use of aggressive and often medical management that increases the risk of postoperative complications. However, minimally invasive approaches have been developed for CD since 1990, and in single-institution retrospective small studies have been shown to improve cosmetic results and potentially reduce postoperative ileus and hospital stay. The impact of laparoscopy on short- and long-term recurrence rates has been poorly studied, and although small, single-institution studies, including the authors', have shown recurrence rates similar to those after open surgery, definitive large prospective studies to adequately answer this important question are lacking.

Modern principles of surgical management dictate that intestinal resections should be limited, without wide margins of normal tissue. Greater understanding of the clinical course of CD has led to a more conservative strategy, with surgery reserved for the treatment of complications of the disease and bowel-sparing approaches advocated. The indications for laparoscopic surgery for CD do not, and should not, differ from those for conventional open surgery (Figure 1). Relative contraindications to a laparoscopic approach include inability of critically ill patients to tolerate pneumoperitoneum because of

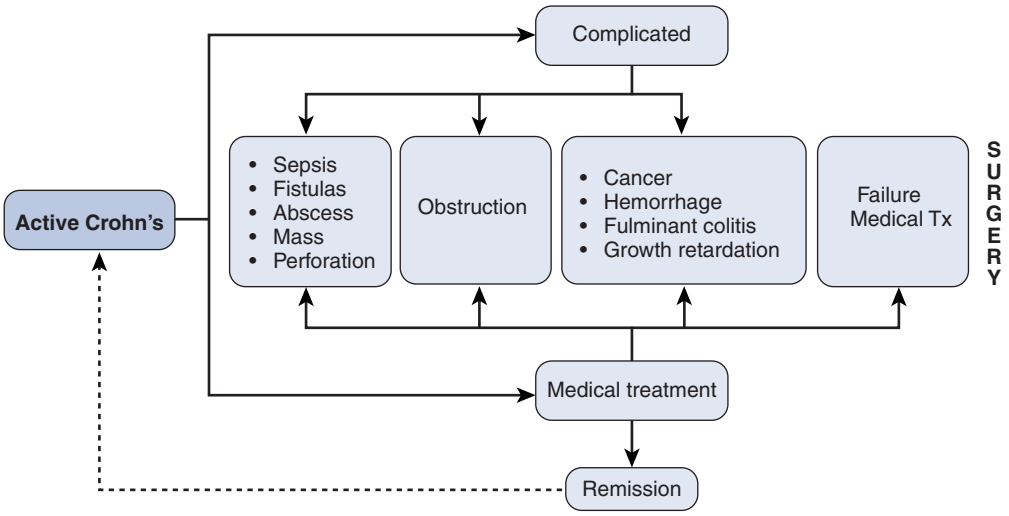

FIGURE 1 Indications for surgery in Crohn's disease. *(© 2009 University of Chicago.)*

hypotension or hypercarbia; the presence of dense adhesions or extensive intra-abdominal sepsis (abscess, free perforation, complex fistula); and difficulty in identifying the anatomy (previous surgery, obesity, adhesions). Because CD is commonly categorized according to the affected intestinal site, this chapter discusses the indications for surgery, surgical technique, and results as they pertain to the specific segment of the gastrointestinal tract.

STOMACH AND DUODENUM

Gastroduodenal involvement in CD is reported in only 2% to 4% of cases and is rarely confined to only the gastroduodenal segment, and 96% of patients have disease elsewhere. About one third of patients affected by gastroduodenal CD will require surgical intervention in their lifetime, most commonly for obstruction resulting from stenotic disease. Options for surgical management of complicated gastroduodenal CD include bypass, stricturoplasty, and, less frequently, resection. Although complex stricturoplasties and resections should be approached through a laparotomy, laparoscopy is a viable alternative in patients in need of a bypass. Traditionally, the "gold standard" for treating obstruction of the duodenum has been to bypass the duodenum via a gastrojejunostomy. An associated highly selective vagotomy is preferred over a truncal vagotomy to reduce the incidence of vagotomy-related diarrhea.

Operative Technique: Laparoscopic Gastrojejunostomy

Gastrojejunostomy can be performed in either an antecolic or a retrocolic fashion with a stapled anastomosis. If the colon is not involved, most surgeons prefer a side-to-side retrocolic approach, in which a window is made in the avascular plane of the transverse mesocolon to expose the posterior wall of the stomach. Care is taken to identify the middle colic artery to avoid injuring it. The most proximal loop of jejunum that lies tension free next to the greater curvature of the stomach is selected. Two stay sutures are placed to hold the stomach and bowel together, an enterotomy and gastrotomy are made, and the linear stapler is inserted and fired. The gastrotomy and enterotomy are closed with one or two layers of interrupted 3-0 sutures or with an additional firing of a laparoscopic stapler.

Outcomes

Although the available studies are very small, a more favorable experience with duodenal stricturoplasty, in comparison with bypass surgery for the treatment of duodenal CD, has been reported in terms of reoperation for recurrence and complications. However, if the duodenal stricture is lengthy, multiple strictures are present, or the tissues around the stricture are too rigid or unyielding, a stricturoplasty should not be performed, and an intestinal bypass procedure should be undertaken instead.

SMALL BOWEL

The small bowel is the most frequently affected gastrointestinal site in CD. Although any portion of the small bowel may be diseased, the terminal ileum is most commonly involved. Ninety percent of patients with CD of the small bowel experience symptoms resulting from obstructive or septic complications. A complete assessment of the gastrointestinal tract is mandatory prior to surgery to evaluate the full extent of disease and any associated complications that may require management before surgical intervention. Small bowel follow-through or enteroclysis can adequately assess the entire small intestine. CD is a relative contraindication for capsule endoscopy because of the high incidence of strictures. If the patient is seen initially with a fever or an abdominal mass, a CT scan should be obtained to assess for the presence of an intra-abdominal abscess amenable to percutaneous drainage.

Operative Technique: Laparoscopy-Assisted Small Bowel Resection

A planned small bowel resection is preceded by exploration of all four abdominal quadrants and the entire small bowel for evidence of coexisting CD, because up to 15% of patients will present with skip lesions. If areas of stenosis are suspected on serosal inspection, these should be marked with either an intracorporeal suture or a clip for subsequent identification upon exteriorization of the specimen. Matted loops of small bowel or omentum are often found adjacent to the diseased segment, especially if the terminal ileum is involved. Care must be taken to adequately mobilize the affected areas, and often mobilization of the ascending colon is needed. The matted loops of bowel can then be separated with a combination of blunt

and sharp dissection, and the area to be resected can be inspected extracorporeally.

Division of the thickened mesentery of the involved small bowel is often the most challenging aspect of the procedure. The introduction of hand-activated advanced bipolar laparoscopic devices that allow for safe control of vessels up to 7 mm in diameter has dramatically improved surgeons' ability to complete these operations laparoscopically. Although the anastomosis could be completed intracorporeally, the authors prefer to exteriorize the specimen to construct the anastomosis extracorporeally. The bowel may be anastomosed in an end-to-end, end-to-side, or side-to-side fashion with a handsewn or a stapled technique. In the authors' practice, the bowel is anastomosed in a double-layered, handsewn, either end-to-end or side-to-side fashion. Clinical data have not demonstrated a significant clinical benefit of one configuration over another.

Nonresectional options such as stricturoplasty have gained popularity as an alternative to lengthy resections in the treatment of stricturing CD of the small intestine. Laparoscopy-assisted stricturoplasty is particularly advantageous when it is associated with a bowel resection, usually an ileocolic resection. The diseased area or areas can be marked with intracorporeal stitches or clips, exteriorized through a small abdominal incision needed for removal of the resected specimen, and the stricturoplasty is performed extracorporeally in a standard fashion.

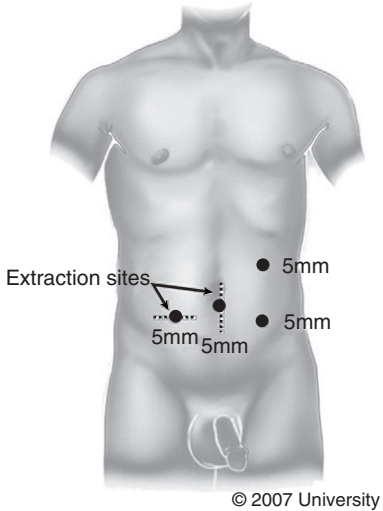

FIGURE 2 Trocar placement (on patient's left) and specimen extraction sites for ileocolic resection. *(Reprinted from Fichera A, Peng SL, Elisseou, NM, et al: Laparoscopic vs. open surgery in patients with ileocolonic Crohn's disease: a prospective comparative study,* Surgery *142[4]:566–571, 2007. © 2007 University of Chicago.)*

Operative Technique: Laparoscopy-Assisted Ileocolic Resection

Laparoscopy-assisted ileocolic resection is currently the most commonly performed laparoscopic procedure for CD. The patient is placed on the operating table in the modified lithotomy position. Every operation for CD, whether open or laparoscopic, should start with a complete examination of the entire gastrointestinal tract, starting from the ligament of Treitz. The patient is in the reverse Trendelenburg position and right lateral decubitus, with the assistant standing on the patient's left side, retracting the transverse colon into the upper quadrants, and the surgeon standing between the patient's legs, evaluating the intestine from the ligament of Treitz all the way to the ileocecal valve. This maneuver is facilitated by progressively rotating the patient from the reverse Trendelenburg to a full Trendelenburg position and left lateral decubitus.

Skip areas of involvement from CD are marked intracorporeally with sutures or clips to facilitate retrieval of the diseased segments when the specimen is exteriorized. A technique employing four 5-mm trocars is utilized (Figure 2). After the bowel has been evaluated in its entirety, the surgeon moves to the left side of the patient (Figure 3), and the assistant places the ileocolic pedicle under tension. The surgeon dissects the mesentery and divides the ileocolic vessels (Figure 4). The ascending colon is mobilized in a medial-to-lateral fashion in the submesenteric plane to the hepatic flexure (Figure 5), and the assistant lifts the colon to allow clear visualization of the submesenteric plane.

When the submesenteric mobilization is complete, the lateral peritoneal reflection is divided to the hepatic flexure (Figure 6). The terminal ileum is completely mobilized by dividing the peritoneum at the level of the pelvic rim to allow a tension-free anastomosis through a small incision. It is often necessary to completely mobilize the hepatic flexure to facilitate exteriorization of the specimen (Figure 7). The instruments are removed, and the umbilical port site or, occasionally, the right lower quadrant port site is enlarged for exteriorization of the specimen. In the presence of skip areas of disease marked intracorporeally, either a resection or a stricturoplasty is performed. In the presence of isolated disease of the terminal ileum, an ileocolic resection is performed with an extracorporeal anastomosis.

Outcomes

Several studies have now confirmed the short-term benefit of a minimally invasive approach in well-selected CD patients with elective, complex, and even recurrent small bowel and terminal ileal disease. The faster postoperative recovery in laparoscopic patients is due in part to the decreased use of intravenous narcotic pain medications. Resection with primary anastomosis can usually be performed with a high degree of safety, and small bowel anastomotic dehiscence rates can be kept to less than 1%. In spite of the technical challenges posed by the hyperemic and thickened mesentery, the risk of postoperative bleeding requiring surgical intervention remains very low.

COLON AND RECTUM

The indications for surgery for colonic CD should not differ between laparoscopic and conventional open surgery (see Figure 1). In the presence of multiple sites of colonic involvement, the decision to perform an ileorectal anastomosis or total proctocolectomy with an end ileostomy is determined by the degree of involvement of the distal sigmoid and rectum. Restorative procedures such as ileal pouch–anal anastomoses are typically not performed in patients with CD because of the high pouch failure rates. However, a small subset of patients—those with disease limited to the colon and rectum without any history of small bowel or perineal involvement—may be considered candidates for a restorative proctocolectomy with a J-pouch ileoanal anastomosis. In this highly selected group of patients, restorative proctocolectomy with ileal pouch–anal anastomosis has been performed with acceptable results.

Operative Technique: Laparoscopy-Assisted Total Abdominal Colectomy

The patient is placed in a modified lithotomy position, which is preferable to the supine position because it allows the surgeon to access the perineum and to stand between the patient's legs during the mobilization of the transverse colon. Both upper extremities are tucked along the side of the body with a draw sheet. The hand-assisted technique through Pfannenstiel's incision is the authors'

preferred approach. The presence of the surgeon's hand is particularly helpful in manipulating markedly inflamed or distended colon. Pfannenstiel's incision allows direct access to the pelvis for dissection, rectal transection, and anastomosis. If an end ileostomy is planned, the authors start with an incision at the ileostomy site and insert a 12-mm trocar, followed by a 5-mm camera port, at the umbilicus; a 5-mm trocar is inserted in the left lower quadrant. Otherwise the authors place a 5-mm camera port inferior to the umbilicus as the starting port for insufflation, followed by two additional 5-mm ports in the left lower and right lower quadrants.

Once pneumoperitoneum has been established, the feasibility of a laparoscopic approach is evaluated, and a hand-port device is placed in the suprapubic area (Figure 8). The small bowel is evaluated from the ligament of Treitz to the ileocecal valve to rule out small bowel involvement, and the right colon is mobilized as previously described. The mobilization of the transverse colon is facilitated significantly by use of the hand, but care must be taken to avoid injury to the duodenum and small bowel mesentery. Placing the greater curvature of the stomach under anterior and cephalad traction

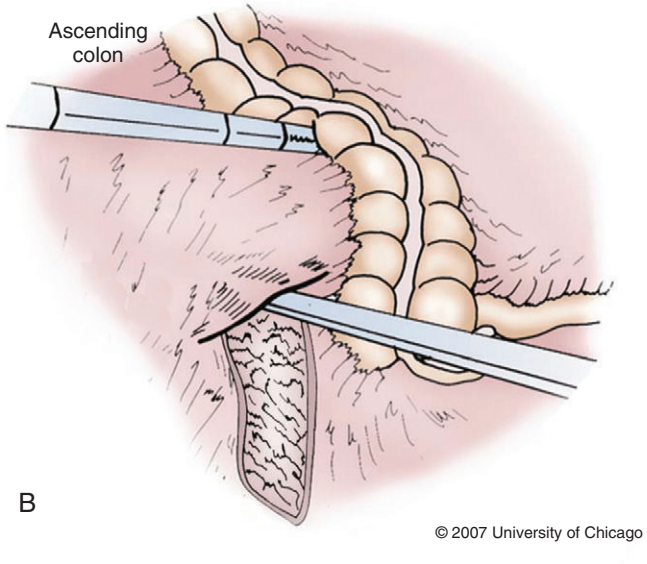

FIGURE 6 Division of the lateral attachments of the ascending colon. *(Reprinted from Michelassi F, Hurst RD, Fichera A: Crohn's disease. In Zinner MJ, Ashley SW [eds]:* Maingot's abdominal operations, *ed 11, New York, 2007, McGraw-Hill, pp 521–550. © 2007 University of Chicago.)*

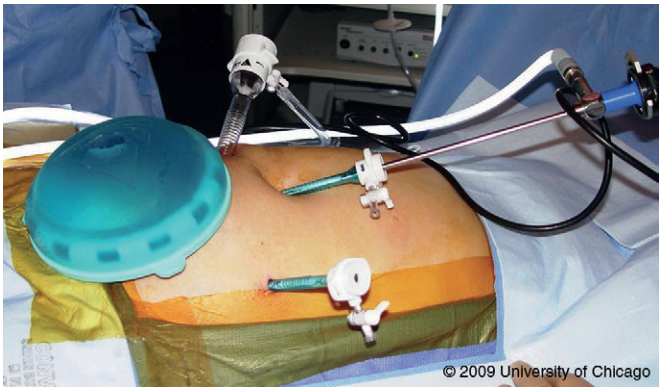

FIGURE 8 Port placement for hand-assisted total abdominal colectomy. *(© 2009 University of Chicago.)*

facilitates exposure of the gastrocolic ligament and entry into the lesser sac. The authors prefer to divide the greater omentum with the specimen, 3 to 4 cm away from the greater curvature of the stomach, taking care not to injure the gastroepiploic artery.

Next, the transverse mesocolon is divided with a bipolar vessel-sealing device after division of the greater omentum and exposure of the lesser sac; the mesocolon division proceeds from the hepatic to the splenic flexure. Chronically inflamed colon can become intimately attached to the inferior pole of the spleen, as the splenocolic ligament becomes foreshortened by inflammation. Traction on the colon or omentum could result in avulsion of the splenic capsule and result in troublesome bleeding that may require splenectomy.

It is imperative to keep the field as dry as possible with the use of a bipolar vessel-sealing device and precise and meticulous dissection. If necessary, the splenic flexure can be approached, so that the dissection alternates between the transverse colon moving distally and the descending colon moving proximally, thus minimizing traction on the spleen and the inflamed colon. The descending colon is then mobilized by division of its lateral attachments along the white line of Toldt and the mesentery.

Once the dissection reaches the level of the pelvic brim, the colon and terminal ileum are exteriorized through Pfannenstiel's incision. When a rectal-sparing technique is used, patients with diffuse colitis are candidates for a side-to-end ileorectal anastomosis, either stapled or handsewn, provided a close endoscopic examination confirms that the rectum is truly free of disease, fecal continence is satisfactory, and the patient does not have perineal complications. On the other hand, malnourished patients and those who are acutely ill should instead undergo an end ileostomy. A rectal tube is typically placed at the completion of the case for decompression of the rectal stump.

Operative Technique: Totally Laparoscopic Total Proctocolectomy

Extensive involvement of the colon and rectum or presence of dysplasia on surveillance colonoscopy requires a total proctocolectomy with permanent ileostomy. A totally laparoscopic approach virtually eliminates the risk of wound complication while providing the benefits of a minimally invasive approach.

The patient is placed in a modified lithotomy position, a 12-mm trocar is inserted at the ileostomy site, and four more 5-mm trocars are placed, as shown in Figure 9. The colon is mobilized

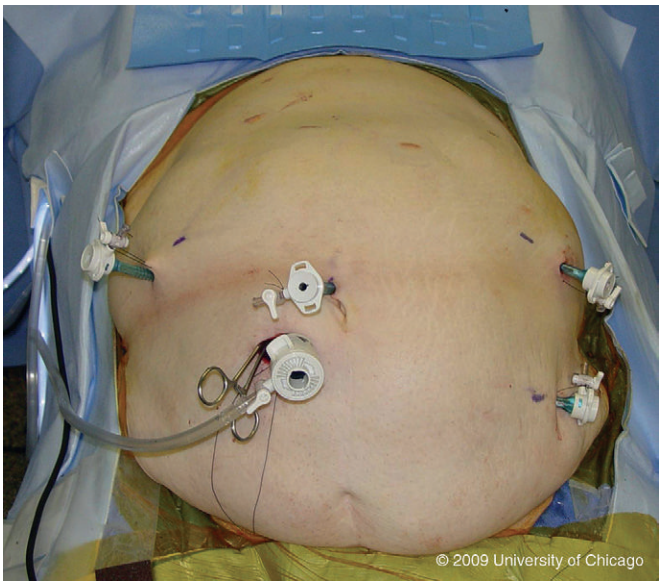

FIGURE 9 Port placement for a totally laparoscopic total proctocolectomy. The patient pictured has had a previous laparoscopic gastric bypass for obesity. The trocar sites in the upper quadrants are from the previous operation. *(© 2009 University of Chicago.)*

FIGURE 10 Perineal specimen extraction at the completion of a totally laparoscopic total proctocolectomy. *(© 2009 University of Chicago.)*

laparoscopically in a fashion similar to the hand-assisted approach described previously. The terminal ileum is intracorporeally divided and delivered through the ileostomy site. The superior hemorrhoidal pedicle is divided, after identification of the left ureter and gonadal vessels, and a totally laparoscopic proctectomy is performed in the avascular presacral space. The operating surgeon and the assistant holding the laparoscope stand on the patient's right, with the second assistant on the opposite side. The rectum is mobilized to the level of the levators, and identification of the pelvic sympathetic and parasympathetic nerves is indicated to avoid postoperative urinary and sexual dysfunction. An intersphincteric dissection is completed through the perineum, the specimen is extracted (Figure 10), and the perineal wound is closed in layers with absorbable sutures.

Outcomes

Adopted rather slowly, laparoscopic colectomy in CD is nevertheless welcomed by patients who are generally young and would prefer an operation that involves minimal scarring and prompt recovery. Furthermore, patients probably require operations over a lifetime, and so a minimally invasive approach is more appealing, as it results in minimal intra-abdominal adhesion formation. In the authors' own series of 55 laparoscopic colectomies for colonic CD, they found potential benefits in favor of laparoscopy with regard to operative blood loss and length of stay, in addition to obvious benefits of improved cosmesis and decreased risk of incisional hernia.

PERINEUM

The goal of surgery in anorectal CD is control of sepsis and relief of symptoms with preservation of continence. The initial approach involves a combination of drainage, seton placement, and intensive medical therapy. In selected patients, to achieve complete healing and control of sepsis, a temporary ileostomy should be considered. Another scenario for consideration of fecal diversion is the presence of active anorectal disease; although it puts the patient in need for proctectomy, it precludes definitive procedure, thus requiring creation of an end colostomy to control the sepsis prior to proctectomy.

When a temporary diversion is indicated, the authors prefer a diverting-loop ileostomy. An end-loop (Prasad) ileostomy can also be constructed, if diversion is likely to be required long term. An end-loop stoma allows for better pouching, as it is similar to the end ileostomy and can be reversed without the need for laparotomy. On the basis of the extent of disease, a permanent stoma could be either a colostomy or an ileostomy. Laparoscopy is currently the authors' preferred technique for fecal diversion with minimal morbidity. Moreover, laparoscopy provides useful information on the extent of disease. An initial incision at the stoma site is used to establish pneumoperitoneum and evaluate the abdomen. With the exception of emergency cases, every patient should undergo preoperative education and stoma marking by an enterostomal therapist.

Operative Technique: Laparoscopic Fecal Diversion

The authors start similarly for both colostomy and ileostomy. The patient is placed in a modified lithotomy position, and the stoma incision is made at the previously marked site. A 12-mm port is inserted, and a purse-string suture is used to cinch the anterior sheath around the port. Laparoscopic exploration is performed next to determine the feasibility of a laparoscopic operation and to determine the extent of disease. For a colostomy, the authors place two additional 5-mm trocars in the right lower and right upper quadrants, and a 5-mm infraumbilical port is placed for the 5-mm, 30-degree camera. The lateral attachments of the sigmoid and descending colon are taken down along the white line of Toldt, and the colon is mobilized to reach the abdominal wall at the stoma opening. Evacuation of pneumoperitoneum will add additional 3 to 4 cm of bowel length sufficient to help the stoma mature.

In the presence of a redundant sigmoid colon, very limited mobilization may be required. A very redundant sigmoid colon or the

presence of adhesions could present a potential challenge in orienting the distal and proximal limbs. Sigmoidoscopy and insufflation with carbon dioxide, which is absorbed rapidly, can aid proper orientation. If an end stoma is planned, the colon is transected intracorporeally, and the transected proximal end is delivered through the stoma opening. Proper orientation must be maintained; when oriented correctly, the mesocolon is caudad. The abdomen is then reinsufflated, and correct orientation is confirmed with the laparoscope. The colostomy is completed in the standard fashion with slight Brooke eversion to allow better pouching.

Conversely, for an ileostomy the authors start at the stoma site as previously described and place two additional 5-mm trocars in the left lower and left upper quadrants, and a 5-mm infraumbilical port is placed for the 5-mm, 30-degree camera. The terminal ileum is identified by the visualization of the antimesenteric fat, the fold of Treves, and its connection to the cecum. It is essential to positively identify the terminal ileum to ensure correct orientation of the bowel. The ileum is then run proximally for at least 20 cm to ensure that an adequate length of healthy bowel is available. No mobilization of the ileum is usually required, as it almost always easily reaches the stoma site.

Once the bowel is correctly oriented, the loop of bowel is delivered through the ileostomy site. The authors orient the bowel so that the proximal limb is located cephalad and the distal limb is caudad. The abdomen is then reinsufflated, and correct orientation is confirmed with the laparoscope. Some authors advocate minimizing the number of ports used for laparoscopic diverting stoma, particularly for laparoscopic ileostomy. Although this approach can be quite tempting, establishing proper orientation of the bowel can be difficult, unless adequate visualization is achieved. The authors find it very helpful to place two 5-mm working ports on the opposite side of the abdomen to allow precise tissue handling and improved exposure, which results in an accurate orientation of the bowel. These benefits outweigh the minimal morbidity and cosmetic considerations of the 5-mm incisions.

Outcomes

The safety and efficacy of the laparoscopic approach for diverting ileostomy or colostomy is now well established. It is the authors' preferred method for fecal diversion.

SUMMARY

Although significant advancements have been made in the medical management of CD, surgical intervention is still required in the vast majority of patients to treat complications and palliate symptoms. Although CD has varying clinical manifestations that necessitate individualized treatment, the main goal of surgery in all individuals is to adequately relieve symptoms while avoiding excessive loss of bowel function or body disfigurement.

Laparoscopic Colon and Rectal Surgery

James W. Fleshman, MD, FACS, FASCRS

BACKGROUND

Even though a laparoscopic colectomy has been performed since 1990, some skepticism about its applicability to colorectal diseases still remains. This reticence is found most commonly in the community practice of colorectal surgery. Patients have not been demanding laparoscopic techniques as they had cholecystectomy and other procedures such as hernia repair. The use of the minimally invasive techniques in colorectal surgery is continuing to increase, but these techniques have not been universally adopted. In fact, in a 2011 survey of 123 expert colorectal surgeons, there was a wide variation in the use of laparoscopic techniques. Only 82% of the expert surgeons surveyed from in the United States professed to using laparoscopy as a primary technique, and only 66% of the experts in colorectal surgery outside of the United States advocated laparoscopy. The percentage of cases in which laparoscopic colectomy was performed increased from 2.2% in the National Inpatient Sample (an administrative database covering private hospitals) in 1996 to 31% in 2009. The increase in adoption of laparoscopic colectomy seemed to coincide in 2004 with the publication of data from the Clinical Outcomes of Surgical Therapy (COST) trial, in which laparoscopic and open colectomy for colon cancer were compared. Laparoscopic colectomy is being adopted most rapidly in urban teaching institutions that serve a highly insured population.

As training programs began adopting the laparoscopic technique, the finishing residents have taken their skills with them to the community hospitals and other teaching programs. As a result, laparoscopic colectomy has descended into the general surgery residency training program as standard of care and is no longer considered a fellow-level procedure. This adoption should continue to increase the utilization of laparoscopic colectomy. Stamos at the University of California, Irvine, in looking at the National Inpatient Sample of 117,177 patients, in 2009 showed an increase in the prevalence of laparoscopic colectomies to 42.6% of cases. This may actually be a

result of the publication of *the International Classification of Diseases,* 9th edition, which facilitated identifying the laparoscopic cases with a new code in 2008.

Reports of numerous randomized controlled trials of laparoscopic colectomy for cancer have improved the visibility of laparoscopic colectomy. The knowledge that laparoscopic techniques are safe, oncologically appropriate, and equivalent in outcome to open colectomy may have improved the surgical community's acceptance of and confidence in colectomy for cancer. The majority of colon cancers are still treated with open operation in nonacademic hospitals and by general surgeons across the country. Obtaining the skills verified by credentialed surgeons in controlled trials is possible at numerous training courses around the country. Most of these are based on cadaveric models. As these newly trained individuals adopt these techniques and perform this procedure on patients with colon cancer, it may become of benefit in treating other diseases. Oncologic outcome after laparoscopic colectomy for cancer is equivalent to that after open technique, but there is an improvement in short-term outcomes. The original concern over an increase in trocar site implantation is no longer valid if an appropriate technique is utilized. Decreased length of hospital stay, decreased pain, and fewer early complications (surgical site infections) are all benefits. Over the long term, the risk of small bowel obstruction and abdominal incision hernia decreased after laparoscopic surgery.

OPERATIVE PRINCIPLES AND TECHNICAL PEARLS

The approach to a colectomy is not always standard and, depending on the disease process, the surgeon may require comfort or experience with different approaches to remove a portion of the intestine. In severe inflammation or extensive cancer with regional progression, a combination of approaches may be required. A simplified classification of these approaches includes a medial-to-lateral approach, a lateral-to-medial approach, superior-to-inferior and inferior-to-superior approaches, and a posterior approach. Each of these approaches can be used in an open procedure to allow exposure of the point of maximum disease at the end of dissection in order to prevent tumor spill or contamination from the inflammatory process. Learning all of these approaches allows the surgeon to address more advanced disease and facilitates curative (R0) resection of cancer and appropriate cancer care for the patient.

The laparoscopic medial-to-lateral approach in the right colectomy can be performed either from a posterior aspect or from a transmesenteric approach. The posterior approach requires incising the peritoneum along the anterior surface of the right iliac vessels and entering the avascular retroperitoneal plane. This areolar tissue plane extends anterior to the ureter and major vessels and all the way behind the right colon, over the anterior surface of the kidney, outside the area curve of the second portion of the duodenum, and up to the level of the liver (Figure 1).

The posterior medial-to-lateral approach begins with the simple act of lifting the base of the cecum towards the anterior abdominal wall and incising along the right common iliac artery from the bifurcation of the aorta to the apex of the mesenteric attachment to the right lower quadrant retroperitoneum. This provides a safe reproducible view, or "critical view," for a right colectomy. The ureter, vessels, and duodenum can be protected and the dissection carried out in a bloodless plane, which limits the amount of energy needed for blood vessel control. Releasing the colon from the retroperitoneum allows the vessels to be identified and divided at the base of the right colon mesentery along the superior mesenteric artery. Appropriate mesenteric resection (total mesocolic excision) for cancer requires division of the feeder vessel at its origin (Figure 2).

The true medial-to-lateral approach begins by lifting of the ileocolic pedicle to facilitate the dissection at the base of the right colon mesentery along the superior mesenteric artery. The retroperitoneal avascular plane is entered after the peritoneal surface is incised along the superior mesenteric artery. This may violate the intact mesocolic envelope of the right colon if not performed exactly along the anterior surface of superior mesenteric artery distal to the origin of the ileocolic artery. Once again, the ileocolic pedicle is ligated at its origin in the patient being treated for cancer.

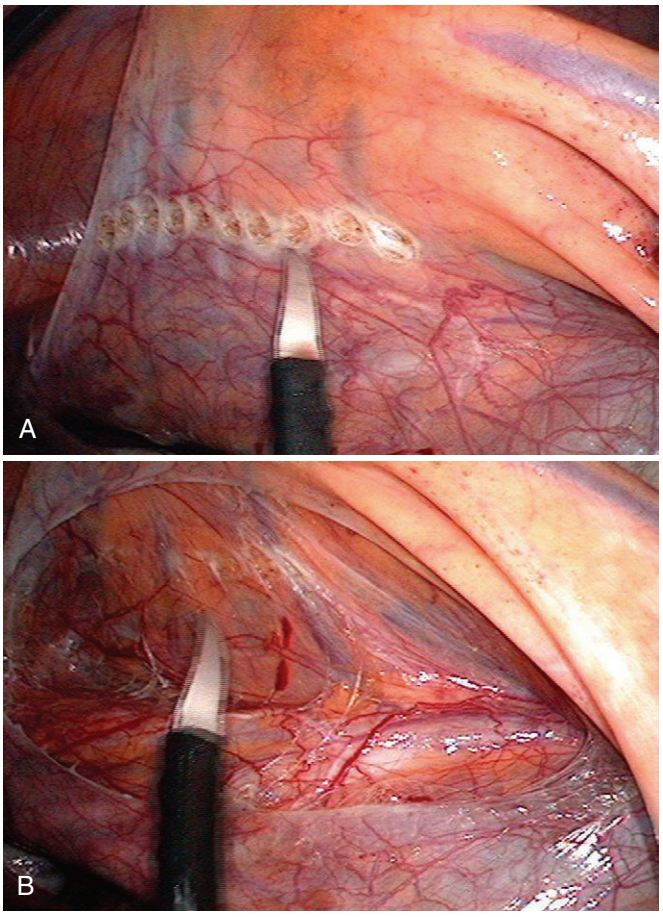

FIGURE 1 **A** and **B,** Laparoscopic medial to lateral approach to the right colectomy: operative images. *(From Fleshman JW, Birnbaum EH, Hunt SR, et al [eds]:* Atlas of surgical techniques for colon, rectum, and anus, *Philadelphia, 2012, WB Saunders.)*

The lateral-to-medial approach is sometimes needed when the tumor has spread down to the base of the mesentery of the right colon along the superior mesenteric artery and when the ileocolic origin is initially difficult to identify or the tumor grows into the retroperitoneal tissue. A lateral-to-medial approach begins with an incision along the right gutter to lift the right colon up toward the midline. The retroperitoneal plane is entered laterally, and the mesenteric envelope is preserved. This approach facilitates a release of the colon from the right side of the abdomen when the posterior aspect of the colon is adherent to the midline structures. The retroperitoneal plane must be uninvolved and free along the side wall the abdomen. Unfortunately, the lateral-to-medial approach pulls the bowel towards the camera, which enters through an umbilical part, and the view may be obscured as tissue is pulled toward the midline. This approach may require moving the camera to the suprapubic site, with a view toward the liver, and the dissection is performed with the surgeon standing between the patient's legs. The tissue is pulled toward the left side of the abdomen, and the working instrumentation originates through the suprapubic trocar site. The point of vascular ligation will need to be adjusted, in these situations, to allow complete removal of mesenteric disease. This may necessitate wider mesenteric resection and additional bowel removal as a result.

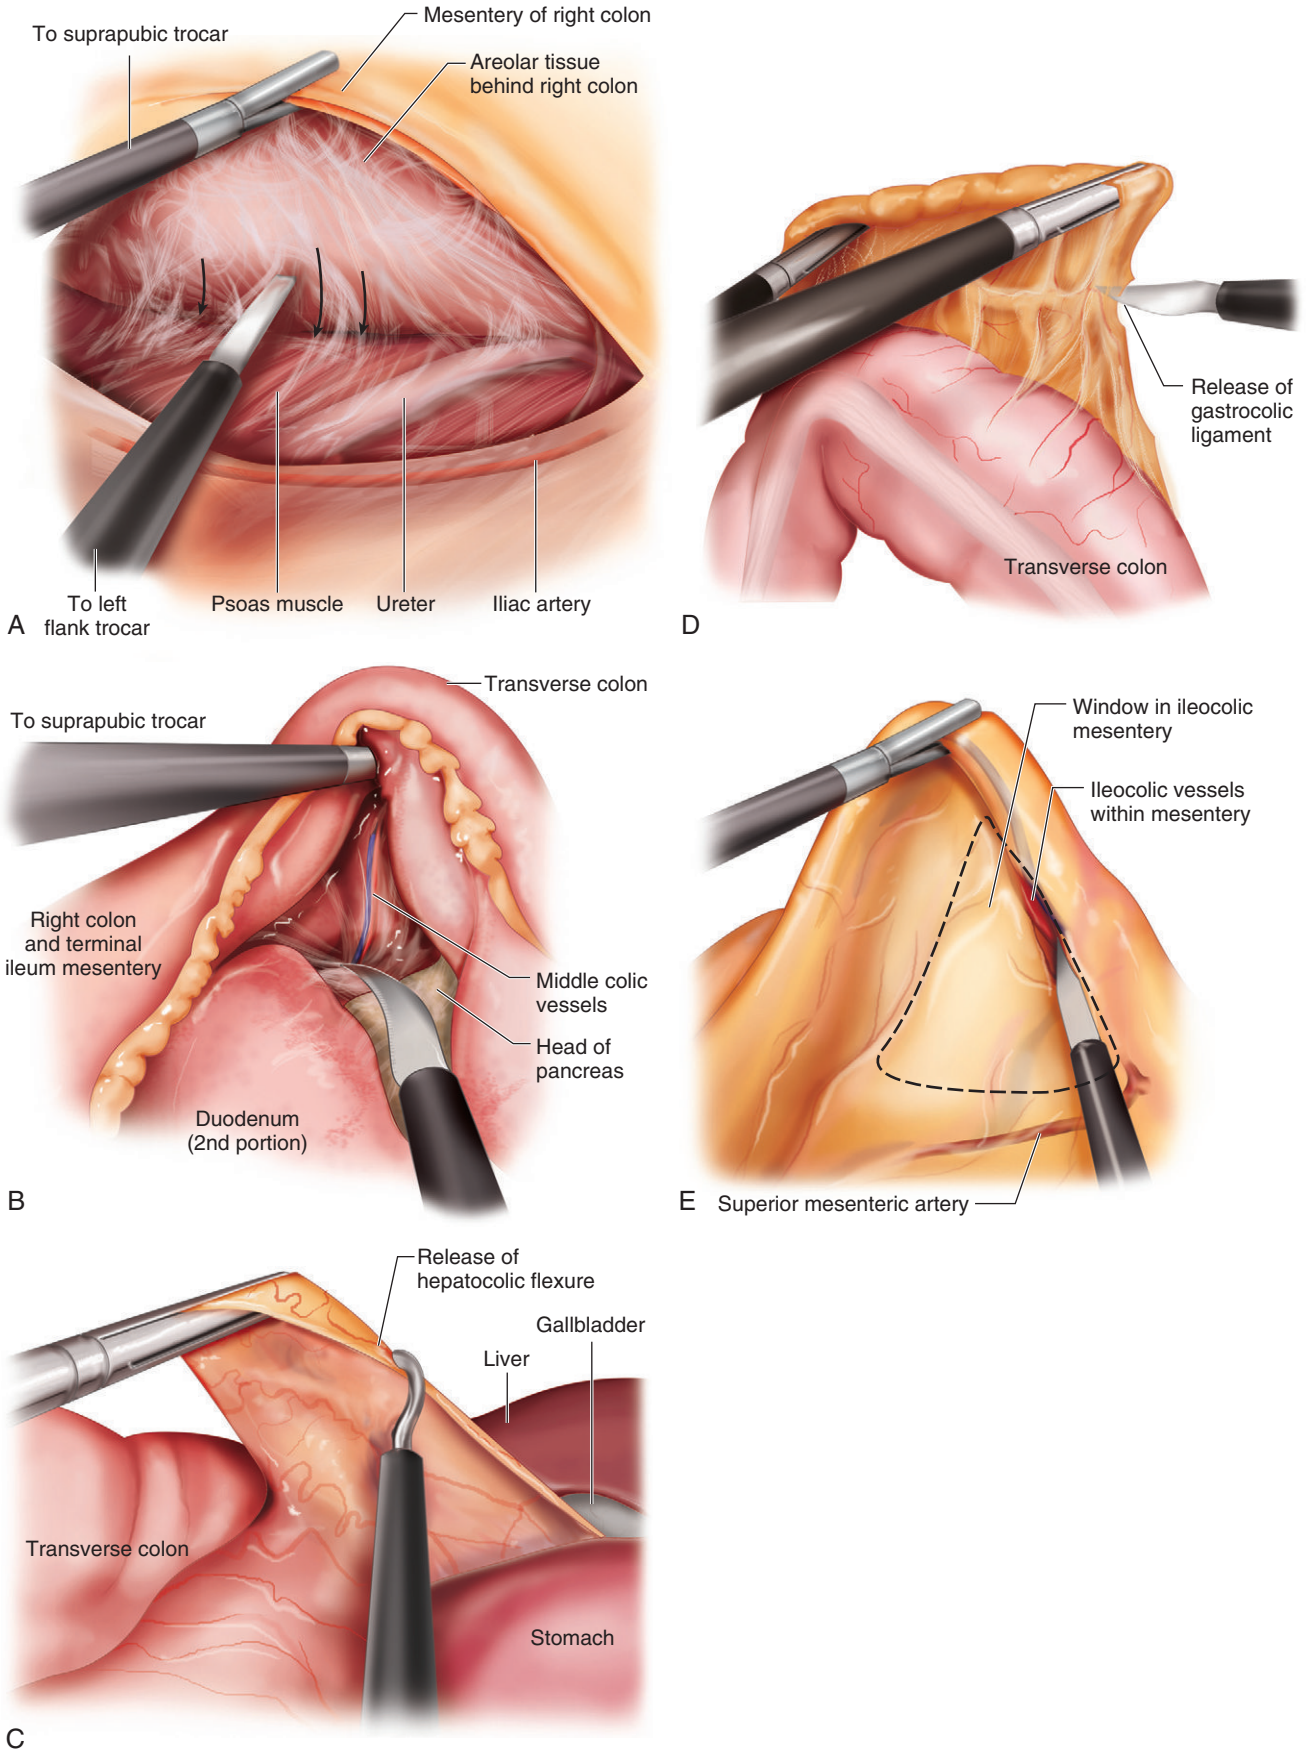

FIGURE 2 **A** to **E,** Laparoscopic posterior medial-to-lateral approach in the right colectomy: schematic views. *(From Fleshman JW, Birnbaum EH, Hunt SR, et al [eds]:* Atlas of surgical techniques for colon, rectum, and anus, *Philadelphia, 2012, WB Saunders.)*

The superior (not necessarily better) approach to the right colon is best suited for patients who have tumors or inflammatory process within the area of the cecum adherent to the pelvic brim, which precludes the posterior, lateral-to-medial, or the medial-to-lateral approach. The superior approach usually requires that the patient be placed in the steep reverse Trendelenburg position while still maintaining the left airplane position. The colon can be pulled from underneath the liver and released from the lateral side wall of the abdomen as tissue falls toward the midline. This maneuver has the advantage of lifting the right colon at the hepatic flexure off of the duodenum, pancreas, kidney, and retroperitoneum, leaving only the attachments at the pelvic brim. Once the ileocolic vessel is identified at its origin, it can be divided from the lateral approach, on the anatomic posterior aspect of the superior mesenteric artery. The attachments of the tumor and inflammatory process are dissected as the final maneuver.

Management of the mesenteric vessels of the right colon usually requires only division of the ileocolic vessel and possibly of a right colic vessel. The extraction of the right colon, with terminal ileum and hepatic flexure, through the abdominal wall allows selective division of the vessels at the extremes of the specimen appropriate to the disease process. It is not necessary to divide all of the blood vessels intracorporeally. Preferred extraction sites include midline at the umbilicus, transverse right upper quadrant, or right lower quadrant as needed. The standard approach, however, is usually to use the umbilical extraction site because the site is almost always positioned over the base of the middle colic and superior mesenteric arteries.

The approach to the left side of the colon can involve a medial-to-lateral, lateral-to-medial, and superior or inferior approach. The medial-to-lateral approach for a left colectomy is the same as that for a low anterior resection (Figure 3). An incision behind the superior hemorrhoidal artery at the level of the sacral promontory allows

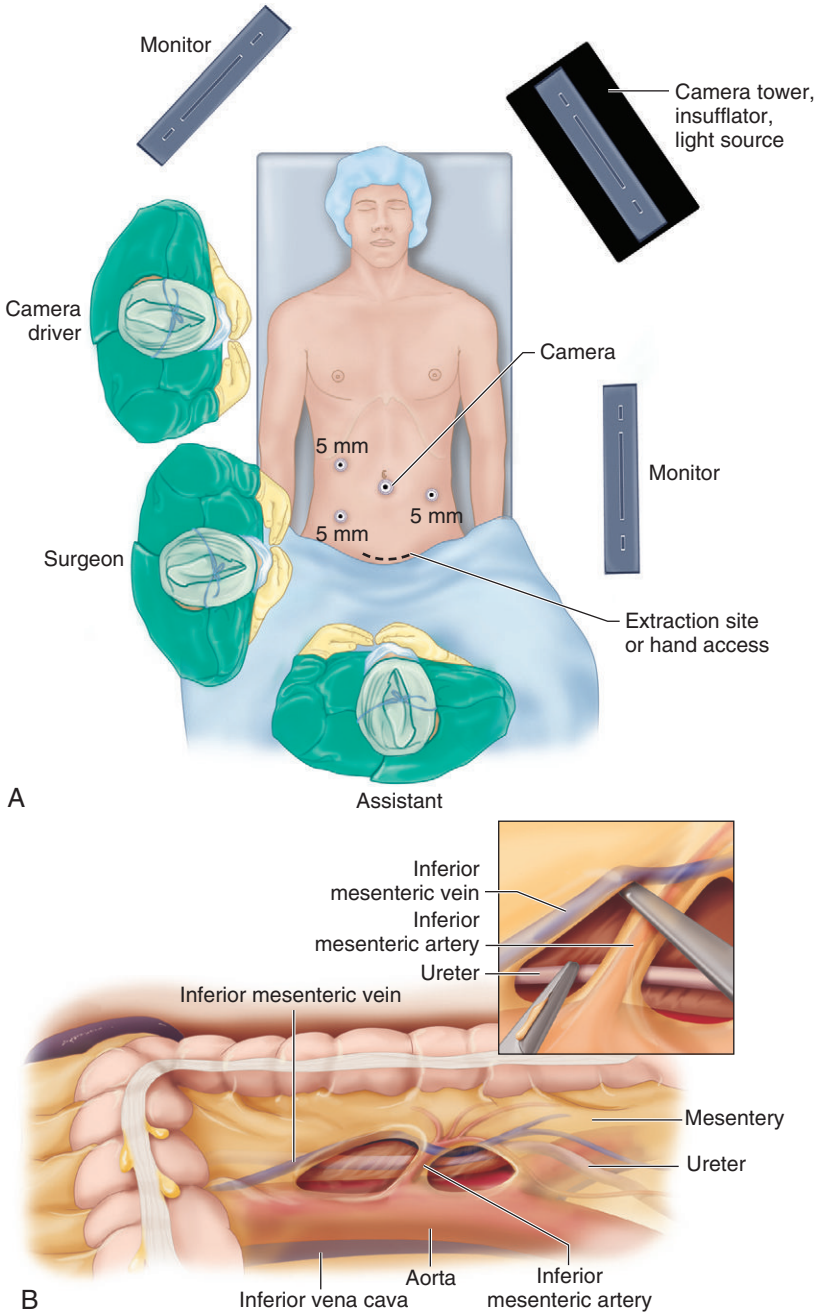

FIGURE 3 Laparoscopic left colectomy to isolate and legate inferior mesenteric artery. **A,** Operating room setup. **B,** Illustration of procedure. *(From Fleshman JW, Birnbaum EH, Hunt SR, et al [eds]:* Atlas of surgical techniques for colon, rectum, and anus, *Philadelphia, 2012, WB Saunders.)*

entry into an avascular plane over the retroperitoneum, which will protect the left ureter, the left common iliac vessel, and the gonadal vessels in that area. Dividing the inferior mesenteric artery at its origin with a sealing device or stapler can immediately release the left colic and sigmoid mesentery from the retroperitoneum. Blunt dissection in this plane all the way to the lateral side wall and up to the pancreas is possible because the embryologic plane has few blood vessels. The patient is positioned in steep Trendelenburg and airplane position to the right to allow gravity to remove the small intestine from the base of the left colon mesentery. The surgeon must remember to dissect in an "upward slope" direction to avoid digging into the retroperitoneal structures. As the dissection is continued toward the duodenum, the inferior mesenteric vein is found along the base of the mesentery. The inferior mesenteric vein is divided proximally at the portion of the vein, which dives behind the pancreas. The vein is transected just below the lower edge of the pancreas along the tail of the pancreas. Sealing or stapling of this vein then releases all of the left colon mesentery from the retroperitoneum. The advantage of the medial-to-lateral approach and dividing the inferior mesenteric vessels at their origin is that it also provides a medial approach to the lesser sac through the peritoneal membrane over the top of the pancreatic tail to create a window behind the stomach. The left colon and splenic flexure are then totally free from the retroperitoneum. The final attachments along the left side wall of the abdomen, which have been supporting the colon and providing countertraction, and the mesenteric attachments over the kidney are easily divided to release the entire colon to the midline.

The lateral-to-medial approach to a left colectomy results in the tissue's falling toward the camera and making it difficult to actually see behind the tissue as the colon is released, similar to the situation with a right colectomy. In circumstances in which an inflammatory process or a large tumor deposit with matted lymph nodes is present at the base of the mesentery, a lateral-to-medial approach may be appropriate. This dissection within uninvolved planes allows the surgeon to attack the worst areas of disease during the very last portion of the procedure and increases safety. The ability to utilize a combination of approaches is critical for the safety of the procedure.

The "superior" approach to the left colon begins with the patient in reverse Trendelenburg position, the release of the omentum from the antimesenteric surface of the transverse colon, and release of the splenic flexure from the attachments to the spleen, kidney, and pancreas (Figure 4). This then allows a lateral-to-medial approach or a medial-to-lateral approach to the base of the left colon mesentery, depending on whether a process prevents early management of the vessels or release of the mesentery from the retroperitoneum. This approach may also be preferred in patients with portal hypertension because collateral vessels around the splenic flexure and large collateral vessels along the omentum must be controlled early during the procedure to provide the safest approach in these patients.

Several techniques should be utilized to increase the safety of any laparoscopic colectomy. General safety maneuvers that should be applicable in all laparoscopic colectomy cases include the following:

1. Avoid grasping the bowel during retraction. Use only closed, blunt-tipped instruments to lift, sweep, push, or suspend it.
2. Always know what is behind the incision that is being made. Blind pushing or cutting is never safe unless the camera can show a clear space or anatomic consistency allows assumption of nonthreatening territory.
3. Never divide a vessel unless it can be immediately controlled if the sealing device fails. Place a grasper at the ready and in the camera field.

Fixation of a beanbag or a foam pad to the operating table, which cradles the patient on the table without risking pressure point nerve injury, is essential. The table is at extreme positions in Trendelenburg or airplane position in either direction and allows gravity to be utilized as the primary retraction mechanism during a colectomy. Reliance on instrumentation for grasping and displacement of intestine can potentially result in damage to portions of the intestine. A flexible-tip laparoscope allows visualization over the top, behind, or underneath structures and provides a view of tissue that would be potentially damaged if the posterior view were obscured. The ideal would be three-dimensional with a flexible tip to improve the depth perception of the operating surgeon. A smoke evacuator or an insufflator system, which functions at a high enough volume, is essential to remove the plume generated by energy devices. Radiofrequency sealing devices, harmonic energy, or mechanical vessel control are all appropriate and should be part of the armamentarium of the surgeon. Because not all devices do everything, familiarity with specific advantages and disadvantages of each is key to maintaining safety during these difficult cases. Instruments at least 45 cm long are preferred, especially if splenic flexure mobilization is a standard part of the technique. The distance of mobilization from the right lower quadrant all the way up to the hepatic flexure and from the pelvic

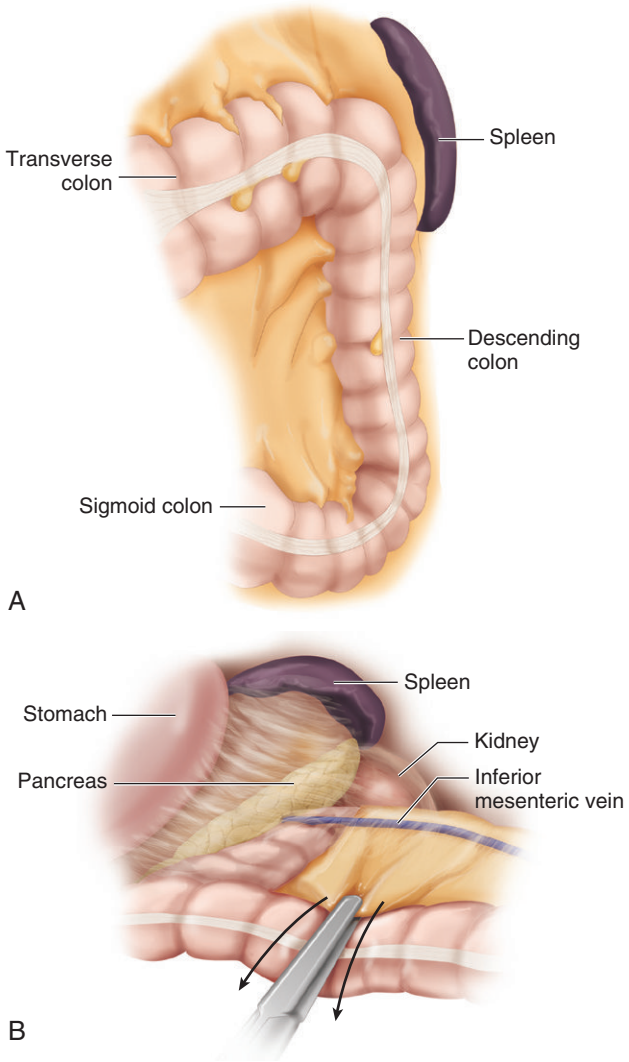

FIGURE 4 Exposure of the kidney. **A,** Anatomic relationships of the splenic flexure of the colon before mobilization. **B,** View of the splenic flexure area after release of the colon from the stomach and spleen. *(From Fleshman JW, Birnbaum EH, Hunt SR, et al [eds]:* Atlas of surgical techniques for colon, rectum, and anus, *Philadelphia, 2012, WB Saunders.)*

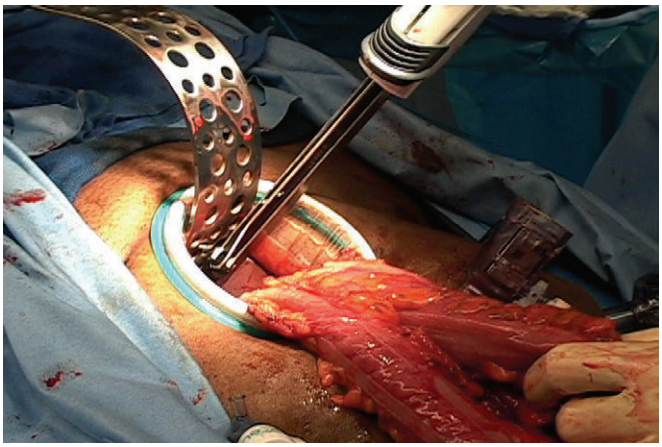

FIGURE 5 The rectosigmoid is transected through the access site at the level of the sacral promontory. *(From Fleshman JW, Birnbaum EH, Hunt SR, et al [eds]:* Atlas of surgical techniques for colon, rectum, and anus, *Philadelphia, 2012, WB Saunders.)*

brim up to the splenic flexure is sometimes very large in a male patient. The tips of instruments should be atraumatic and blunt; the wavy Raptor grasper is the most suitable. A Babcock tip is also preferred over a Kelly clamp–type instrument, which damages tissue with pressure.

At the extraction site of the specimen, a wound protector is recommended to prevent surgical site infection and to stretch the opening to its maximum without damaging the surrounding tissue (Figure 5). It is possible to insert small sponges through the extraction sites or hand access ports to improve visualization. Care must always be taken to remove each sponge before inserting another, rather than allowing them to accumulate in the abdominal cavity.

The use of robotics for colectomy has not been definitely shown to provide any advantage or safety over laparoscopy. The use of single-incision laparoscopic surgery (SILS), however, may have some advantage over multiport laparoscopy: SILS is very difficult to perform, requires a higher skill level, and requires longer operating times. Robotic SILS may be an answer to these technical difficulties. Time will tell.

Tattooing the disease site with India ink during colonoscopy for neoplasm has become the standard of care, even before laparoscopic colectomy. This is especially helpful in the setting of small lesions to be able to identify the site of the disease externally. A small nonpalpable cancer or polyp, which is identified colonoscopically, may not always be in the area reported by the endoscopist because of the telescoping of the bowel over the endoscope and the numerous twists and turns, which may result in overestimation of distance.

Hand-assisted laparoscopic surgery (HALS) is useful for addressing more complex disease processes and to help nonlaparoscopic surgeons to get started on minimally invasive surgery. The GelPort (Applied Medical, Rancho Santa Margarita, Calif) may be used to reduce the learning curve for surgeons who are not accomplished laparoscopic specialists. The use of HALS can be helpful to reduce the rate of conversion to an open procedure in the approach to more extensive disease, even by experienced laparoscopic surgeons. The short-term outcomes of HALS techniques have been shown to be equivalent to those of total laparoscopic approaches. However, limitation of the incision size on the abdominal wall or achieving a totally laparoscopic approach is the best way to achieve maximal benefit from a minimally invasive technique. HALS should be part of every surgeon's skill set to complete a laparoscopic case successfully.

Rectal dissection requires attention to anatomic detail to maintain dissection in the posterior avascular plane, outside the mesorectum as the preferred line of dissection (Figure 6). The embryologic avascular plane, which begins at the sacral promontory behind the

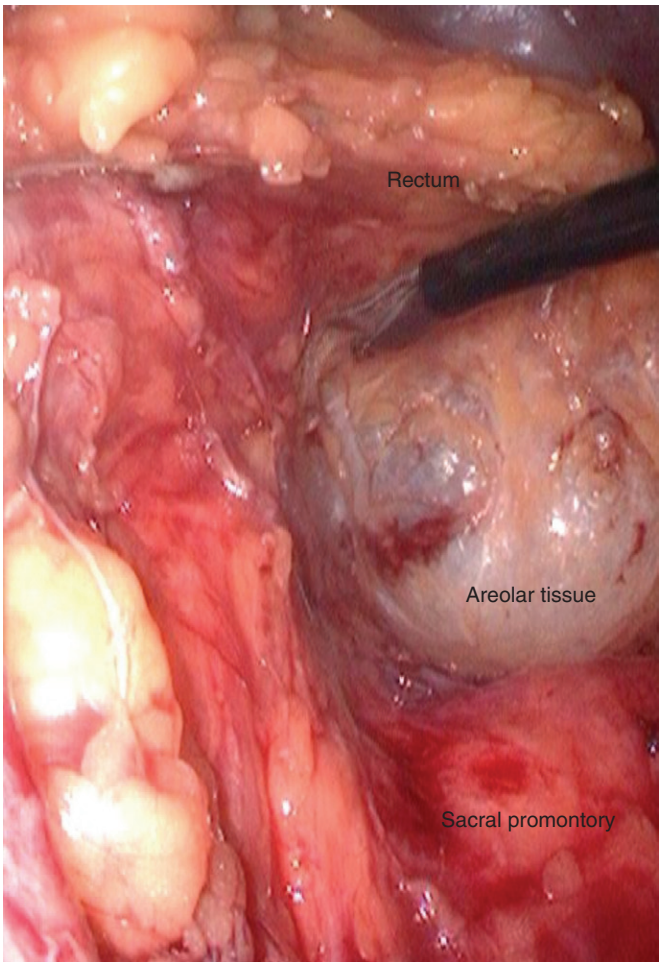

FIGURE 6 Laparoscopic low anterior resection. The dissection is carried further into the pelvis, all the way down to the pelvic floor posteriorly, to release the mesentery up and away from the sacral curve. *(From Fleshman JW, Birnbaum EH, Hunt SR, et al [eds]:* Atlas of surgical techniques for colon, rectum, and anus, *Philadelphia, 2012, WB Saunders.)*

superior hemorrhoidal vessels, extends all the way down to the pelvic floor. Waldeyer's fascia is the reflection of the presacral fascia onto the posterior fascia of the mesentery and is the end of the avascular plane. In patients with rectal cancer, this plane is the "holy plane." The avascular plane is also present below Waldeyer's fascia and requires incision to release the rectum from the pelvic floor musculature. A total mesorectal excision with complete intact mesenteric envelope is essential to decrease local recurrence of the cancer in the pelvis.

The laparoscopic retraction of the rectum should be performed bluntly without grasping of the bowel or mesorectum. The retraction of the bladder and the uterus or prostate can be made safe with blunt retraction by an open grasper to lift the anterior tissues away from the rectum. Long (45-cm) instruments are essential. During the anterior dissection at the level of the cul-de-sac, the rectum is then gently pushed posteriorly to provide downward countertraction. The dissection plane in the anterior pelvis is critical to the protection of nerves behind the prostate or vagina that control sexual function. Denonvilliers's fascia is the plane that marks the anterior extent of the mesenteric envelope of the rectum below the cul-de-sac. A cancer in the anterior rectum should be treated with removal of Denonvilliers's fascia. This places the nerves at risk for damage along the anterior surface of Denonvilliers's fascia, behind the seminal vesicles

and the prostate. The rectovaginal septum in female patients is also very close to the anterior surface of the rectum, and Denonvilliers's fascia is a landmark for protecting the rectum and maintaining an intact mesorectal excision. The avascular tissue plane outside Devonvilliers's fascia provides a guide to safe appropriate pinpoint dissection in the low anterior pelvis caudal to the cul-de-sac.

The middle hemorrhoidal vessels cross from the internal iliac vessels in the lateral pelvic side wall to enter the mesentery of the rectum at the lower portion of the pelvis in the anterolateral position. The splanchnic nerves run just outside the mesentery along this pelvic side wall, and the crossing fibers of the nerves carrying motor and sensory impulses to the rectum extend along the sides of the blood vessels through the anterolateral ligaments. A dissection plane in the middle of these ligaments provides protection to the laterally placed splanchnic nerve trunks and avoids damage to the mesenteric envelope and lymphatic vessels along the side of the rectal wall. The division of these vessels can be accomplished with the electrocautery or with sealing devices, deep in the pelvis to control blood loss. Precise use of electrocautery is important to protect the lateral nerves. A hook cautery or "paddle" tip can be used to reduce spread of damage. Division of the anterior lateral ligaments releases the rectum from the attachments in the low pelvis. Upward traction on the rectum then provides exposure to the deep pelvis posteriorly. Low rectal transection may not be accomplished adequately with laparoscopic stapling instruments. The author's preference is to place a double staple line with cutting transverse stapler through Pfannenstiel's incision in the suprapubic site. A wound protection or hand access port provides radial retraction of the edges of the incision (Figure 7). Control of the transverse staple line with adequate distal margin below the tumor is essential in cases of malignancy. Multiple staple firings with endoscopic GIA-type staplers may actually increase the risk of anastomotic leak in patients undergoing laparoscopic low anterior resection.

Results of numerous studies available suggest that a robotic approach may facilitate dissection of the pelvis. The parallel alignment of the three instrument arms in the pelvis and the three-dimensional camera, all controlled by the surgeon, gives better control of traction-countertraction and sharp dissection with depth perception. The Robotic versus Laparoscopic Resection for Rectal Cancer (ROLARR) study is underway to compare the surgical outcomes and conversion rate between robotic and laparoscopic anterior resection of the rectum. The University of Leeds in the United Kingdom is the lead institution, and the study includes international investigational sites.

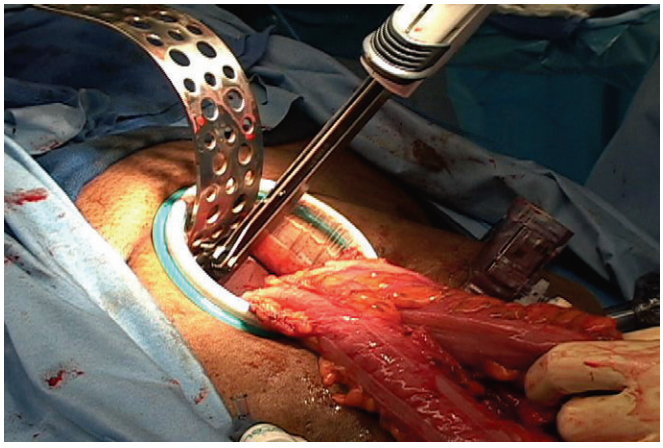

FIGURE 7 Laparoscopic low anterior resection. The rectum and sigmoid are pulled through the incision. *(From Fleshman JW, Birnbaum EH, Hunt SR, et al [eds]:* Atlas of surgical techniques for colon, rectum, and anus, *Philadelphia, 2012, WB Saunders.)*

When rectal resection is performed and a low anastomosis may be needed, splenic flexure mobilization should be performed and the inferior mesenteric artery and vein should be divided at their origins to allow the left colon to reach all the way into the pelvis. Because of the sigmoid colon's poor blood supply and noncompliant wall of thick muscle, it should not be used as the anastomotic or preanastomotic segment. The sigmoid is almost inevitably affected by the neoadjuvant radiation in cases in which pretreatment is indicated. The functional outcome is compromised in an end-to-end anastomosis with the sigmoid. Some surgeons always use a pouch made from the last 5 cm of the bowel if the sigmoid is used as the proximal component. If the splenic flexure is freed to allow the left colon to act as the proximal component, the more compliant portion of colon is able to function as a reservoir without a pouch.

Crohn's Disease

Laparoscopy is well recognized as a minimally invasive approach in patients with Crohn's disease and is beneficial to their early recovery and quality of life. The reduction in postoperative adhesions allows an easier second operation in patients who are at high risk for needing a repeat surgical treatment. The lower risk of surgical site infection is a true benefit in patients who are usually immunocompromised. In fact, a review of the National Surgical Quality Improvement Projects showed that ileocolic resection for Crohn's disease results in lower rates of sepsis or pneumonia, shorter length of hospital stay, and overall improved outcome.

The recurrence after resection with laparoscopic approaches is unchanged from that after open surgical approaches. The use of HALS facilitates the minimally invasive approach to complicated cases of Crohn's disease. For example, a patient with a phlegmon and a fistula might be amenable to a laparoscopic approach with a hand-assisted technique. The use of the surgeon's hand clarifies anatomy and prevents converting to an open operation. Fracture of inflammatory adhesions by the finger facilitates identification of individual loops of secondarily involved intestine and limits the amount of intestine that otherwise might have been resected. As a result, short bowel syndrome is avoided. The principle of starting with a laparoscopic approach and converting to a hand-assisted approach early on can usually avoid an open conversion and all the associated problems such as a longer hospital stay, high infection rate, and more adhesions. Therefore, the recommendation should be to attempt a minimally invasive approach in most circumstances.

Ulcerative Colitis

Numerous researchers have investigated the use of a laparoscopic approach to a total proctocolectomy, ileal pouch, and anal anastomosis for ulcerative colitis. The results of their retrospective studies show that there is a decrease in fistula formation if a laparoscopic approach is utilized and a stoma is in place for protection. A three-stage procedure for patients who have severe fulminant colitis may be an improvement in the management of these patients because of the avoidance of pouch leak and abscess. Decreases in overall complications have been documented in patients undergoing three-stage procedures, in comparison with two-stage procedures. The three-stage procedure incorporates a laparoscopic total abdominal colectomy, ileostomy, and construction of Hartmann's pouch of the rectum, followed by a laparoscopic completion proctectomy and pouch construction with a diverting loop ileostomy. The third stage is closure of the ileostomy. The laparoscopic approach has been shown to result in ileostomy closure 20 days sooner for the laparoscopic two-stage ileal pouch anal anastomosis than for the open version. In comparison with the open procedure, the three-stage laparoscopic procedure results in accomplishment of the ileoanal pouch anastomosis 49 days sooner and ileostomy closure for the third stage 17 days sooner.

Selecting criteria of patients for the three-stage approach include high dose of immunosuppressants in the presence of fulminant colitis and malnutrition. All other patients are well served by a two-stage approach.

The National Inpatient Sample data show that 29% of patients with ulcerative colitis have been treated laparoscopically since 2004. In the single year 2008, that number increased to 41%. A database review also showed a decrease in complications—specifically, surgical site infection, pneumonia, blood loss, and sepsis—for the laparoscopic components of total abdominal colectomy and ileoanal pouch anastomosis.

A retrospective review from the Cleveland Clinic showed that laparoscopic total proctocolectomy and ileoanal pouch anastomosis resulted in fewer complications than did open surgery. This has the "downstream" effect of improving fertility in female patients, with a 50% conception rate in such women who tried to become pregnant (in compared with <30% of those who underwent open operation).

The literature now has several small series of SILS approaches to ulcerative colitis. There seems to be no increase in complications, even though the operative approach is lengthier and is more of a struggle than the laparoscopic approach. Patients should be selected carefully for undergoing this technically demanding procedure. One might add that the patient should carefully select the surgeon as well. Robotic-assisted SILS may make this procedure more feasible when wristed instruments become available for SILS robotic instrumentation.

Diverticulitis

Diverticulitis can be one of the most complicated and difficult disease processes that a colorectal surgeon or general surgeon encounters in the operating room. For this reason, the laparoscopic approach for diverticulitis was slow to be accepted within the surgical community. Numerous studies in the 1990s elucidated the limitations of laparoscopic surgery for the treatment of diverticulitis. Surgeons feared an increase in anastomotic leak rate and bowel injury beyond the area of disease. Although these fears have not been supported and the potential complications have not appeared, the use of the laparoscopic approach to diverticulitis is still under a fair amount of scrutiny. A systematic review of diverticulitis and laparoscopy included 21 studies that are currently in the literature. The review concluded that laparoscopy provided a shorter length of hospital stay and a slightly increased operating time. Complication rates in patients with complicated diverticulitis were decreased in the laparoscopic cases, even though there was wide variability in conversion rates (between 30% and 70%). Hand-assisted laparoscopic sigmoid resection, however, may actually decrease the operating time and decrease the conversion rate by adding an additional safety factor of having a hand through a small incision present in the abdomen during the dissection, as mentioned in the section on Crohn's disease. Several reports suggest that laparoscopic lavage for treatment of diverticular perforation is safe and may be a treatment for the future. The majority of these reports concern patients with abscess perforations (Hinchey class III) and very few suggest this is appropriate for feculent peritonitis (Hinchey class IV). Oversewing of the perforation and placement of drains may be the only treatment needed. With laparoscopic and hand-assisted techniques for sigmoid resection, the rate of complications was decreased, and the numbers of complications of these two techniques were equal. The complication rate was improved over the open procedures. Regardless of the chosen technique, a complete resection of the sigmoid colon down onto soft normal rectum is necessary to prevent recurrent diverticulitis. A simple technique to guarantee resection at the normal rectum is to pass a 29-mm circular stapler to the level of planned resection. If the bowel easily accepts this large diameter, the surgeon can be confident the resection line is on the soft rectum.

Enthusiasm for transanal extraction of the diverticular segment at the end of the procedure is limited. This step may reduce infection in the abdominal wall by eliminating an extraction site. Even when the patient has a positive culture from the pelvis after the rectal stump is opened to remove the specimen, there is no increase in infection. A report from Argentina showed that there was no decrease in sexual function 34 months after the transvaginal specimen extraction that followed laparoscopic sigmoid colectomy in middle-aged women. Transanal extraction would not be expected to affect sexual function, but it might result in a pelvic inflammatory process that would affect fertility negatively.

The National Inpatient Sample Database has provided data that confirm laparoscopic sigmoid colectomy increased to 39% of elective cases being performed for diverticulitis. Overall, laparoscopic sigmoid colectomy was being performed in 32% of patients with diverticulitis, and 94% of all patients undergoing elective surgery received a primary anastomosis. The urgent procedures performed laparoscopically still had a fairly high rate of stoma formation (54%). A review from the Mayo Clinic showed that a leak rate of 1.5% could be expected, even when complicated and uncomplicated cases were compared. A hand-assisted approach was utilized in the majority of these patients and may explain the lack of difference between the leak rates in complicated and uncomplicated cases. In the setting of extreme fibrosis and inflammation, early conversion to an open operation is the best approach for the patient and the surgeon. It reduces the chance of intraoperative complication and shortens operative time to reasonable length.

Colon Cancer

Numerous international and national trials in which laparoscopic and open resection of colon cancer were compared have shown that the laparoscopic approach is safe and results in equivalent, if not slightly improved, oncologic outcomes for colon cancer. The most recent report of laparoscopic treatment of colon cancer documented that laparoscopy may actually reduce the circulating levels of cancer-supporting growth factors, in comparison with open resection. This may have some implications for distant recurrence and may be an indicator that a less invasive approach is important for long-term treatment of cancer.

Conversion to an open operation during a laparoscopic approach does not seem to affect cancer outcomes. The original fear that laparoscopy would cause an increase in intraabdominal carcinomatosis and seeding of tumor in the trocar sites has been unfounded. Good oncologic technique has prevented both of these possibilities.

The experience of the surgeon and willingness to convert early may be important with regard to the fact that conversion does not result in higher local tumor recurrence rates. The most common reasons for converting to an open operation are large tumor size with local invasion and adhesions. These can be identified early in the procedure, and the operation can be switched to either a hand-assisted approach or an open approach to avoid untoward oncologic outcomes. The SILS approach to colon cancer has been shown to be almost equal to a laparoscopic procedure with regard to lymph node harvest, negative margins, and recurrence. The case-matched controlled, retrospective study from Scott and White Clinic revealed that the patients who underwent laparoscopy had a higher rate of conversion to an open procedure than those who underwent the SILS approach (15.4% vs 11.5%). It is important to remember that a conversion to a multiport technique or a HALS approach preserves the majority of benefits of a minimally invasive approach.

Rectal Cancer

Rectal cancer is being considered an opportunity for laparoscopic treatment. There are numerous reports of rectal resection. The

Colorectal Cancer Laparoscopic or Open Resection (COLOR II) trial showed that laparoscopic treatment of rectal cancer is safe and feasible and results in similar complication rates and early oncologic outcomes as an open procedure. The Alliance Z6051 trial has closed to accrual after entering the required 480 patients. The endpoint of this trial is the surgical specimen, as a surrogate for oncologic outcome. Negative radial and distal margins and a good quality total mesorectal excision (TME) specimen are the primary outcomes for this trial. For the first time in a trial, photodocumentation of the rectal specimen has been utilized for quality control of the surgical technique. The quality of the TME specimen (complete, nearly complete, incomplete) is being incorporated into the pathology reports for these patients to document the quality of the surgery that was performed. A report from the COREAN (from Korea) trial showed that a randomization of laparoscopic versus open technique resulted in equivalent outcomes for stage II and III rectal cancer. Patients who underwent the laparoscopic procedure showed less blood loss, shorter length of hospital stay, less requirement for pain medicine, and a 91% of complete to near-complete TME in the rectal specimen, in comparison with 88% of patients who underwent the open procedure. There was only a 1.2% conversion rate for the patients who underwent laparoscopy.

Innovations are ongoing in the surgical treatment of rectal cancer. Transanal endoscopic proctectomy for rectal cancer has been reported in a small group of men treated in France, with a 6% conversion rate, and 80% to 87% specimens were of good quality. However, there was 30% incidence of local recurrence in 30 patients reported (12% at 21 months) with this technique. This technique needs further study.

Robotic proctectomy has been compared retrospectively with laparoscopy in a large group of patients treated in Melbourne, Australia. The oncologic outcomes have been shown to be equivalent. A decreased conversion rate was noted in patients who underwent robotic proctectomy.

In another study from Brisbane, Australia, the laparoscopic approach to a proctectomy was compared with the hybrid laparoscopic approach, in which the rectal dissection is performed with open technique through a small open incision above the pubis. The incidence of pelvic abscess and complications was much higher in the patients who underwent the hybrid procedure, but there was no change in local recurrence or survival. Transanal endoscopic total mesorectal excision and SILS left colectomy and transanal/transabdominal laparoscopic and endoscopic proctectomy have been shown to be feasible in both cadavers and living humans. No long-term data are available.

COMPLICATIONS AND LEARNING CURVE OF LAPAROSCOPIC COLECTOMY

Even though laparoscopy provides a minimally invasive approach with smaller incisions, there is a minimal change (1 to 2 days) in the length of hospital stay and recovery of the patient in comparison with the open approach. Much of the improvement in recovery was noted after the discharge time frame; laparoscopically treated patients tend to return to activities of daily living faster. There is an emphasis on the early recovery program in combination with laparoscopic colectomy. The early recovery program seems to improve recovery, beyond the improvements contributed by the laparoscopic approach, by shortening the length of hospital stay to as little as 2 days after a laparoscopic colectomy. The early recovery program is a hospital wide, multidisciplinary approach that focuses on the patient to "improve" recovery by limiting complications, reducing iatrogenic effects on postoperative bowel functioning, and controlling pain. Fluid restriction, limits on narcotics, early ambulation, and feeding all contribute.

The learning curve for a laparoscopic colectomy has been shown to be variable. A study from Osaka, Japan, showed that the time needed for a surgeon to perform laparoscopic colectomy stabilizes after 50 cases. Conversion rates greatly diminish after 150 cases, and the complications decrease after 200 cases. The leak rate was 14% at the beginning and decreased to 4% after 200 cases. Other studies have shown that HALS can reduce the number of cases needed to decrease conversion and operating room time to approximately 100 cases. The operating time is decreased with HALS without compromising length of hospital stay or complication.

The American College of Surgeons' National Surgical Quality Improvement Program (NSQIP) database has shown that the likelihood for high-level complications is lower for laparoscopic than for open cases, even after risk adjustment. The National Inpatient Sample Database showed that thromboembolic complications after colectomy in 149,000 patients was decreased by almost half in the patients who underwent the laparoscopic procedure, in comparison with patients who underwent the open procedure, and seemed to be related to the presence of inflammatory bowel disease, rectal operation, malignancy, obesity, and congestive heart failure as risk factors.

In conclusion, laparoscopic colectomy and proctectomy are feasible techniques in the treatment of colorectal disease. The studied approach to adopting these techniques is based on surgical research that provides data for evidence-based care in colorectal disease. The use of new technology is sometimes enticing for marketing purposes or for the pleasure of performing a new operation. Early adoption of these procedures must be balanced against the realities that on occasion, new technology is not of benefit to the patient or the medical system. An example in which enthusiasm has outdistanced evidence-based evaluation is the case of robotic colectomy and proctectomy. As time goes forward, cost effectiveness will need to be evaluated as resources become more limited. Patient care must always be at the forefront of concern when surgeons adopt new techniques in the technology.

Minimally Invasive Esophagectomy

Luis F. Tapias, MD, and Christopher R. Morse, MD

OVERVIEW

Transhiatal esophagectomy and Ivor Lewis esophagectomy are the two most commonly performed operations for esophageal pathology. Both are complex procedures that are often associated with high morbidity and mortality. Because esophagectomy is frequently performed in elderly patients with many coexisting medical comorbidities, increasing interest has been found in minimally invasive approaches in an attempt to improve early postoperative outcomes. Minimally invasive esophagectomy (MIE) has the potential for an easier postoperative recovery with fewer cardiopulmonary and infectious complications. In addition, enhanced visualization of abdominal and mediastinal structures by means of a minimally invasive approach may facilitate intraoperative steps, reduce injury to neighboring structures, improve lymph node harvest, and decrease blood loss.

In 1992, Cuschieri and colleagues described a technique of esophagectomy with a staged procedure that combined a right thoracoscopic approach in the prone position with a midline laparotomy and cervical anastomosis. In 1995, DePaula and colleagues reported a small series of laparoscopic transhiatal esophagectomies. Subsequently, in 1998, Luketich and colleagues reported a combined thoracoscopic and laparoscopic approach to esophagectomy that consisted of a thoracoscopic mobilization of the esophagus, the laparoscopic creation of the gastric conduit, and a neck anastomosis. Watson and colleagues later reported a minimally invasive Ivor Lewis technique in 1999 and described a laparoscopic construction of the gastric conduit followed by thoracoscopic intrathoracic anastomosis.

INDICATIONS

The most common indication for MIE is esophageal cancer (stages I to IIIA), although esophagectomy may be used in rare, end-stage, benign esophageal disorders such as achalasia. At present, no absolute contraindications exist, although advanced training in minimally invasive esophageal surgery is encouraged. Minimally invasive esophagectomy as performed for cancer can be performed in patients who have or have not received neoadjuvant chemoradiation. Obesity and previous abdominal or thoracic surgery can lead to more technically demanding MIE, but they are not contraindications. In any case, safety should be foremost, and the surgeon must maintain a low threshold to convert the operation to an open procedure, either in the abdominal or thoracic stages of the operation, if needed. The most common esophageal cancer in the United States is adenocarcinoma, often associated with Barrett's esophagus, which leads to a preference for a minimally invasive Ivor Lewis approach, although the steps are easily modified to a laparoscopic transhiatal or a modified McKeown's technique. The steps to an Ivor Lewis approach and the additional modifications to include a cervical anastomosis are described.

PREOPERATIVE PREPARATION

The preoperative evaluation for a minimally invasive esophagectomy is no different than that for a patient undergoing an open procedure. The two primary issues are whether a patient is resectable and whether the patient has sufficient cardiopulmonary reserve to tolerate the operation. Staging of esophageal cancer includes an upper endoscopy, endoscopic ultrasound scan (EUS), computed tomographic (CT) scanning, and positron emission tomographic (PET) imaging. Upper endoscopy is performed to identify the proximal and distal extent of the tumor, which may impact on the type of procedure; this is often done in the operating room at the time of the operation. The primary benefit of EUS is to determine the degree of invasion of the esophageal wall by tumor and adjacent lymph node status. Patients with T3 or N1 disease are typically treated with induction chemoradiotherapy before esophagectomy. CT imaging is useful to determine the presence of bulky nodal disease within the abdomen. Bulky disease limited to the celiac nodal basin does not preclude esophagectomy, provided significant response to induction therapy is seen. The addition of PET imaging, often in conjunction with CT scan, increases the sensitivity in detection of distant metastatic disease. PET is not particularly helpful in identification of periesophageal nodal disease because activity within these nodes often is obscured by the primary tumor.

Patients should undergo a thorough evaluation to determine medical suitability for operation. This includes a cardiac stress test and, if indicated, coronary angiography. Patients with a significant tobacco history also should undergo pulmonary function testing. In addition, most patients with locally advanced cancer have some degree of dysphagia and weight loss before diagnosis. Dysphagia often improves with induction therapy. The placement of either an esophageal stent or a percutaneous gastrostomy tube is strongly discouraged for any patient who may be an operative candidate. Esophagectomy may still be performed in these situations, although it is technically more challenging.

MINIMALLY INVASIVE IVOR LEWIS ESOPHAGECTOMY

A minimally invasive Ivor Lewis esophagectomy is preferred because it allows excellent visualization of mediastinal structures and a complete thoracic lymph node harvest and minimizes recurrent laryngeal nerve injuries and the creation of a tension-free anastomosis. A minimally invasive Ivor Lewis esophagectomy is performed in two stages. In the first stage, laparoscopic mobilization of the stomach and construction of the gastric conduit is performed with the patient in a supine position. In the second stage, the patient is repositioned to a left lateral decubitus position for mobilization of the thoracic esophagus, mediastinal lymph node dissection, removal of the surgical specimen, gastric pull-up, and construction of an intrathoracic esophagogastric anastomosis. Narrowing of the gastric tube too much is discouraged, and an attempt should be made to preserve the width at approximately 5 to 6 cm. A pyloroplasty or pyloromyotomy is not routinely performed. A jejunostomy is routinely performed in all patients.

Surgical Technique

The patient is placed supine, and the surgeon stands to the patient's right and the assistant to the left. The initial step is to perform an on-table esophagogastroduodenoscopy (EGD) to confirm tumor location, the presence of Barrett's esophagus, and the suitability of the stomach as a conduit for reconstruction. Five initial laparoscopic ports are placed in the upper abdomen in a paramedian fashion (Figure 1). A 10-mm, 30-degree laparoscope is used. The abdomen is examined for metastatic disease, and a liver retractor is placed through the most lateral port on the right side. Dissection is begun

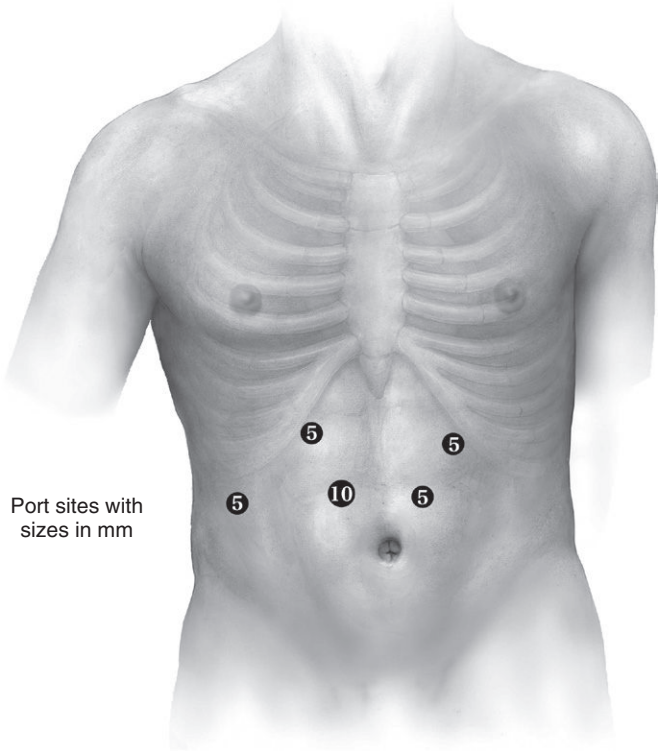

FIGURE 1 The patient is initially positioned in the supine position, and a double lumen endotracheal tube is placed in preparation for the thoracoscopic mobilization of the esophagus. Five abdominal ports are used for the gastric mobilization. A marking pen is used to trace the midline from the xiphoid to the umbilicus, and this line is further divided into thirds. To avoid potential injury to any abdominal viscera or organs, the initial port is placed via an open technique. The two midclavicular ports are placed on the lower third of the marked line to assist with gastric mobilization. *(From Tsai WS, Levy RM, Luketich JD: Technique of minimally invasive Ivor Lewis esophagectomy,* Op Tech Thorac Cardiovasc Surg *14(3):177, 2009; Fig. 1.)*

by taking down the gastrohepatic ligament and exposing the right crus. The phrenoesophageal ligament is divided, and the distal esophagus is mobilized, with care taken to keep all of the surrounding tissue with the specimen. The gastrocolic omentum is divided, and careful attention is paid to preserving the right gastroepiploic artery (Figure 2). Dissection is carried up the greater curve, further mobilizing the stomach by dividing the short gastric arteries where the dissection moves close to the greater curvature. The left crus is exposed, and the esophagus is mobilized into the mediastinum. All attachments between the posterior aspect of the stomach and the anterior surface of the pancreas are divided to the level of the pylorus. From the lesser curve side of the stomach, the left gastric artery is dissected to its base with all nodal tissue included in the specimen. A stapler is placed at the base of the artery and vein, and they are divided.

The authors do not routinely perform a pyloroplasty because they have observed at their institution a low incidence of gastric outlet obstruction after esophagectomy among patients who did not undergo a pyloric drainage procedure. Furthermore, should delayed gastric emptying present in the postoperative period, it can be managed conservatively or with endoscopic balloon dilation of the pylorus in most patients. If a pyloroplasty is to be performed, the pylorus is opened with ultrasonic shears and the pylorus closed transversely in an interrupted fashion with an Endostitch device (Covidien, Mansfield, Mass) with nonabsorbable suture. Alternatives to pyloroplasty include pyloromyotomy or botulinum toxin injection of the pylorus.

The gastric conduit is created with endoscopic staplers, starting at the incisura; a sixth laparoscopic port is placed in the right lower quadrant for this purpose. The right gastric artery is often preserved. Remember to withdraw or remove the nasogastric tube before conduit creation. The stomach is divided up to the cardia with multiple fires of an endoscopic stapler, keeping a 5-cm to 6-cm width to the conduit along the greater curvature (Figure 3). The first staple firing along the lesser curve is typically a vascular load to control vessels in this area. To set up conduit creation, the assistant grasps the fundus along the greater curvature and gently stretches it towards the spleen; a second grasper is placed on the antrum, and a slight downward retraction is applied. Light tension superiorly and inferiorly on the stomach can extend the length of the conduit and allow the creation of a straight staple line. Prevention of spiraling of the stomach is critical as the staple line is advanced proximally.

A jejunostomy is placed (Flexiflo Laparoscopic Jejunostomy Kit, Abbott Laboratories, Abbott Park, Ill) in the left lower quadrant. Rotating the transverse colon up towards the hiatus, the ligament of Treitz is identified. Moving 30 to 40 cm down the jejunum, a loop of small bowel is tacked to the abdominal wall with an endostitch device. Facilitating this step is the additional 12-mm port initially placed in the lower right quadrant during creation of the gastric conduit. A needle and then a guidewire are passed into the jejunum with laparoscopic vision. Proper placement of the catheter is confirmed by observing distension of the jejunum as air is insufflated into the needle catheter. The jejunum surrounding the feeding tube is then tacked to the abdominal wall with several additional endostitches.

Finally, with an endostitch, the most superior portion of the gastric tube is then stitched to the specimen (Figure 4). The stitch maintains correct orientation of the gastric conduit as it is delivered into the chest. The laparoscopic portion of the procedure is completed by dividing the phrenoesophageal membrane. The crura are also assessed to determine whether a stitch should be placed to avoid herniation of the conduit into the chest.

The patient is turned to the left lateral decubitus position for the thoracoscopic mobilization of the esophagus and creation of an intrathoracic anastomosis. The surgeon stands to the back of the patient, and the assistant stands to the front. After lung isolation is achieved, five thoracoscopic ports are placed (Figure 5). A 10-mm camera port is placed in the 7th or 8th intercostal space, anterior to the midaxillary line. A 10-mm port is placed at the 8th or 9th intercostal space, posterior to the posterior axillary line, for the ultrasonic coagulating shears. A 10-mm port is placed in the anterior axillary line at the 4th intercostal space, through which a fan-shaped retractor retracts the lung anteriorly to expose the esophagus. A 5-mm port is placed just anterior to the tip of the scapula and is used for retraction by the surgeon. A final port is placed at the sixth rib, at the anterior axillary line for suction, and is critical in the creation of the anastomosis.

The initial step is to place a stitch in the central tendon of the diaphragm to facilitate visualization of the gastroesophageal junction; this suture is brought out through a 1-mm incision in the anterior chest wall, retracting the diaphragm inferiorly and anteriorly. Dissection in the chest begins by dividing the inferior pulmonary ligament. In taking down the inferior pulmonary ligament, dissection onto the pericardium is important because it is the medial aspect of the dissection. The inferior pulmonary vein is retracted anteriorly, and the dissection is carried along the pericardium, mobilizing the subcarinal lymph packet. At risk during the mobilization the subcarinal nodes is the posterior, membranous wall of the right mainstem bronchus, which should be clearly identified. With complete dissection of the subcarinal space, the left mainstem bronchus should be identified. The subcarinal nodal package is removed with the specimen. The mediastinal pleura is then opened along the hilum to the level of the azygos vein. The mediastinal pleura is opened above the azygos vein, and with complete dissection around the azygos vein, it is divided with a vascular load of an endoscopic stapler.

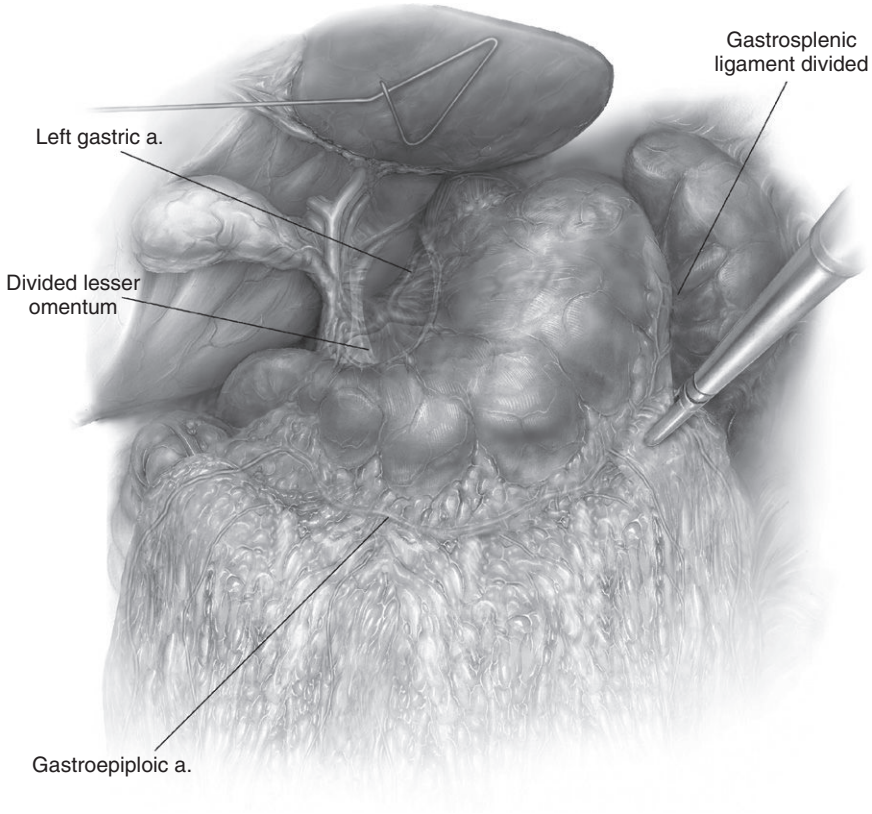

FIGURE 2 After an initial inspection of the peritoneal surfaces and the liver to rule out any metastatic disease, the gastrohepatic omentum is opened. The left gastric artery/vein pedicle is identified, and by tracing its course proximally, the celiac lymph nodes are then examined. A complete lymph node dissection is performed to include the celiac nodes, sweeping all nodal and fatty tissue with the specimen; the nodal dissection is continued along the splenic artery and the superior border of the pancreas. This plane continues cephalad toward the right and left crus, continuous with the preaortic dissection plane into the lower thoracic cavity. If any lymph nodes appear suspicious for metastatic involvement, they are dissected and sent for frozen-section analysis. If the nodes do not appear malignant or are pathologically free of cancer on analysis, dissection of the right crus is initiated to mobilize the lateral aspect of the esophagus. *(From Tsai WS, Levy RM, Luketich JD: Technique of minimally invasive Ivor Lewis esophagectomy,* Op Tech Thorac Cardiovasc Surg *14(3):178, 2009; Fig. 2.)*

Posteriorly, the pleura is divided and the esophagus dissected away from the chest wall and aorta. All aortoesophageal vessels encountered during this portion of the procedure should be clipped before division. Any tissue suspicious for lymphatic branches arising from the thoracic duct is meticulously clipped and divided to prevent chylothorax. If injury to the thoracic duct is a concern, this structure can be ligated en masse at the level of the diaphragm. With the esophagus mobilized medially and laterally, the specimen is pulled into the chest with the attached gastric conduit. Care should be taken to only bring in enough gastric tube to reach the proximal esophageal remnant because redundant gastric conduit above the diaphragm is a source of delayed poor gastric emptying as a result of the S loop of gastric conduit this may create. The gastric tube must remain properly oriented with the staple line, continuing to face the lateral chest wall with this avoiding spiraling or 360-degree twisting of the conduit. The stitch is cut between the specimen and the conduit, and the specimen is retracted anteriorly and superiorly. The dissection continues posteriorly to mobilize the esophagus completely off the contralateral pleura. When dissecting the esophagus above the level of the azygos vein, the dissection plane moves to the wall of the esophagus. This avoids injury to the recurrent laryngeal nerve. Lymph nodes above the azygos vein are not routinely harvested.

The posterior incision is increased to a total of 4 cm; a wound protector is placed. The esophagus is transected with Endo Shears (Covidien, Mansfield, Mass) at a level appropriate for the tumor. The specimen is removed through the wound protector and sent for pathologic analysis of the margins. The anvil of a 28-mm end-to-end anastomosis (EEA) stapler is placed in the proximal esophagus, and a purse-string suture is placed and tied to secure the anvil in position (Figure 6). A second purse-string suture is placed to further secure the anvil and pull in any mucosal defects. The gastric conduit is then pulled to the apex of the chest, and the ultrasonic shears are used to open up the tip of the gastric conduit along the staple line. The EEA stapler is placed through the posterior- inferior port, which had been enlarged and positioned in the conduit. The stapler tip is brought out along the greater curve of the gastric conduit to join the anvil. Before the anastomosis is created, the amount of conduit that will lie in the chest is carefully ascertained. A common mistake is to bring an excess amount of stomach into the chest in an effort to minimize tension on the anastomosis. This excess conduit often assumes a sigmoid curve above the diaphragm and may lead to significant problems with gastric emptying. In addition, ensuring proper orientation of the stomach is critical to prevent twisting. The tip of the stapler and the anvil are docked, and the stapler is fired, creating a circular esophagogastric anastomosis (side of gastric conduit to end of esophagus) at approximately the level of the azygos vein. The excess stomach (the gastrostomy through which the stapler was placed) is trimmed with several loads of an articulating linear endoscopic stapler, and a 28F chest tube and a Blake drain (Ethicon Inc., Somerville, NJ) are placed adjacent to the anastomosis (Figure 7).

LAPAROSCOPIC TRANSHIATAL ESOPHAGECTOMY

Laparoscopic transhiatal esophagectomy is a two-stage operation. The patient is initially positioned supine for the laparoscopic construction of the gastric conduit and transhiatal mobilization of the esophagus. In a second stage, the cervical esophagus is mobilized through a neck incision with removal of the esophageal specimen and gastric pull-up. An esophagogastric anastomosis is performed in the neck. The initial port placement and mobilization of the stomach are similar to the Ivor Lewis approach. The esophagus at the hiatus is initially mobilized, the greater curve of the stomach dissected from the greater omentum to preserve the gastroepiploic artery, the lesser curve of the stomach is mobilized dividing the left gastric artery and vein, and the gastric conduit is created. A jejunostomy is placed. In the last step of the abdominal phase of this procedure, the esophagus

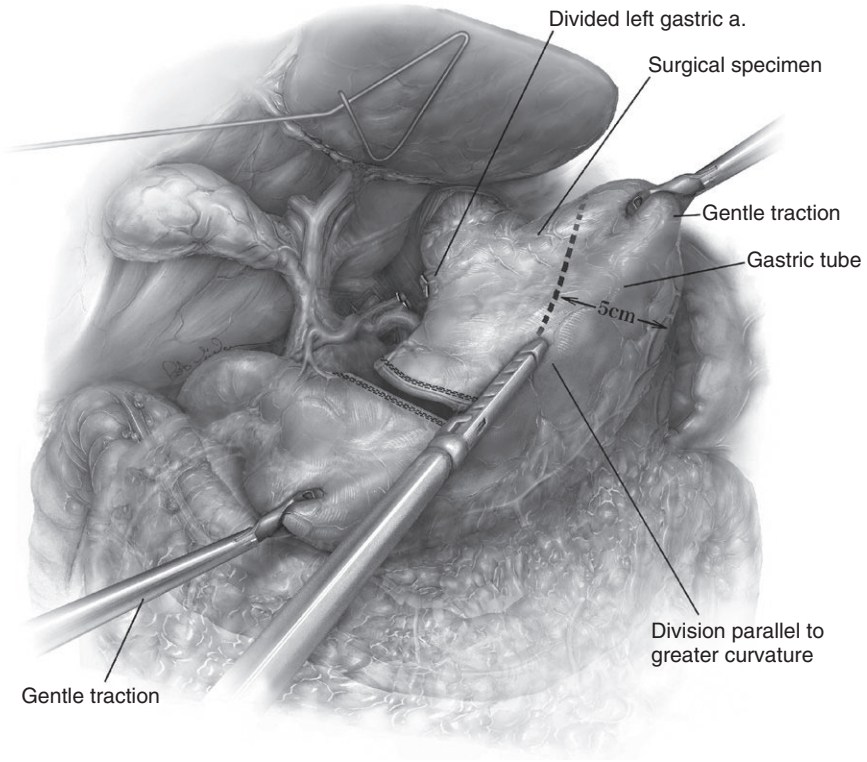

FIGURE 3 Once the stomach and celiac lymph nodes are completely mobilized, the left gastric artery and vein are divided with a vascular load on the Endo GIA (Covidien, Mansfield, Mass) stapler. This is done by approaching the pedicle from the lesser curve. The pedicle must be dissected completely clean with all celiac nodes swept up into the specimen. Once the pedicle is divided, the distal esophagus, gastric fundus, and antrum should be completely mobilized. The gastric tube is usually created before the completion of the pyloroplasty and placement of the feeding jejunostomy tube because this provides time to assess the viability of the gastric tube as a conduit before bringing it into the chest. The first stapler used for creating the gastric conduit contains a vascular load to control bleeding from the adipose tissue and vessels along the lesser curve. The stapler is placed just up to, but not onto, the gastric antrum, which is usually thick and requires staples appropriate for thick tissue. The initial 5/12-mm right midclavicular port is changed to a 15-mm port to allow for the placement of a 4.8-mm Endo GIA stapler (Autosuture, Covidien). An additional 12-mm port is placed in the right lower quadrant to assist with the creation of the gastric tube. *(From Tsai WS, Levy RM, Luketich JD: Technique of minimally invasive Ivor Lewis esophagectomy,* Op Tech Thorac Cardiovasc Surg *14(3):181, 2009; Fig. 5.)*

is mobilized through the esophageal hiatus circumferentially as high as possible in an effort to reach the cervical esophageal dissection plane. If needed, a portion of the crus of the diaphragm is divided to enlarge the esophageal hiatus to facilitate exposure and transhiatal delivery of the surgical specimen. The tip of the gastric conduit is sutured to the surgical specimen. The abdominal operation is now halted, and the neck procedure is started. Through a horizontal left neck incision, the platysma is divided and the sternocleidomastoid muscle is retracted laterally. The inferior thyroidal vessels and the omohyoid muscle are divided. Blunt dissection of the esophagus is carried inferiorly to join the laparoscopic mediastinal dissection plane. Once the entire esophagus is mobilized, the specimen is removed through the cervical incision, pulling along with it the gastric conduit. The laparoscope is now placed back into the abdomen to allow direct visualization of the gastric tube and avoid trauma or spiraling of the conduit. The esophagus is divided 4 cm distal to the upper esophageal sphincter. On confirmation of a negative margin for carcinoma or Barrett's esophagus, an esophagogastric anastomosis is performed in the neck with either a two-layer hand-sewn or a stapled technique.

THORACOSCOPIC AND LAPAROSCOPIC ESOPHAGECTOMY WITH CERVICAL ANASTOMOSIS

A combined thoracoscopic and laparoscopic esophagectomy with cervical anastomosis is a three-stage operation. Initially, the patient is placed in the left lateral decubitus position, and the thoracic esophagus is mobilized in a similar fashion to a minimally invasive Ivor Lewis esophagectomy. However, above the azygos vein, the parietal pleura is left intact to limit mediastinal contamination in the event of a cervical anastomotic leak. Dissection is carried up to the thoracic inlet with circumferential mobilization of the esophagus. Once the esophagus is completely mobilized, the patient is placed supine, and the abdominal portion of the operation begins. Again, this portion of the procedure is similar to the previously described gastric mobilizations. At the conclusion of the gastric mobilization, the neck dissection is completed in a similar fashion as that described for a minimally invasive transhiatal approach. Once the cervical anastomosis is complete, the surgeon returns to the laparoscopic view and

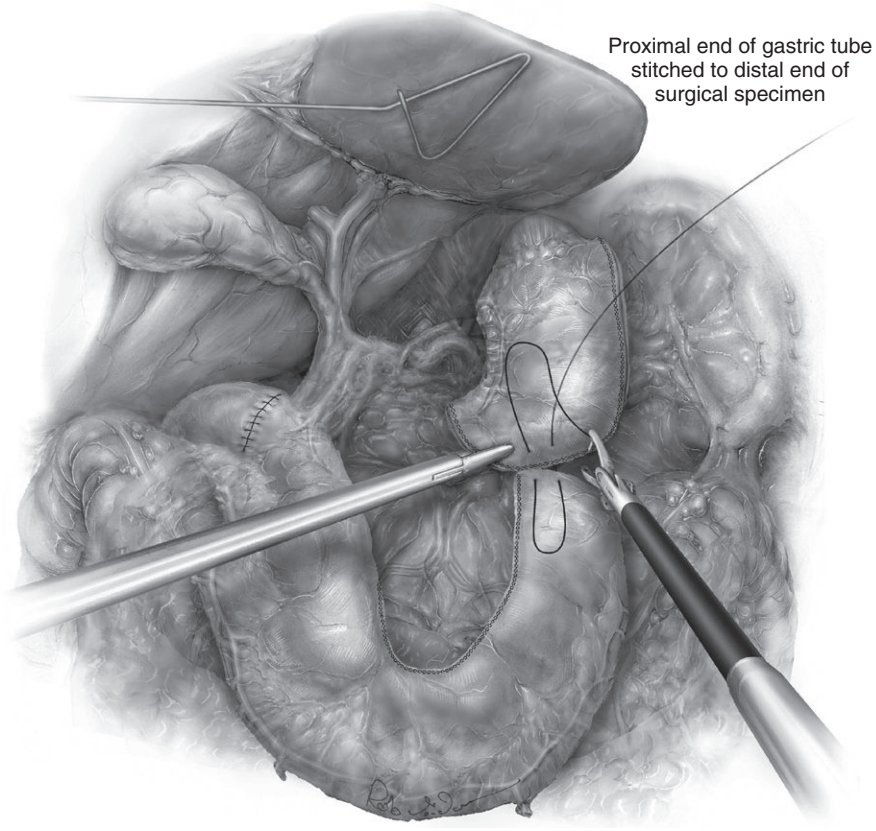

FIGURE 4 The most superior portion of the gastric tube is stitched to the specimen. The stomach must be kept aligned correctly so that, during the mobilization of the conduit into the chest, it does not twist in the abdomen. This is ensured by suturing the greater curvature along the short gastric vessels to the staple line of the proximal gastric remnant. *(From Tsai WS, Levy RM, Luketich JD: Technique of minimally invasive Ivor Lewis esophagectomy,* Op Tech Thorac Cardiovasc Surg *14(3):185, 2009; Fig. 9.)*

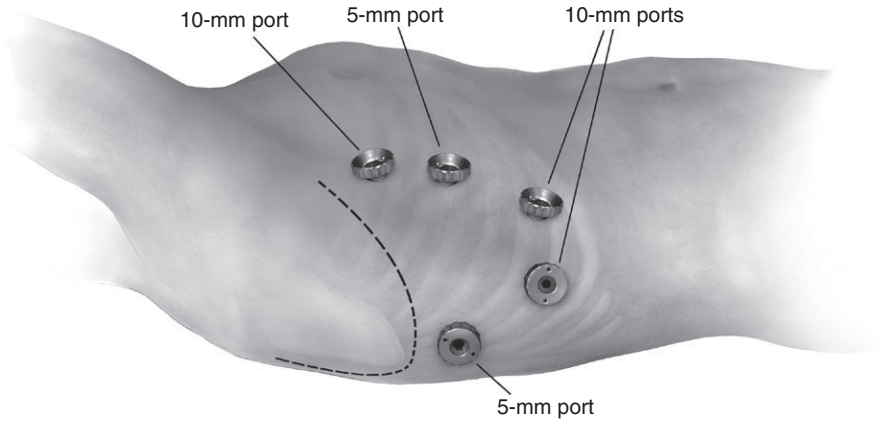

FIGURE 5 The patient is then turned to the left lateral decubitus position for the thoracoscopic mobilization of the esophagus and creation of the intrathoracic anastomosis. Five thoracoscopic ports are used. A 10-mm camera port is placed in the 7th or 8th intercostal space, just anterior to the midaxillary line. The working port is a 10-mm port that is placed at the 8th or 9th intercostal space, posterior to the posterior axillary line. Another 10-mm port is placed in the anterior axillary line at the 4th intercostal space, through which a fan-shaped retractor aids in retracting the lung to expose the esophagus. A 5-mm port is placed just inferior to the tip of the scapula, and this is used by the surgeon's left hand for countertraction. A final port is placed at the sixth rib, at the anterior axillary line for suction, and is important in the creation of the anastomosis. *(From Tsai WS, Levy RM, Luketich JD: Technique of minimally invasive Ivor Lewis esophagectomy,* Op Tech Thorac Cardiovasc Surg *14(3):187, 2009; Fig. 11.)*

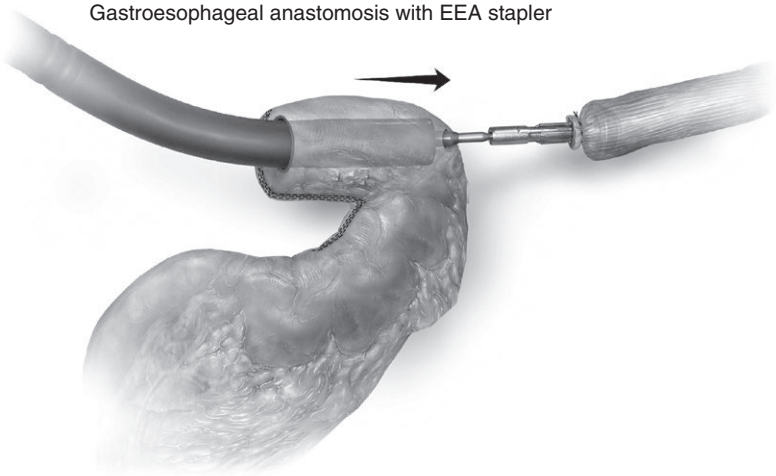

FIGURE 6 The anvil of a 28-mm end-to-end anastomosis *(EEA)* stapler is placed in the proximal esophagus and a 2.0 endo stitch purse-string suture is placed and tied (intracorporeal technique) to secure the anvil in position. It is technically challenging to make this first stitch perfect because the anvil has a tendency to migrate out of the open end of the proximal esophagus. For this reason, a second purse-string suture is placed to further secure the anvil and pull in any mucosal defects, thereby ensuring complete rings after EEA firing. Ordinarily, a 28-mm EEA stapler is used in an attempt to minimize the risk of stricture and decrease need for postoperative dilations. In most cases, the 28-mm anvil is secured without difficulty. On rare occasion, a Foley balloon catheter must be used to dilate the proximal esophagus. Should the Foley balloon catheter fail, a 25-mm stapler is then used. The gastric conduit is then pulled to the apex of the chest, and the ultrasonic shears are used to open up the tip of the gastric conduit along the staple line. The EEA stapler is placed through the posterior-inferior port, which had been enlarged, and positioned in the conduit. The stapler tip is brought out along the greater curve of the gastric conduit to join the anvil. Before creating the anastomosis, the amount of conduit that will lie in the chest is carefully estimated. A common mistake is to bring an excess amount of stomach into the chest in an effort to minimize tension on the anastomosis. This excess conduit often assumes a sigmoid conformation above the diaphragm and may lead to significant problems with gastric emptying. In addition, ensuring proper orientation of the stomach is critical to prevent twisting. *(From Tsai WS, Levy RM, Luketich JD: Technique of minimally invasive Ivor Lewis esophagectomy,* Op Tech Thorac Cardiovasc Surg *14(3):189, 2009; Fig. 13.)*

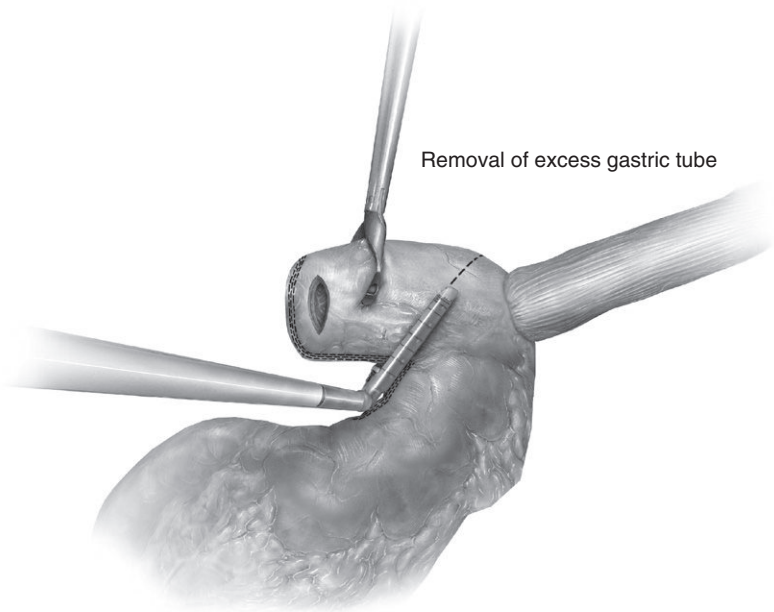

FIGURE 7 The tip of the stapler and the anvil are docked, and the stapler is fired, creating a circular esophagogastric anastomosis, joining the side of the gastric conduit to the end of esophagus, at approximately the level of the azygos vein. The excess gastric tip (the gastrostomy through which the stapler was placed) is trimmed with several loads of an articulating linear stapler, with care taken not to injure the omental pedical wrap that was mobilized along the greater curvature. Endoscopy is not routinely performed to evaluate the anastomosis. *(From Tsai WS, Levy RM, Luketich JD: Technique of minimally invasive Ivor Lewis esophagectomy.* Op Tech Thorac Cardiovasc Surg *14(3):190, 2009; Fig. 14.)*

gently pulls downward on the pyloroantral area to retrieve any excess gastric tube that may have been pulled up into the chest during the neck anastomosis and mobilization. The gastric conduit is then tacked to the hiatus.

POSTOPERATIVE CARE

Patients undergo extubation in the operating room. Epidural analgesia is not routinely used after MIE Ivor Lewis at the authors' institution, and pain is managed with rib blocks, patient-controlled analgesics, and ketorolac. Postoperative management includes the initiation of tube feeds on postoperative day 2. The nasogastric tube is typically removed on postoperative day 5, and a barium swallow is performed to assess gastric emptying and anastomotic integrity. If results are normal, this is followed by the initiation of a clear liquid diet, advanced over 3 weeks. Tube feedings are cycled to the evenings, and the jejunostomy is removed at the first office visit.

RESULTS

Luketich and colleagues published in 2012 the largest series to date on MIE with 1011 patients, including 481 patients who received a minimally invasive three-field McKeown's-type esophagectomy and 530 patients who received a minimally invasive Ivor Lewis esophagectomy. Among the patients who underwent an Ivor Lewis MIE, they reported a median intensive care unit (ICU) length of stay of 2 days and a median hospital length of stay of 7 days. Conversion to open rate was 4%. Major morbidity included empyema in 5% of the cases, anastomotic leak requiring reoperation in 5%, gastric tube necrosis in 2%, and vocal fold paresis or paralysis in 1%. In addition, in the authors' experience, chylothorax occurred in 5% of patients, with only 2.5% needing ligation of the thoracic duct. Furthermore, Luketich and colleagues reported an operative mortality rate of 1.68%. Adequacy of resection was reported in terms of a negative margin, achieved in 98% of patients, and the median number of lymph nodes examined was 21.

When compared with open esophagectomy, the authors found at their institution that minimally invasive Ivor Lewis esophagectomy is associated with decreased intraoperative blood loss, less intraoperative intravenous fluid administration, shorter duration of nasogastric tube drainage, faster initiation of oral intake, and decreased ICU and hospital length of stay. Oncologic outcomes were comparable when examining the number of lymph nodes retrieved and compromise of resection margins. Importantly, MIE was associated with a significantly lower incidence of pulmonary complications when compared with open procedures.

SUMMARY

Minimally invasive esophagectomy can be performed safely with reasonable operative times, markedly less morbidity and mortality, excellent anastomotic integrity, and consistent initial oncologic outcomes. Because pulmonary complications carry a poor prognosis, the ability to decrease and eliminate them is critical, which seems to be achieved with a minimally invasive esophagectomy in several studies. Although long-term oncologic outcomes are being evaluated, initial short-term results indicate that a minimally invasive esophagectomy is at least equivalent to its open counterpart. MIE should be performed in centers with experience in advanced minimally invasive esophageal surgery. Certainly, further prospective studies are needed to confirm these results, such a large multicentered, randomized, controlled trial.

Laparoscopic Treatment of Esophageal Motility Disorders

Edward D. Auyang, MD, MS, and
Carlos A. Pellegrini, MD, FACS, FRCSI (Hon)

INTRODUCTION

Esophageal motility disorders are the result of disruption of the complex swallowing mechanism that simultaneously propels food boluses through the esophagus and prevents aspiration. The etiology of these disorders is not clearly understood, although the several proposed theories have included genetic, immunologic, and infectious mechanisms. These disorders usually manifest themselves in one of the two ends of the spectrum: hypercontractility in the form of "nutcracker" esophagus or diffuse esophageal spasm or hypocontractility, as with the complete aperistalsis of achalasia. Most of these disorders have no effective cure and are only treatable symptomatically with medications and endoscopic or surgical therapy. Achalasia is the most common esophageal motility disorder. Etiology is not known and cure is not possible, but surgery is extremely effective to resolve dysphagia, which is its main symptom. Patients present clinically with dysphagia and regurgitation. The gold standard for diagnosis is manometry, and the hallmark of the disease is the absence of peristalsis combined with impaired relaxation of the lower esophageal sphincter (LES). In 60% of patients, LES pressure is elevated. Barium esophagram, a useful study, typically has the pathognomonic appearance of a dilated esophagus with a distal esophageal "bird's beak" tapering. Upper gastrointestinal (GI) endoscopy further confirms the radiographic finding and is used to rule out other disease processes that may mimic achalasia, such as peptic strictures or neoplasms. In addition to achalasia, patients with esophageal dysmotility may present with the rare entity of epiphrenic diverticula.

These diverticula, found in the distal 10 cm of esophagus, are formed when weakness of the esophageal muscularis in the setting of esophageal dysmotility results in a functional obstruction. Symptoms and diagnostic evaluation are identical to those for achalasia.

In this chapter, the authors describe the technique for laparoscopic Heller myotomy for the treatment of achalasia, address the challenges of revisional surgery after previous surgical myotomy and treatment of end-stage achalasia, and describe the technique for the laparoscopic treatment of epiphrenic diverticula.

LAPAROSCOPIC HELLER MYOTOMY AND PARTIAL FUNDOPLICATION FOR ACHALASIA

Before elective surgery, patients who have a dilated esophagus as identified on preoperative studies are instructed to be on a liquid-only diet for 4 to 5 days in advance of the operation to help reduce the risk of aspiration of esophageal contents during induction of anesthesia. Preoperative subcutaneous heparin for deep vein thrombosis (DVT) prophylaxis and a first-generation cephalosporin for antibiotic prophylaxis are routinely administered before incision. The patient is positioned on the operating table on top of a bean bag. An upper-body warming device and bilateral lower extremity sequential compression devices (SCDs) are applied. A Foley catheter is placed given the anticipated duration of the operation. General anesthesia is induced, and the patient is placed in a low-lithotomy position. The bean bag is evacuated to form a "seat," thus preventing slipping when the patient is in reverse Trendelenburg's position. Both arms are tucked to allow for placement of a self-retaining retractor by the patient's right arm. The surgeon stands between the patient's legs, and the laparoscopic monitor is placed in the midline directly over the patient's upper chest for direct viewing.

Pneumoperitoneum is obtained with a Veress needle technique at the left subcostal margin. Preference, for safety reasons, is placement of the first trocar with direct vision with an 11-mm bladless optical trocar. A 10-mm trocar is placed at a left supraumbilical location approximately 1 hand width below and medial to the left subcostal port. A 10-mm left flank assistant port and a 5-mm right subcostal working port are then placed. Finally, a Nathanson's liver retractor is placed at a subxiphoid location without a port, or for patients with a large liver, a paddle liver retractor is placed through a right flank 11-mm port. The patient is then placed in steep reverse Trendelenburg's position (Figure 1).

A point approximately one third of the way distal to the gastroesophageal junction (GEJ) along the greater curve is chosen, and the short gastric vessels are divided proximally with an energy device. The hiatus is then dissected starting along the left crus and proceeds counter-clockwise anteriorly. The gastrohepatic ligament is then divided, and the right crus is dissected in a clockwise fashion to meet the left-sided dissection (Figure 2). The posterior window of the GEJ is opened so that a ½-inch Penrose drain can be placed around the GEJ to facilitate inferior retraction of the esophagus. This allows for a high mediastinal dissection to be performed to lengthen the esophagus and create the distance for an anterior esophagomyotomy 8 cm proximal to the GEJ. In addition, this window is used for creation of the Toupet fundoplication after the myotomy is completed (Figure 3).The anterior vagus nerve is identified and preserved during this dissection (Figure 4). The gastroesophageal fat pad is dissected away from the GEJ and resected to facilitate identification of the exact place in which the esophagus becomes stomach so that the distal extent of the myotomy on the anterior cardia of the stomach can be appropriately identified.

Once the anterior surface of the esophagus, GEJ, and cardia are free and the anterior vagus nerve is mobilized, the myotomy can be performed. A 52F lighted esophageal bougie is passed transorally by the anesthesiologist or the surgeon with the tip positioned in the

body of the stomach. A clamp is placed through the left lateral assistant port to spread the anterior esophagus and stomach over the Bougie to provide tension on the muscle fibers, facilitating the division of the muscle. The myotomy is started distally on the cardia of the stomach from a distance at least 3 cm distal from the previously identified GEJ. This is absolutely critical to ensure a complete myotomy and adequate division of the fibers of the GEJ. The superficial muscle is carefully scored with an L-hook monopolar cautery, with extreme care taken not to cauterize too deeply and cause a mucosal perforation. The L hook is then used to divide the longitudinal and oblique muscle fibers of the stomach without the use of energy. This is the most difficult portion of the myotomy as the fibers cross in multiple directions and do not separate easily from the underlying mucosa. The dissection progresses proximally to the GEJ and further along the distal esophagus to a point at least 8 cm proximal to the GEJ. In the vicinity of the GEJ, the anterior vagus needs to be retracted from the right lateral position to the left lateral position to facilitate the proximal progression of the myotomy (under the vagus nerve). The esophageal longitudinal and circular muscle fibers are also divided without the use of energy because the underlying mucosa is very thin. The lighted Bougie helps for identification of undivided esophageal circular muscle fibers as the myotomy is completed (Figure 5). If bleeding is encountered during the myotomy, it can usually be controlled with direct pressure. Electrocautery is not recommended on the mucosa because thermal injury is very likely. Perforations can occur during the creation of the myotomy and should not be regarded as a complication. If a perforation of the mucosa occurs, it is usually easily identified and can be repaired primarily with 4-0 absorbable interrupted stitches.

Once a myotomy of adequate length is completed (6 to 8 cm proximal to the GEJ on the esophagus and 3 cm onto cardia of stomach), the antireflux procedure is performed. A fundoplication is routinely performed because the incidence rate of reflux after Heller myotomy is more than 50%. A partial fundoplication is chosen over a complete fundoplication as to avoid persistent dysphagia. The authors' preference is for the Toupet partial posterior fundoplication because of the lower rate of postoperative dysphagia compared with an anterior Dor fundoplication. The first step in creation of the Toupet fundoplication is passage of the tip of the gastric fundus posterior to the GEJ and securing it to the right crus with 2-0 silk at two locations, anterior and posterior. Next, the fundic tip is sutured to the right edge of the myotomy with three 2-0 sutures. The proximal fundus is then sutured to the left edge of the myotomy with three 2-0 silk sutures and finally to the left crus. This configuration not only helps reduce reflux but also "tents" the myotomy apart, in theory reducing the chance of scarring and reformation of anterior muscular fibers (Figure 6). An anterior Dor fundoplication is used when one of the following two scenarios is encountered: (1) a mucosal perforation has occurred, and the fundoplication is used as a buttress for the mucosal repair; and (2) the Toupet fundoplication when fashioned creates too much bulk and posterior angulation of the GEJ. Experience reported by Duranceau's group at the University of Montreal with the use of the Nissen fundoplication has shown that although this operation is more effective in preventing reflux, a larger number of patients have recurrent dysphagia compared with a partial (posterior or anterior) fundoplication. On very rare occasion when a patient is older, has near end-stage achalasia, and has a severely dilated esophagus, a fundoplication is not performed at all for concern of causing dysphagia. The risk of reflux is accepted, and the patient is placed on life-long proton pump inhibitor therapy.

At the completion of the operation, an intraoperative upper endoscopy is performed to evaluate for adequate length of the myotomy and appropriate anatomic configuration of the fundoplication and to look for evidence of mucosal perforation. The abdomen

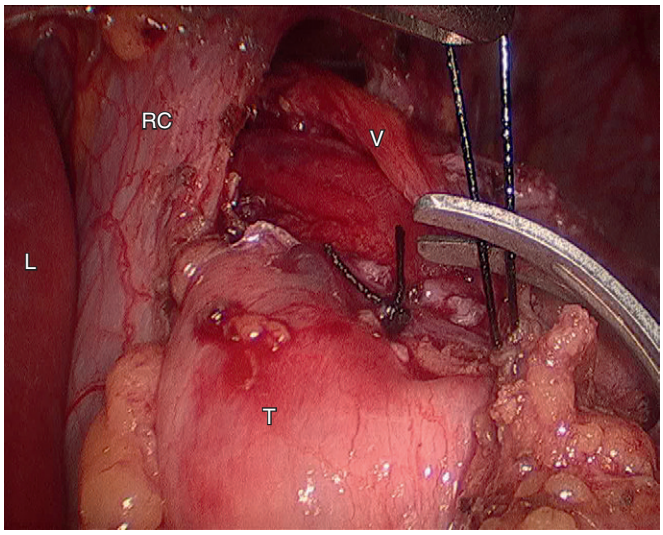

FIGURE 6 Toupet fundoplication. *L,* Liver, *RC,* right crus; *T,* Toupet fundoplication; *V,* vagus nerve.

is finally desufflated, and the incisions are closed with 4-0 dissolvable suture. After surgery, patients are started on a clear liquid diet the day of the operation and advanced to a soft diet the following day. Patients are typically discharged on the first postoperative day. For the subsequent 6 weeks, while inflammation and edema from the operation are resolving, patients are on a modified diet and instructed to specifically avoid eating breads, raw vegetables, and pieces of meat to avoid food impaction.

REVISIONAL SURGERY AFTER HELLER MYOTOMY

Treatment of recurrent or persistent dysphagia after previous Heller myotomy can be very challenging. The most important element is to define the anatomy and its relationship to the patient's recurring or returning symptoms (overwhelmingly dysphagia). A thorough evaluation is necessary to determine the etiology of dysphagia and whether it is amenable to surgical revision. The first step involves obtaining all possible records before the patient's initial myotomy, in particular finding confirmatory testing that the patient had an accurate diagnosis of achalasia to begin with. The patient's operative report is critical to determine whether an adequate length myotomy was performed initially and what type of, if any, fundoplication was performed. A thorough history from the patient can provide further information. Whether or not symptoms improved after initial myotomy and how soon they recurred can suggest whether the operation performed was initially effective. Specifically, whether a patient had moderate or substantial weight gain after an operation is a key determinant of prior surgical success.

After a thorough history and review of records, multiple tests are used to determine the cause of dysphagia. To use each test, the etiologies for dysphagia need to be recognized. The three most common etiologies for persistent or early dysphagia are: (1) inaccurate diagnosis of achalasia; (2) incomplete myotomy (or excessive scarring of a well-done myotomy); and (3) excessively tight fundoplication or crural closure. Recurrent or late dysphagia is most likely the result of late scarring and fibrosis at the site of previous myotomy, although peptic strictures, herniated fundoplication, and esophageal neoplasms also should be considered. On the basis of this understanding, the information that each test provides can be interpreted. Upper GI barium swallow provides anatomic and functional information about the esophagus. If there is a specific point of obstruction or if there is a problem with the fundoplication, such as wrap herniation, this can be identified on the upper GI examination. Upper endoscopy can identify additional causes of dysphagia, such as esophagitis, esophageal diverticuli, strictures, and neoplasms. In the absence of anatomic causes for dysphagia, esophageal manometry is used to confirm the diagnosis of achalasia and for assessment of the LES. With a diagnosis of achalasia and persistent incomplete LES relaxation, a patient with these findings may be a candidate for a redo myotomy. Finally, 24-hour pH testing can assess whether the patient has quantitative acid reflux that may be responsible for dysphagia.

Initial treatments for patients with post-Heller dysphagia from incomplete myotomy or recurrent scarring may include endoscopic therapies such as pneumatic dilation. However, for patients who have a clearly identifiable stricture or area of narrowing and are fit for surgery, a redo myotomy, or a laparoscopic revision, may provide a benefit. The redo operation is approached laparoscopically with ports placed in an identical fashion to a laparoscopic Heller myotomy. If a fundoplication was previously performed, this is taken down and all adhesions are lysed to restore the original anatomy as best as possible. The myotomy is then made lateral to the original myotomy and extended at least 4 cm onto the gastric cardiac and as far proximally up the esophagus as is possible with a minimal distance of 6 to 8 cm. Extreme care must be taken for this dissection to avoid making a myotomy over the previous location and perforating the stomach or esophagus because the contour of the muscular fibers may be altered from fibrosis. After completion of this new myotomy, a Toupet fundoplication is typically performed that is constructed in a similar fashion as described previously. Criteria for choosing to perform a Dor fundoplication or no fundoplication are identical for the revisional operation as they are for a first-time operation.

Revisional surgery after previous Heller myotomy for achalasia is an operation that should only be undertaken by surgeons who have a large amount of experience with Heller myotomy and revisional foregut operations. Distortion of original anatomy from adhesions and scar can make a redo operation particularly challenging and can result in a higher complication rate when performed by the less experienced surgeon. Furthermore, an injury to the mucosa, most often a laceration during the dissection, may require an esophagectomy, and the surgeon should be prepared to do so. It is, therefore, important for the surgeon to understand the etiologies of recurrent or persistent dysphagia and recognize when a referral should be made to a more specialized center for a redo operation.

LAPAROSCOPIC TREATMENT OF END-STAGE ACHALASIA

Although laparoscopic Heller myotomy with partial fundoplication is a successful treatment for most patients diagnosed with achalasia, there is a subset of patients who have end-stage achalasia and a severely dilated and tortuous esophagus in which a myotomy will not improve symptoms. It is in this patient population that esophagectomy is considered. Critical decision-making points for offering an esophagectomy are focused around a patient's age, comorbidities, and ability to tolerate the operation. Unfortunately, end-stage achalasia is usually diagnosed in elderly, severely malnourished patients. These are also the patients who are less likely to tolerate an esophagectomy and in whom endoscopic therapies such as botulinum toxin or pneumatic dilation should be strongly considered (Figure 7).

LAPAROSCOPIC TREATMENT OF EPIPHRENIC DIVERTICULA

Surgical treatment of epiphrenic diverticula is composed of three components: resection of the diverticulum, esophagomyotomy, and fundoplication. Historically, this procedure has been performed with a thoracic approach, either with video-assisted thoracoscopic

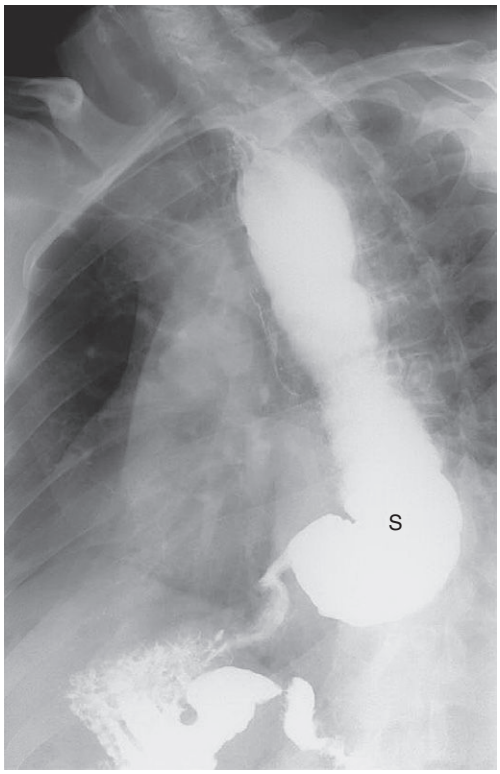

FIGURE 7 Sigmoid esophagus. *S,* Dilated, sigmoid esophagus.

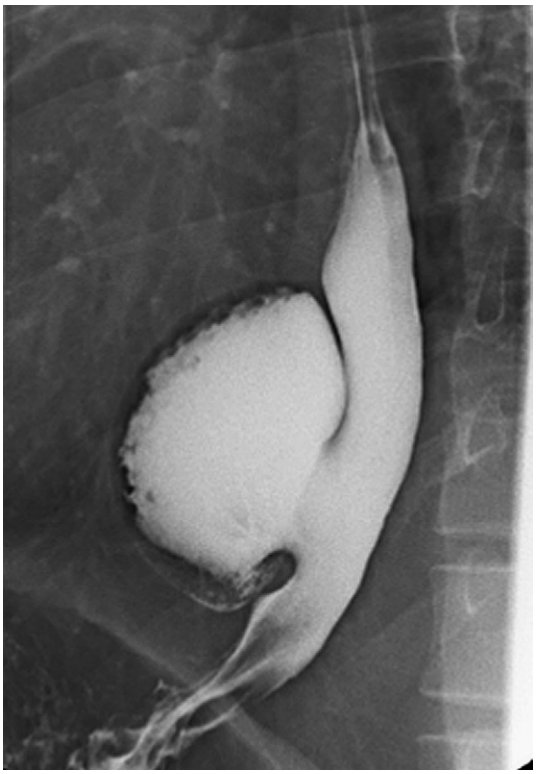

FIGURE 8 Epiphrenic diverticulum.

surgery (VATS) or open thoracotomy. In fact, many institutions still prefer the thoracic approach. With the development of laparoscopy, the transabdominal approach has been shown to provide good visualization and access to the distal esophagus. In addition, there may be less pain and morbidity compared with a thoracic approach (Figure 8).

The operative approach to the epiphrenic diverticulum is identical to the approach for laparoscopic Heller myotomy. Five ports are placed as described previously. The short gastric vessels are divided, the left and right crus are dissected free from the esophagus, and the esophageal attachments to the mediastinum are dissected as superiorly as possible. Any adhesions between the diverticulum and esophagus are also freed to show the neck of the diverticulum. The vagus nerve, which often is overlying the diverticulum, is protected and retracted. The diverticulum is then resected with an endoscopic linear stapler (3.5-mm staple width) over a 50F lighted bougie to prevent esophageal narrowing. The Heller myotomy and fundoplication are then performed with the technique described previously. The fundoplication may be a Dor or a Toupet. It usually does not reach the area of the diverticulum, and thus, the choice has to do with the myotomy, not with the diverticulectomy. With that in mind, the principles and rationale described previously for patients with achalasia are applied. An esophagram is obtained 2 days after the operation to evaluate for esophageal leak and narrowing. If the esophagram does not show any residual diverticulum or leak, the patient is started on a liquid diet and is discharged the following day on the modified diet described previously.

SUMMARY

Esophageal motility disorders are rare and complex diseases that can manifest themselves in a variety of clinical forms. Achalasia is a disorder in which aperistalsis leads to severe dysphagia, regurgitation, and weight loss. Laparoscopic Heller myotomy with Toupet fundoplication is the preferred approach to patients who have achalasia. Revisional surgery for persistent or recurrent dysphagia is a feasible option in patients who have a clear surgically correctable problem but should be performed by experienced foregut surgeons. In addition, esophagectomy may provide an option for patients with severe end-stage achalasia who can tolerate the operation and in whom Heller myotomy will not provide a benefit. Epiphrenic diverticula are rarer entities that may be the result of esophageal dysmotility. A laparoscopic diverticulectomy in combination with Heller myotomy with Toupet fundoplication can provide a successful result and may have less pain or morbidity compared with thoracic and thoracoscopic approaches.

Laparoscopic Adrenalectomy

Lee L. Swanstrom, MD, FACS

INTRODUCTION

Since laparoscopic access to the adrenal gland was first introduced in the early 1990s by Gagner, Park, and others, it has become the standard approach for almost all indications. This includes both benign and malignant indications, with the sole exceptions being more advanced cancers and when it is part of a secondary resection such as a radical nephrectomy. The techniques of laparoscopic adrenalectomy have mostly reproduced the approaches of open approaches with some important exceptions: the first being the lateral decubitus approach, which is now the standard technique. Other variations have paralleled the evolutions of laparoscopic surgery in general: single port approaches, mini-laparoscopy, and robot-assisted laparoscopy. Finally, there have been some animal studies of flexible endoscopic adrenalectomy by natural orifice transluminal endoscopic surgery (NOTES) approaches.

INDICATIONS

Indications for adrenalectomy can be either benign or malignant. By far the most common indications for adrenalectomy are benign endocrine tumors or lesions suspected of being endocrine tumors. Endocrinologically active tumors can secrete cortical steroids (cortisol, adrenal androgens, and aldosterone) or medullary hormones (epinephrine or norepinephrine) and therefore be detected by various hormone-related systemic symptoms. They can also be nonsecreting and picked up as incidental findings on computed tomographic (CT) scans or magnetic resonance imaging (MRI)—hence the term *incidentalomas.* In general, any patient documented to have an adrenal lesion and symptoms related to hormone secretion—and even those who have an asymptomatic lesion but elevated adrenal hormones—should have an adrenalectomy. Particularly problematic are symptomatic patients with elevated hormones and no lesion seen on imaging studies. For these patients, more sophisticated methods such as radionuclide scans or radiologically performed direct venous sampling may be helpful to localize the tumor. Finally, one or both normal glands may be removed in patients with medically uncontrollable Cushing's syndrome caused by pituitary tumors.

Primary adrenal malignancies are relatively rare. They include the malignant transformation of the usual endocrine tumors as well as some others, such as adrenal cortical cancer, lymphomas, leiomyosarcomas, pheochromocytomas, and metastatic cancers. Early and incidentally discovered cancers are treated effectively by laparoscopic approaches, but more advanced tumors requiring nodal field or adjacent organ resection are most commonly approached through open surgery or at least undergo a high conversion rate. Finally, the adrenal is a not infrequent site of metastases from a variety of tumor types (lung and ovarian being perhaps the most common). Indications for laparoscopic adrenalectomy are summarized in Table 1.

TECHNIQUES

Patient preparation is generally as it would be for any patient undergoing laparoscopic surgery: preoperative single shot of a first-generation cephalosporin, antithrombosis measures (aggressive ones in the case of adrenal malignancy), as well as addressing electrolyte imbalance frequently seen in hormonally active tumors. The exception is active pheochromocytomas, where surgical manipulation of the tumor can lead to wild swings of blood pressure, although less so with laparoscopic resection. It is recommended that these patients have 3 weeks of preoperative beta and alpha blockade managed by an endocrinologist.

Patient Position

Patients undergoing an adrenalectomy will be placed in one of three basic positions: anterior (supine), lateral (lateral decubitus), or prone. Anterior is seldom used unless an additional procedure is indicated, as retraction and exposure of this most deeply placed organ is difficult and requires additional ports. A suspected cancer might be one such indication, as wide nodal resection is indicated as well as an abdominal exploration. Either the lateral or the posterior approach can be used routinely, although a relative indication for the posterior approach is the need for bilateral adrenalectomy, and a relative contraindication for the posterior approach is a large tumor.

Lateral Approach

The lateral approach works because the position allows the multitude of organs overlying the adrenal gland to fall away. A beanbag support should be placed on the table and the patient positioned with the umbilicus over the break in the table. After anesthesia, the patient is rolled to almost a full lateral decubitus position (lesion facing up) with an axillary roll for nerve protection and the arms appropriately positioned. The table is "broken" enough that the flank is even with the iliac crest and the lower rib margin. The beanbag is deflated and the patient taped well to the operating table and checked carefully for pressure points (Figure 1). After draping, the table is rolled dorsally, and initial access is obtained by either the Veress or the Hasson technique. The initial port is placed in the lateral rectus margin 10 cm below the costal margin. Two or three additional ports (2.5-5 mm) are placed along the costal margin, as illustrated in Figure 2. The surgeon and assistant stand on the same side of the table facing the patient's belly.

On the left, the native attachments of the colon splenic flexure are taken down if needed to place the posterior-most port. Because the adrenal gland lies behind the spleen, the lateral splenic peritoneal attachments are divided to let the spleen roll forward by gravity. The upper margin of the left kidney is identified by palpation and a small window in Gerota's fascia. Alternatively, particularly in very obese patients, laparoscopic ultrasound can identify the key landmarks of the superior kidney and left renal vessels, which is the angle that contains the left adrenal gland. In most cases, the lateral and inferior margin of the gland is first identified. This is done by carefully dividing the retroperitoneal fat to visually identify the unique greenish/yellow color of the adrenal (Figure 3). Dissection is performed using an energy device like an ultrasonic scissor and a "no touch" technique in which the surgeon concentrates on retracting the adrenal gland without grasping it directly but rather grasping peri-adrenal fat or simply pushing it or levering it with a grasper or suction. The gland is progressively dissected free, heading toward the deepest portion, which lies next to the renal vasculature. It should be noted that every millimeter of the dissection should be done with hemostatic instruments. This is because small vessels enter the gland in unpredictable patterns and energy prevents blood staining the tissues, which can make identification of the tissue planes difficult. The adrenal vein on the left is usually the last attachment to be divided, and division is usually safely done with bipolar or harmonic energy.

TABLE 1: Current indications for surgical intervention in adrenal pathology

Indication	Benign	Malignant
Incidentaloma	Growing	>5 cm
Aldosteronoma	Symptomatic	Evidence of invasion
Cortisolinoma	Hypertension	Adjacent invasion, large size
Pheochromocytoma	Blood pressure problems	Invasion or metastasis on imaging
Adrenal metastasis	Lesions on imaging	Associated lung, kidney, ovarian, and other lesions

The resected gland is placed in an impervious specimen bag and retrieved by slightly increasing the largest port site. After carefully inspecting the resection bed for hemostasis, this widened port site is closed with a suture passer and full-thickness absorbable sutures.

For the right adrenal gland, port placement is the same. The triangular ligament of the right liver lobe is completely divided to free the bare area and let the right lobe roll forward. There is typically little fat in the retroperitoneum of the right side, due to the compression of the liver. The adrenal, in fact, is often visible through the peritoneum. The peritoneum is opened vertically over the gland and once again with a "no touch" technique and energy the whole way. Dissection progresses from lateral to medial until the lateral margin of the vena cava is visualized. Precise and gentle dissection is performed to separate the medial gland from the vena cava until the right adrenal vein is well visualized. It should be controlled by clips, at least on the vena cava side, before being divided. Once again, the gland is placed in a bag and the bag withdrawn to the incision to allow the gland to be extracted.

Posterior Approach

For the posterior approach, the patient is positioned in the prone position. An orthopedic spine bed is best, but a standard bed is possible with specialized pads and bolsters. Before prepping and draping the bed or table, all possible points of pressure to the patient are addressed (Figure 4).

As the "landscape" for posterior port placement is quite limited, being confined in the angle between the posterior costal margin and the lateral edge of the paraspinous muscle, it is critical that small ports be used and placed very precisely (Figure 5). There is typically only room for three ports on each side, but if well placed, this is all that is needed, as there are no adjacent organs to retract with this approach. External ultrasound can be used to map out the position of the kidney and adrenal gland and mark the position on the skin. This allows for the most accurate placement of two 5-mm ports. The central port is 10 mm. Either an "optically directed" port or a direct cutdown technique is used to access the retroperitoneal space. A hernia-dissecting balloon is inflated to create the retroperitoneal space. Relatively high pressure carbon dioxide (CO_2) is used for insufflations (15-16 mm Hg). Often the adrenal gland can be seen at the base of this dissection (Figure 6). The additional 3-mm or 5-mm ports are placed under vision. Dissection of the gland is performed as previously described, using a "no touch" technique as much as possible and a sealing energy technology. As the dissection starts on the posterior aspect of the gland, it is not unusual for the main vascular supply to be encountered early in the dissection, requiring its control with energy or clips, depending on its size. Care must be taken to avoid injury to the peritoneum, as this can result in the collapse of the retroperitoneal space and loss of exposure. The specimen is bagged and removed through a widened port site. The port site fascia is usually not closed.

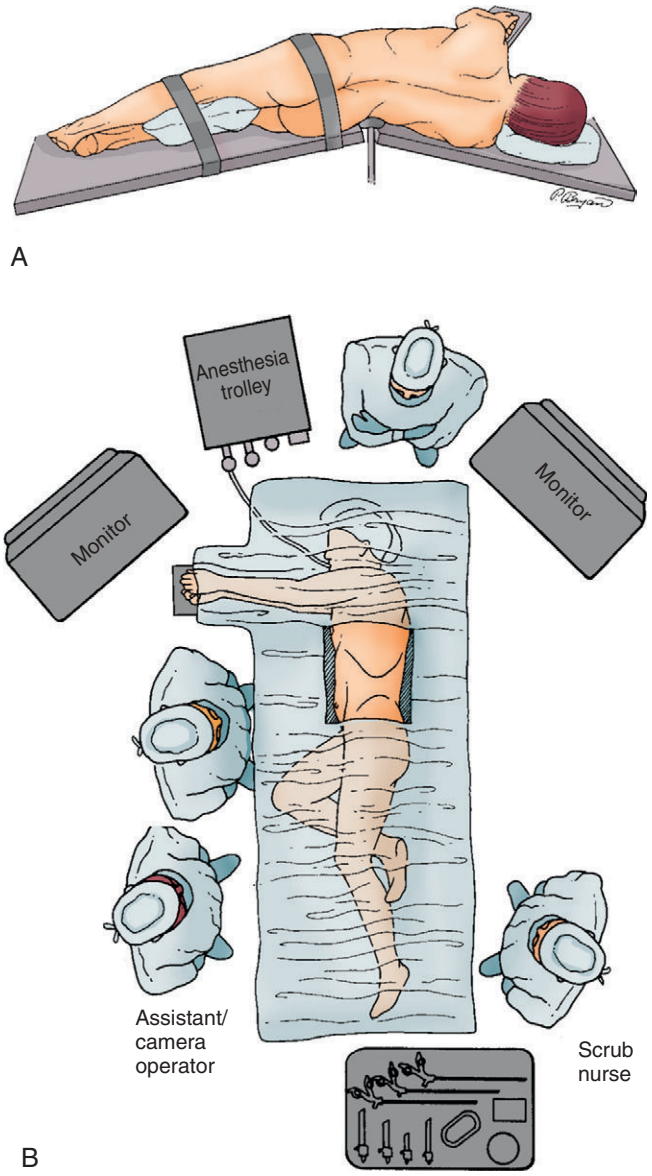

FIGURE 1 **A,** Patient positioning for lateral approach to left laparoscopic adrenalectomy (kidney rest and table break are positioned at the iliac crest). **B,** Operating room setup and patient positioning for laparoscopic adrenalectomy. *(Modified from Smith CD, Weber CJ, Amerson JR: Laparoscopic adrenalectomy: new gold standard,* World J Surg *23:389-396, 1999.)*

COMPLICATIONS

Laparoscopic adrenalectomy is not a particularly risky surgery; mortality due to the surgery is essentially unknown, although certain disease states, such as adrenal cortical cancer and Cushing's syndrome, have high associated morbidity and mortality rates. Intraoperative morbidity is primarily related to organ injury during surgery, for example, injury to proximal organs (spleen, liver, colon, etc.). Although this happens less than 5% of the time, it often occasions

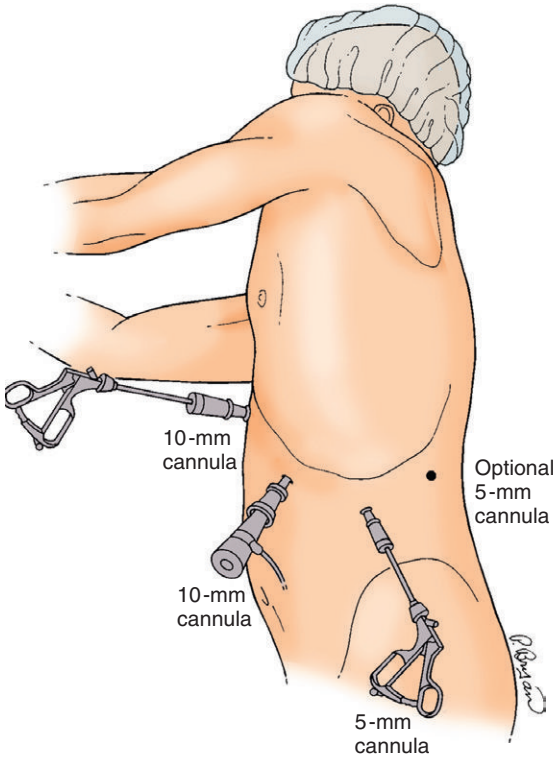

FIGURE 2 Trocar placement and instrument placement for left laparoscopic adrenalectomy. *(Modified from Smith CD, Weber CJ, Amerson JR: Laparoscopic adrenalectomy: new gold standard,* World J Surg *23:389-396, 1999.)*

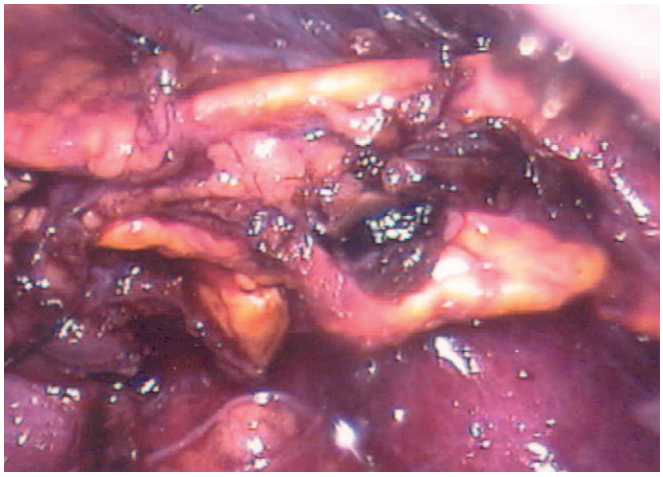

FIGURE 3 Division of the retroperitoneal fat reveals the distinctive green/yellow color of the adrenal gland.

conversion to open surgery. Injury or disruption of the gland may not be strictly a "complication," but it represents a technical error that may compromise patient treatment and therefore should be avoided. The major dramatic complication associated with laparoscopic adrenalectomy is the same as for open adrenals, that is, bleeding. This can be intraoperative bleeding due to adjacent organ injury (spleen, liver), an escaped blood vessel (arterial or venous), or, most dramatically, an injury to one of the major vessels that lie close to the adrenal gland. It can also be delayed bleeding happening typically hours to days following the procedure and primarily due to the vascular nature of the paraadrenal environment.

FIGURE 4 The posterior approach requires the patient to be placed in the prone position.

The dreaded complication of an injury to a major vascular structure during dissection justifies its concern, as conversion to control is difficult to impossible depending on the patient position (lateral decubitus vs posterior). Fortunately, structures most at risk are the vena cava or renal vein, and positive pressure CO_2 insufflation tamponades the bleeding and can permit a careful clip application or suture repair if the surgeon does not panic and lose control of the situation.

Other complications might include wound problems or hernias but more commonly would be associated with underlying endocrine disorders associated with the primary disease states, such as electrolyte disturbance or endocrine insufficiency. These potentialities may be a good opportunity for surgeons to establish a close working relationship with endocrinology specialists.

POSTOPERATIVE CARE

Patients can be expected to have a moderate amount of pain following laparoscopic adrenalectomy. Typically they would stay in the hospital for approximately 24 hours with at least a hematocrit/hemoglobin check before discharge. Patients with more complex problems such as extreme hypertension, profound electrolyte problems, or need for replacement steroid therapy, may need longer hospital stays as well as more frequent blood work. For most patients, no physical restrictions are placed, and most return to full work activities in 2 weeks.

OUTCOMES

Laparoscopic approaches to adrenal pathologies are highly successful. Conversion to an open procedure is needed less than 5% of the time for benign disease and 20% for malignancies. Otherwise, success rates for disease cure or palliation closely mimic results from open surgery with documented advantages of less pain, shorter hospital stays, and a quicker return to normal activity.

THE FUTURE: EVEN LESS INVASIVE SURGERY

There is movement afoot to further reduce the physiologic impact of laparoscopic surgery. Single-incision surgery (e.g., single-incision laparoscopic surgery [SILS], laparoendoscopic single-site surgery

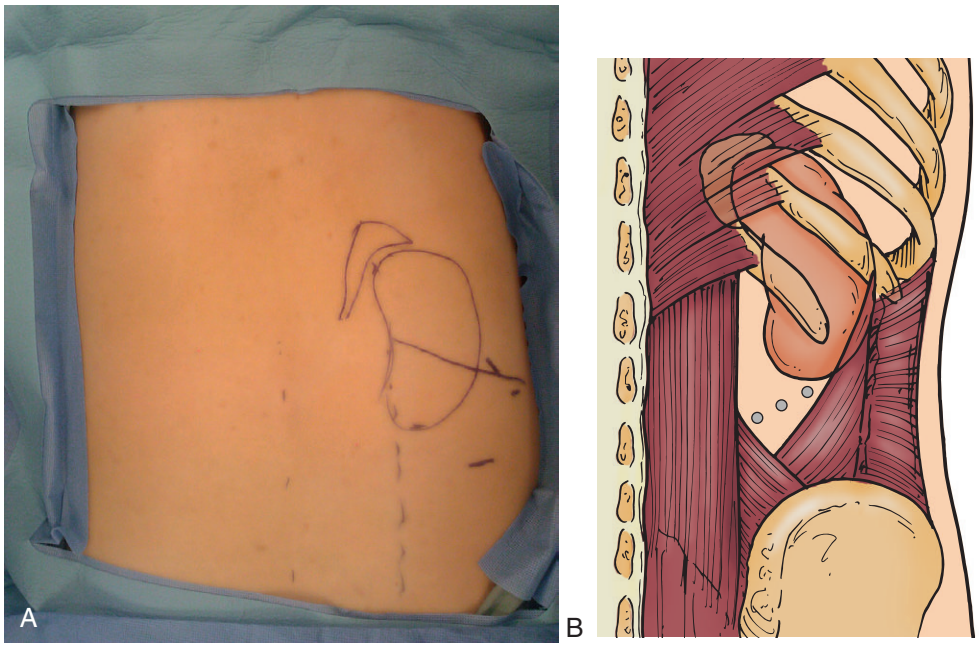

FIGURE 5 Posterior port placement has to be done carefully as there is limited space for placement.

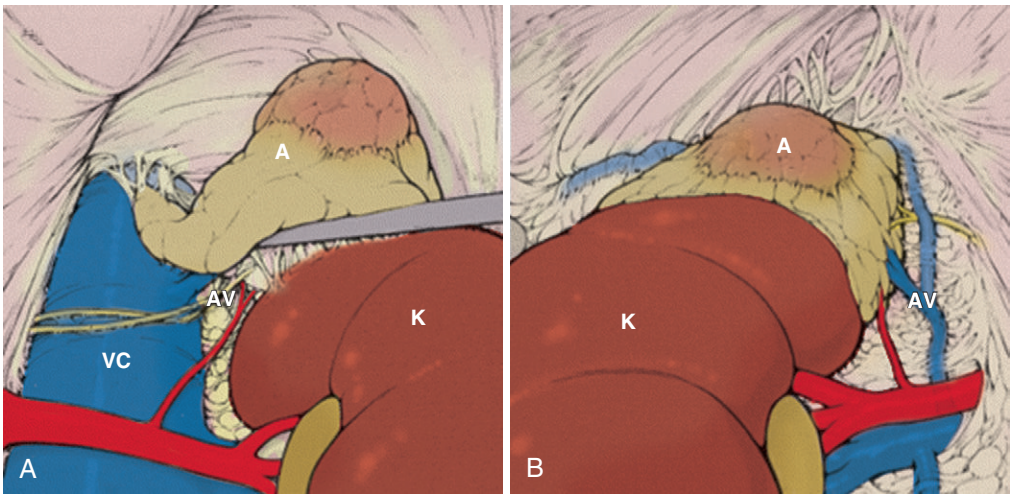

FIGURE 6 Posterior retroperitoneal endoscopic adrenalectomy. **A,** Right. **B,** Left. *A,* Adrenal; *AV,* adrenal vein; *K,* kidney; *VC,* vena cava. *(Modified from Walz MK: Minimally invasive adrenal gland surgery [in German],* Chirurg *69:613-620, 1998.)*

[LESS], trans umbilical surgery [TUS]), mini-laparoscopy, and NOTES are being explored in hopes of improving cosmesis, decreasing postoperative pain, and speeding recovery. These less invasive approaches are either just in the process of being adopted (SILS) or are in the exploratory stage, and there are no definitive outcomes data to define their exact place in adrenal surgery.

Single-incision Laparoscopic Surgery Approach

Accessing the adrenal laparoscopically through a single incision (the SILS approach) has the best comparative outcomes data to support its use. Several prospective studies have been published showing feasibility and some patient advantages: decreased pain and better cosmetics primarily. Single-incision adrenalectomy is performed either with a specially designed multiple-port device, placed through a 1.5-cm to 2.5-cm incision, or by making a single skin incision and placing several small laparoscopic ports through the fascia (Figure 7). Drawbacks of such an approach include the ergonomic difficulties of multiple parallel instruments and the laparoscope, which make

FIGURE 7 One technique of single-port surgery involves a single 2.5-cm skin incision with three 5-mm ports placed through the fascia. The fascial incisions can be connected at the end of the case to remove the specimen.

such approaches more technically demanding, and theoretic concerns about increased wound problems. Still, most would recognize that adrenalectomy is almost the perfect procedure for this approach, as it involves a small organ, in a tight space, with a limited number of instruments needed, and requiring no suturing.

Mini-Laparoscopy

Laparoscopy using 2-mm to 3-mm instruments, so-called mini-laparoscopy, is enjoying somewhat of a renaissance as surgeons and patients aim to further reduce the morbidity rate of standard laparoscopy. It has also been facilitated by the availability of new alloys and materials that make very rigid, small instruments possible. Adrenalectomy certainly makes sense for this approach, as the adrenal gland is a small lightweight organ and is usually located in a tight constrained space. Perhaps because it is so close to the, now standard, 5-mm port approach, there has been little in the literature documenting benefits or problems with mini-lap adrenalectomy.

Robot-Assisted Laparoscopic Adrenalectomy

As with all laparoscopic surgery, robots have invaded the field. There are several reports describing the use of the da Vinci telemanipulator (Intuitive Surgical, Sunnyvale, Calif) to perform adrenalectomy. Users report great benefits in surgeon ergonomics but no documented clinical outcomes benefit to the patient. Also, the use of the da Vinci is expensive, takes longer, and requires the use of larger ports than standard laparoscopy. It would seem that, until a surgeon/computer interface is fully realized (e.g., image registration for the localization of the gland and its vasculature), the "robot," as it currently exists, is little else than a marketing deception.

NOTES Adrenalectomy

NOTES is perhaps the ultimate expression of minimally invasive surgery. This postulates the fusion of the low-impact nature of even fairly aggressive endoscopic interventions, such as endoscopic retrograde cholangiopancreatography (ERCP), pancreatic pseudocyst drainage, and endoscopic submucosal dissection (ESD), which typically resulted in patients being pain free and back to work in a day or two, with true surgical procedures such as adrenalectomy. Although laparoscopic adrenalectomy is a true advance over open surgery in terms of patient impact, it still entails an operating room, a hospital stay, weeks off work, scars, and pain. The possibility of doing this as an outpatient procedure under sedation, with full activity the next day (as after polypectomy or ERCP), has been the driving force behind the push for an endoscopic surgical approach. Because of its small size, extraabdominal location, and distinctive anatomy, the adrenal gland was an early target of the NOTES investigations. Initial animal and cadaver studies documented its accessibility either transvaginally or transrectally using flexible retroperitoneoscopy. Whether these approaches are the future of treatment of adrenal disease is conjectural, but it does open the door to thinking beyond the traditional surgical approaches to the gland and its diseases.

Minimally Invasive Parathyroidectomy

Tracy S. Wang, MD, MPH, and Julie Ann Sosa, MD, MA, FACS

Primary hyperparathyroidism (pHPT) is defined as the presence of elevated serum calcium levels in the setting of elevated or inappropriately high normal serum parathyroid hormone (PTH) levels. Recent studies have shown that a small subset of patients with normal serum and ionized calcium levels but elevated PTH levels may also have the disease, termed normocalcemic pHPT. Overt manifestations of pHPT include nephrolithiasis, pancreatitis, peptic ulcer disease, pathologic bone fractures, and neuropsychiatric disorders; more subtle symptoms, such as fatigue, weakness, forgetfulness, depression, and bone and joint pain, are subjective and more difficult to attribute solely to parathyroid disease. The overwhelming majority of patients today presents with asymptomatic disease that is identified serendipitously on the basis of automated serum screening.

Surgery remains the sole curative treatment for pHPT and is recommended for all patients with symptomatic disease and for patients with asymptomatic disease who meet current consensus guidelines for parathyroidectomy. These guidelines include age less than 50 years, serum calcium 1.0 mg/dL or more above the upper limit of normal, osteoporosis (T score, ≤–2.5), history of a pathologic bone fracture, and reduced renal function (glomerular filtration rate [GFR], <60). However, given recent evidence that shows improved neurocognitive performance and quality of life in patients after curative parathyroidectomy, the authors believe that parathyroidectomy by experienced parathyroid surgeons should be considered as a treatment option for all patients with pHPT who are amenable to surgical consultation and who are deemed to be reasonable surgical candidates.

The most common etiology of pHPT is a single parathyroid adenoma (80% to 85%); other causes are multigland hyperplasia, including double adenomas (10% to 15%), and rarely, parathyroid cancer (<1%). Given that most cases result from a single abnormal parathyroid, the development of improved imaging techniques for

preoperative localization and the introduction of intraoperative parathyroid hormone (IOPTH) monitoring have allowed minimally invasive parathyroidectomy (MIP) to become the new gold standard for patients undergoing parathyroidectomy for sporadic pHPT, with equivalent cure rates and lower complication rates (recurrent laryngeal nerve injury and hypoparathyroidism) than with conventional bilateral neck exploration. Another benefit of a focused approach is the ability to perform parathyroidectomy with local anesthesia with an ipsilateral cervical block and sedation in the ambulatory setting.

Considerable debate exists, however, regarding the definition of a minimally invasive parathyroidectomy, with respect to extent of surgical exploration, length of incision, and use of intraoperative adjuncts, such as IOPTH monitoring. The authors believe that the appropriate definition of a minimally invasive parathyroidectomy is a focused, uniglandular exploration based on accurate preoperative localization, with use of IOPTH measurements as a guide for determination of intraoperative biochemical cure and with use of the radio-guided gamma probe or ex vivo parathyroid aspiration as intraoperative confirmation of the culprit lesion.

PREOPERATIVE PARATHYROID LOCALIZATION

Minimally invasive parathyroidectomy is dependent on accurate preoperative localization; failure of preoperative localization may necessitate conversion to bilateral exploration with attendant increases in operative time, increased hospital stay, and risk of complications. Common imaging studies include cervical ultrasound scan, technetium Tc 99m sestamibi with single-photon emission computed tomography (SPECT), and four-dimensional computed tomographic (4D-CT) scan. The preoperative imaging algorithm is highly surgeon and institution dependent, although patient characteristics such as renal function, contrast allergies, and body habitus also must be taken into consideration.

Cervical ultrasound scan is inexpensive and noninvasive and provides detailed anatomic information regarding both thyroid and parathyroid pathology (Figure 1). The sensitivity of ultrasound scan in detection of abnormal parathyroid glands ranges from 48% to 93%, with a recent meta-analysis finding a pooled sensitivity of 76% and a positive predictive value (PPV) of 93%, whether performed by surgeons or radiologists. Ultrasound scan has the advantage of being able to detect any thyroid pathology that may require further evaluation with fine-needle aspiration biopsy before surgery. Ultrasound scan is limited by the inability to accurately identify ectopic parathyroid adenomas in the mediastinum and retroesophageal locations.

Sestamibi scans use the metabolic activity of hyperfunctional parathyroid glands to identify abnormal parathyroid tissue, and the addition of SPECT provides three-dimensional information, rather than a planar view alone (Figure 2). Pooled sensitivity of sestamibi-SPECT is 79%, with a PPV of 91%; factors that influence accuracy of sestamibi-SPECT include the severity of pHPT, serum calcium, PTH, 25-OH vitamin D levels, and oxyphil cell content in the parathyroid adenoma. Adenoma location, size, and presence of multiglandular disease or thyroid nodules further limit the sensitivity of both sestamibi-SPECT and ultrasound scan.

Because of the limitations of both ultrasound scan and sestamibi-SPECT, 4D-CT scan has emerged as an additional modality for preoperative imaging; it uses the three-dimensional aspect of CT scans with the added dimension of changes in perfusion of intravenous contrast over time. Visualization of differences in perfusion (rapid uptake and washout) allow for identification of hyperfunctional parathyroid glands (Figure 3). The sensitivity and PPV of 4D-CT scan in detection of abnormal parathyroid tissue are 89% and 94%, respectively, but decrease to 72% and 75% when performed in patients with previously negative or inconclusive ultrasound scan and sestamibi-SPECT. Limitations of 4D-CT scan include the use of intravenous contrast and exposure to ionizing radiation.

The diagnosis of pHPT is not influenced by the results of imaging because the diagnosis is biochemical. However, imaging studies are crucial because accurate preoperative localization allows surgeons to maximize opportunities for a minimally invasive approach. A recent cost analysis suggests that the combination of ultrasound scan, sestamibi-SPECT, and if necessary, 4D-CT scan was the most cost-effective approach to preoperative imaging, followed by a combination of ultrasound scan and 4D-CT scan. The use of sestamibi-SPECT alone and bilateral exploration with no preoperative imaging were the least cost-effective modalities. The cost effectiveness is dependent on the accuracy of each study, which is highly dependent on institutional idiosyncrasies in technique and interpretation. Therefore, surgeons must know their institutional data to determine the optimal algorithm for preoperative imaging.

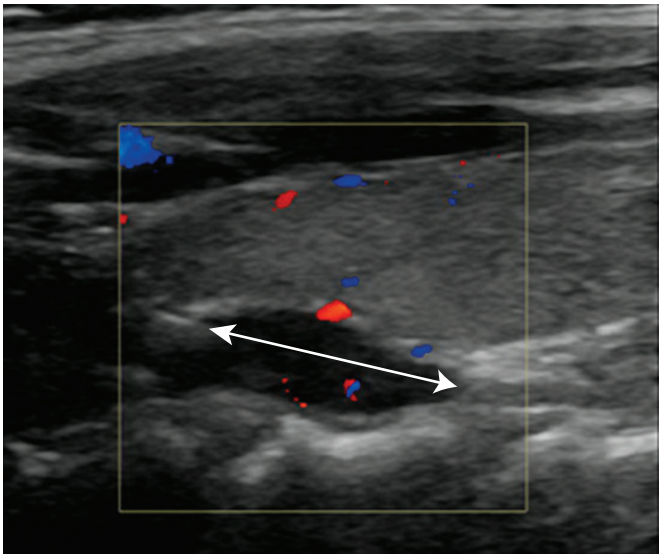

FIGURE 1 Ultrasound scan, depicting parathyroid adenoma.

FIGURE 2 Sestamibi scan, depicting left-sided parathyroid adenoma.

Given all of the previous considerations, the authors favor the use of cervical ultrasound scan and sestamibi-SPECT in all patients with pHPT before parathyroidectomy. If these imaging study results are negative or discordant, 4D-CT scan is then used. For patients undergoing reoperative parathyroidectomy for persistent or recurrent pHPT, concordant preoperative localization studies are crucial to facilitating minimally invasive parathyroidectomy, and consideration should be given to obtaining a 4D-CT a priori. Additional invasive localization techniques may include ultrasound scan with aspiration and PTH sampling of nodules presumed to be abnormal parathyroid tissue or arteriography with venous sampling. Any patient with thyroid nodules that meet criteria for fine-needle aspiration (FNA) based on size or appearance should undergo further evaluation so that concomitant thyroidectomy can be performed, if necessary (Figure 4).

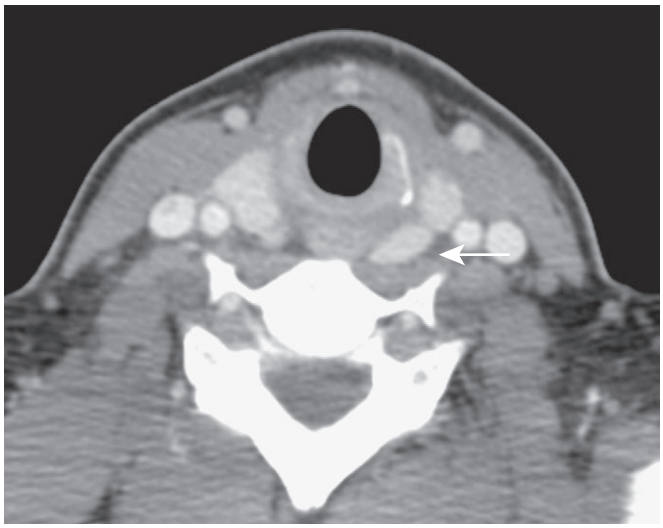

FIGURE 3 Four-dimensional computed tomographic scan, depicting left-sided parathyroid adenoma.

INTRAOPERATIVE ADJUNCTS

A major advance in the surgical management of pHPT was the development of a rapid immunoassay, predicated on the short half-life of PTH (approximately 3 to 5 minutes), that allowed for intraoperative PTH testing. IOPTH monitoring is a crucial adjunct for parathyroid surgery, and minimally invasive parathyroidectomy should not be performed without it. In brief, PTH levels are obtained before incision (baseline), at the time of excision of the parathyroid gland (time zero, when a spike in the PTH level can occur as a result of manipulation of the culprit gland during resection), and at 5-minute to 10-minute intervals after excision until the PTH level has fallen by an appropriate decrement. PTH levels can be obtained from either a peripheral intravenous catheter (preferred) or an arterial line.

Several valid criteria are used for interpretation of IOPTH testing. The Miami criterion consists of a drop of 50% or more from the baseline or time-zero level, whichever is higher, 10 minutes after removal of all abnormal glands; with this criterion, the reported cure rate (eucalcemia and normal PTH levels at 6 months after surgery) is 97%. The authors favor a more stringent criterion, which requires a decrease of 50% or more from the baseline or time-zero level, whichever is higher, *and* a decrease into normal range 10 minutes after removal of all abnormal glands. Failure to meet criteria, whichever is used, mandates further operative exploration and is highly suggestive of the presence of multigland disease. Overall success rates for parathyroidectomy are equivalent (95% to 98%), irrespective of the criterion used.

Radio-guided parathyroidectomy with the handheld gamma probe is a less frequently used intraoperative adjunct. The principle behind use of the gamma probe is that hyperfunctional parathyroid tissue retains technetium 99m sestamibi longer than surrounding tissues; therefore, a handheld gamma probe is used to localize the abnormal parathyroid gland during surgery. The patient receives an injection of sestamibi approximately 1 hour before surgery. In the operating room, a background count is determined with scanning of normal thyroid tissue; after incision, the gamma probe is used to scan for in vivo counts that are higher than background. After identification and resection of the parathyroid gland, an ex vivo count of the resected gland is obtained; parathyroid tissue is confirmed if the ex

vivo–to-background ratio is 20% or more. Although radio-guided parathyroidectomy can facilitate dissection in reoperative cases, use of the gamma probe has not been shown to have improved success rates compared with IOPTH monitoring and does not confirm that all hyperfunctional tissue has been removed; therefore, the authors do not use radio-guided parathyroidectomy in their practices.

SURGICAL APPROACH

All patients undergoing consideration for parathyroidectomy should undergo a thorough history and physical examination, with careful review of biochemical results to confirm the diagnosis. Patients who report voice hoarseness or who have had prior anterior neck surgery, including previous thyroidectomy, parathyroidectomy, carotid endarterectomy, or cervical spine surgery, should undergo laryngoscopy for documentation of recurrent laryngeal nerve function. All localization studies should be reviewed by the operating surgeon. In addition, sequential compression devices are used in all patients; perioperative antibiotics are not routinely used.

The surgical approach for minimally invasive parathyroidectomy requires consideration of several factors, including appropriate venous/arterial access to obtain IOPTH samples, type of anesthesia (general or locoregional), placement of the incision, and extent of exploration based on the results of IOPTH testing. Patients should have a peripheral, large-bore intravenous catheter placed, preferably in the antecubital position, for administration of medications and fluids and for IOPTH sampling. In patients with difficult venous access, a second intravenous catheter or radial arterial line is sometimes necessary.

The two options in the anesthetic management of patients undergoing parathyroidectomy are general anesthesia and monitored anesthesia care with a surgeon-administered cervical block. General anesthesia is the mainstay of parathyroidectomy and is appropriate for patients with known multigland, familial, or secondary hyperparathyroidism; nonlocalized parathyroid disease on patient imaging; patient anxiety or claustrophobia; and patient preference. However, for patients with well-localized disease, cervical block anesthesia can be considered. Patients are given intravenous sedation by the anesthesia team; propofol has been shown to distort the results of the IOPTH assay and should be avoided, particularly if there is not a dedicated catheter for IOPTH measurements. A superficial cervical block with a 1:1 mixture of 1% lidocaine and 0.25% bupivacaine is administered posterior and deep to the sternocleidomastoid muscle; local infiltration also is performed at the incision (Figure 5). This approach is generally well tolerated; in one recent study, reasons for conversion to general anesthesia included unrecognized thyroid pathology requiring thyroidectomy, technical difficulties related to adequate protection of the recurrent laryngeal nerve, and patient discomfort. Potential advantages of cervical block anesthesia include decreased operating time, costs, reduced postoperative nausea and vomiting and more rapid discharge, and decreased need for oral pain medication. Importantly, it allows the surgical team to test the patient's phonation during the operation to ensure the continued integrity of the recurrent laryngeal nerve during the dissection. If a bilateral exploration is needed, a contralateral cervical block can be performed safely as long as the patient is comfortable and the surgeon deems that it is safe to proceed. Confirmation of intact patient phonation must be ensured because inadvertent block of bilateral recurrent laryngeal nerves can result in an airway emergency.

Irrespective of choice of anesthesia, patients should be placed in a beach-chair position, with arms tucked and adequate protection afforded to pressure points, and a shoulder roll (the authors use an inflatable intravenous [IV] bag) is inserted under the upper back to facilitate slight extension of the neck (Figure 6). A traditional Kocher's incision used for thyroidectomy is a transverse, slightly curved incision approximately two fingerbreadths above the sternoclavicular joint. A similar incision of approximately 2 to 4 cm in length is preferred for parathyroidectomy. In patients with good preoperative localization, some surgeons favor placing the incision to the right or left of midline. However, should bilateral exploration be necessary, the incision needs to be substantially extended; therefore, a symmetrical, midline incision is preferred. The subcutaneous tissues and platysma are divided transversely; subplatysmal skin flaps can be raised with electrocautery. The median raphe should be identified, and the strap muscles divided vertically in the midline and separated from the thyroid gland.

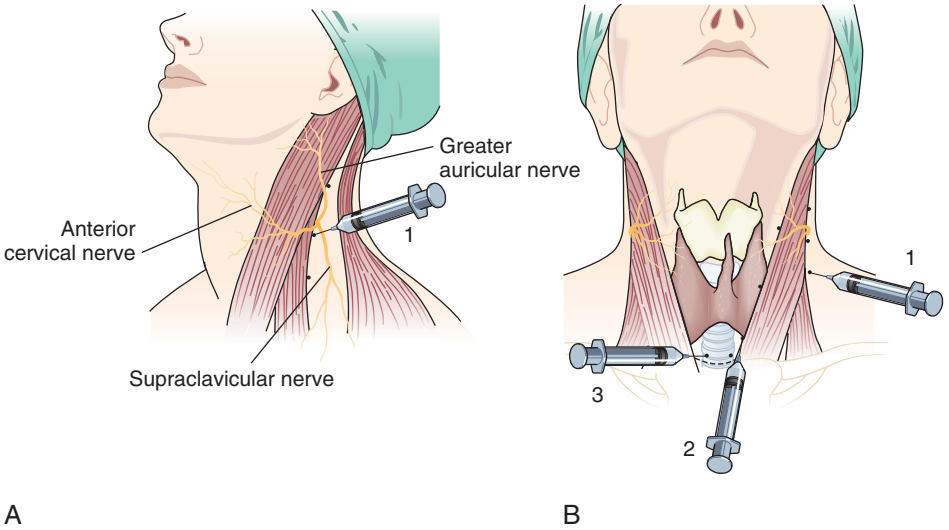

FIGURE 6 Patient positioning in the operating room, when cervical block anesthesia is used. **A,** A superficial cervical block is administered posterior and deep to the sternocleidomastoid muscle. **B,** A local field block also is performed. *(From Udelsman R: Unilateral neck exploration under local or regional anesthesia. In Gagner M, Inabnet W III, editors:* Minimally invasive endocrine surgery, *vol 1, Philadelphia, 2002, Lippincott Williams & Wilkins.)*

Surgical exploration should begin on the side suggested by preoperative imaging. Understanding of parathyroid gland embryology is essential for surgeons performing parathyroidectomy. Most patients have four parathyroid glands: two superior glands (derived from the fourth pharyngeal pouch) and two inferior glands (derived from the third pharyngeal pouch). The superior glands typically are located posterior to the recurrent laryngeal nerve and posteromedial to the superior thyroid lobe; ectopic glands may be located in a retroesophageal location. The inferior glands are more variable but typically are anterior to the recurrent laryngeal nerve and inferior and lateral to the inferior portion of the thyroid lobe. Ectopic inferior parathyroid glands may be located in the thymus, thyrothymic tissue, anterior mediastinum, or carotid sheath.

Several technical considerations are to be noted during exploration. First, depending on location of the adenoma, the thyroid may need to be mobilized; however, if possible, ligation of arteries and veins to the thyroid should be minimized, for risk of postoperative hypothyroidism. Second, care must be taken at all times to protect the recurrent laryngeal nerve, particularly for superior, retroesophageal parathyroid glands. Once the nerve is identified, electrocautery and suction irrigation should be used with caution. Third, the parathyroid adenoma should be manipulated as little as possible, so that the gland does not secrete PTH and cause a spike in IOPTH levels and to avoid rupture of the parathyroid capsule, leading to potential seeding of parathyroid cells and future parathyromatosis. If the parathyroid capsule is ruptured, the parathyroid bed should be copiously irrigated with hypotonic solution (water) before closure. A small amount of an absorbable hemostatic agent may be placed in the area of dissection before closure. The strap muscles and platysma are closed with running or interrupted 3-0 vicryl sutures, and the skin is closed with a 5-0 polypropylene suture, which is removed before patient discharge, or an absorbable subcutaneous stitch or skin adhesive alternative.

Assuming an abnormal parathyroid gland is identified and resected (Figure 7), IOPTH results should be obtained before leaving the operating room. If IOPTH levels fail to decrease appropriately, further exploration is mandatory. The authors prefer to identify all remaining parathyroid glands before resection, beginning with the ipsilateral parathyroid gland. Once all glands have been identified, the decision can be made as to the extent of surgical resection. If all four parathyroid glands are clearly abnormal, a subtotal parathyroidectomy should be performed, with the remnant parathyroid gland chosen being the gland that might easiest be accessed (usually an inferior gland) should the patient have recurrent pHPT develop and need a reoperative procedure. The subtotal parathyroidectomy

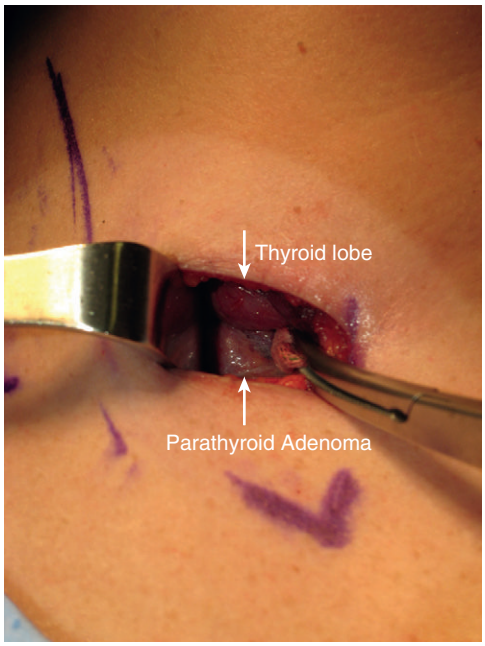

FIGURE 7 Identification of an inferior parathyroid adenoma.

should be performed first to ensure viability of the remnant parathyroid gland, followed by resection of remaining abnormal glands and repeat IOPTH monitoring. A titanium clip can be left on the subtotal parathyroid gland to facilitate future identification of the remnant if there is a recurrence of pHPT. The authors do not routinely biopsy glands that appear to be normal to avoid potential devascularization of that gland. Rarely, because of manipulation of the parathyroid gland during exploration and a spike in preexcision PTH levels, IOPTH levels may fail to normalize at 10 minutes after excision. If, based on the judgment of an experienced parathyroid surgeon, preoperative imaging results and adenoma size suggest that multigland disease is unlikely, the operation can be terminated and a PTH result obtained in the recovery room, with return to the operating room should the appropriate decrease in PTH levels fail to occur there. If a suspected parathyroid carcinoma is encountered based on disease presentation, imaging, and intraoperative findings, conversion to general anesthesia should occur, followed by ipsilateral thyroid

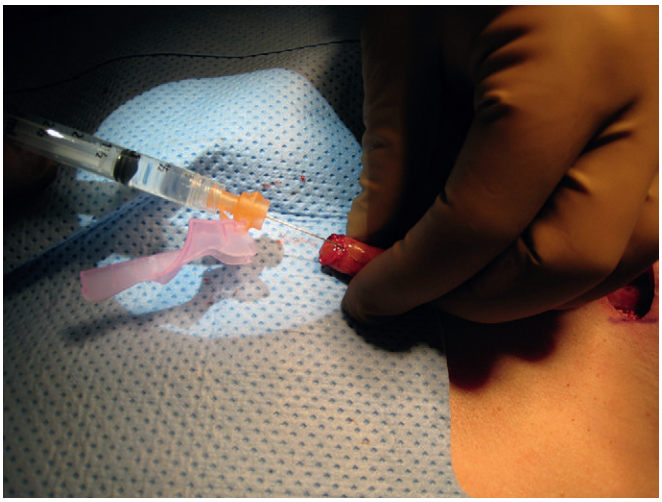

FIGURE 8 Ex vivo parathyroid aspiration.

lobectomy en bloc with the involved parathyroid gland and central lymph node dissection. Frozen section biopsy of the involved parathyroid gland should not be performed.

In addition to IOPTH monitoring, confirmation that parathyroid tissue has been resected is helpful, either with a frozen section or with ex vivo parathyroid aspiration (Figure 8). After resection of the parathyroid, a 25-gauge needle is used to aspirate tissue from the parathyroid gland; the syringe should contain a small amount of saline solution. This sample can then be run with the IOPTH samples; PTH levels that are significantly above serum PTH or above the upper limit of detection on the laboratory machine are considered to be positive confirmation that the resected tissue is parathyroid.

POSTOPERATIVE MANAGEMENT

Minimally invasive parathyroidectomy may be performed as an outpatient procedure; considerations for overnight observation include conversion to bilateral exploration, resection of more than one parathyroid gland, patient comorbidities, distance travelled, and patient preference. Inpatients should have a serum calcium and PTH level obtained on the morning after surgery. Patients should be discharged on calcium supplementation and instructed on recognition and management of symptoms of postoperative hypocalcemia, including perioral and extremity tingling or numbness. Vitamin D supplementation with calcitriol is used in patients who experience hypocalcemic symptoms overnight that is refractory to calcium supplementation alone and in those who have undetectable PTH levels on postoperative day 1.

Patients are seen in the clinic approximately 1 week after surgery; serum calcium, PTH, and 25-OH vitamin D levels are obtained at that time and supplementation adjusted accordingly. Daily calcium supplementation is recommended for at least 6 months after surgery. Patients are seen in follow-up, in conjunction with their endocrinologist or primary care physician, with serum calcium and PTH levels at 6 months, 12 months, and annually, because 2% to 3% of patients have recurrent pHPT develop. Cure from primary hyperparathyroidism is defined as normalization of serum calcium level 6 months after parathyroidectomy. Studies have shown that up to 44% of patients have elevated PTH levels in the setting of normal calcium levels after curative parathyroidectomy, possibly from vitamin D deficiency, chronic renal disease, or bone remineralization.

Postoperative complications include recurrent laryngeal nerve injury that leads to transient or permanent voice changes and permanent hypoparathyroidism that necessitates chronic calcium and vitamin D supplementation. In the hands of experienced parathyroid surgeons, rates of these complications should be 1% to 2%, in conjunction with cure rates of more than 95%. Recent studies have shown the importance of surgeon volume in parathyroid surgery and suggest that surgeons who perform 30 to 50 or more parathyroidectomies per year are most likely to achieve appropriate cure rates with acceptable rates of morbidity.

LAPAROSCOPIC LIVER RESECTION

Jay A. Graham, MD, and
Lynt B. Johnson, MD, MBA, FACS

OVERVIEW

Laparoscopy has forever changed the landscape of surgery. Although hepatobiliary surgery remained the last bastion of "maximal invasiveness," recently there has been a rise in the implementation of laparoscopy for complex liver operations. The inherent high risks associated with hepatic resection initially tempered enthusiasm for these laparoscopic pursuits, but in recent years, techniques to safely perform hepatic resections have evolved.

Concerns about the perceived lack of control of hemorrhage from hepatic vasculature during laparoscopic procedures gave pause to even the heartiest surgeons. As a result, early experience with laparoscopic liver surgery began with nonanatomic wedge resection for lesions located on the anterior surface. While some attempted the relatively straightforward left lateral segmentectomy laparoscopically, it was not until the advent of the hand-assisted technique that formal liver resection became feasible for many hepatobiliary surgeons.

This divergence from the purely laparoscopic instrumentation of the liver had many distinct advantages. Practically, the hand is the most useful retractor, offering expedient conformational change and unmatched haptic feedback. As such, intracorporeal hand insertion during laparoscopic resection gives the surgeon enhanced tactile stabilization of the liver, allowing for more precise mobilization and dissection of the target lobe. In addition, the hand port serves as a retrieval site for the surgical specimen.

This new approach has offered the patient an alternative to the traditional bilateral subcostal incision and thereby tendered the marked benefits of limited incisions inherent to minimally invasive surgery. This laparoscopic advance has extended into all forays of surgery with an ensuing decrease in incision size, which translates into less pain for the patient. With less pain comes earlier mobility, which results in decreased morbidity and reduced length of stay. Secondarily, direct costs may be reduced with the use of laparoscopic techniques as a result of the earlier hospital discharge.

Heretofore laparoscopic hepatic resection has seemed far afield, but the subsequent innovation has shifted the paradigm. To this end, laparoscopy as applied to hepatic surgery is germane to discussions of "best practices" and offers a technical approach that should be considered for many patients with liver pathology.

PREOPERATIVE EVALUATION

Evaluation of patients suitable for laparoscopic hepatic resection begins in the clinic. Patients often have preconceived notions, so it is important to balance heightened expectations with the reality of the situation. As such, preoperative evaluation generally begins with a comprehensive assessment of all organ systems. Although this approach is no different for any surgical candidate, particular attention should be paid to the cardiac and pulmonary physiology of the patient. These systems, more so than others, can be severely impacted during insufflation of the abdomen.

Systems-Based Clinical Evaluation

At a minimum, a complete blood count, chemistry, and coagulation panel should be obtained. In addition, a chest x-ray and an electrocardiogram (EKG) should be acquired if the patient is older than 50 years or has a history of heart disease. Cardiac risk stratification is of upmost importance, and every effort should be made to follow the American Heart Association (AHA) guidelines for cardiovascular evaluation for noncardiac surgery. Surgeons should also familiarize themselves with the assessment of metabolic equivalents (METs), as this is a reflection of estimated functional capacity and is paramount to guiding the appropriate preoperative testing. Generally, patients with good or borderline functional status may not have pulmonary issues that preclude surgery. However, patients with chronic respiratory disease should be optimized with bronchodilators, steroids, anti-inflammatory agents, breathing exercises, and/or chest physiotherapy (Box 1).

BOX 1: Preoperative evaluation

Complete blood count
Basic metabolic panel
Coagulation panel
Chest x-ray
Electrocardiogram
Cardiac risk stratification (AHA)
Pulmonary function optimization
Physical examination
Axial imaging

AHA, American Heart Association.

Physical examination of the patient's heart and lungs may clue the clinician into possible cardiopulmonary disease and prompt further testing. Examination of the abdomen is also crucial to the preoperative evaluation. A larger body habitus will make the target lobe mobilization more difficult. Visual inspection and the finding of scars can often hint at the difficulty and improbability of pursuing laparoscopic resection due to suspected adhesive disease. Additionally, physical examination may promote a dialogue with the patient regarding the likelihood of conversion to an open approach. Axial imaging also plays an important role in operative planning.

Axial Imaging Preoperative Planning

Patients generally seek clinical evaluation with a computed tomographic (CT) or magnetic resonance imaging (MRI) scan in hand. It is important to assess lesion location and morphology with an understanding of segmental liver anatomy. As such, the location of the lesion and its relationship to the hepatic vasculature can predicate a partial, formal right, left, or extended hepatectomy.

This preoperative method of evaluation is not consigned solely to laparoscopic liver surgery, and the tumor growth pattern, prior foregut surgery, or liver morphology may contriandicate for minimally invasive surgery. Evidence of extrahepatic tumoral extension or hepatomegaly can make intracorporeal mobilization difficult and therefore preclude laparoscopic resection. Although these findings are relative contraindications, they are not binding, and some espouse the notion that one can always begin laparoscopically and convert if necessary. In our experience, the conversion rate is approximately 5%.

Relative Contraindications to Laparoscopy

Although refractory hypotension is the only absolute contraindication to laparoscopy, there are many situations that make its use ill advised. In general, patients with an American Society of Anesthesiologists (ASA) classification of 4 or higher should not undergo laparoscopic procedures because hemodynamic instability is likely to arise in the setting of a pneumoperitoneum. As such, patients with poor cardiopulmonary reserve should temper the surgeon's enthusiasm for laparoscopic pursuits. However, rarely is the surgeon confronted with such obvious and straightforward clinical decisions.

The assessment of the risks and benefits of alternative operative approaches underscores the relative contraindications for laparoscopic liver resection. In our experience, patients who have had prior open foregut surgery are generally poor candidates for a laparoscopic approach, given the likely adhesive disease. Moreover, bulky pathology or hepatomegaly usually predicates open surgery, as hepatic mobilization can be problematic (Box 2). In contrast, laparoscopic resection for malignancy has been shown to be safe, which parallels the findings for treatment of other intraabdominal organ cancers.

BOX 2: Relative contraindications to laparoscopic hepatic resection

ASA classification ≥ 4
Poor cardiopulmonary reserve
Prior open foregut surgery
Large (>10 cm) posterior lesions
Hepatomegaly

ASA, American Society of Anesthesiologists.

ANESTHESIA AND INTRAOPERATIVE MONITORING

Surgeons must be intimately aware of the physiologic consequences of laparoscopy. Open communication with the anesthesiologist is crucial to anticipating and correcting the various problems that may arise. Patients with significant comorbidities need to be mindfully approached because profound changes in cardiopulmonary regulation may result from relatively minor alterations in abdominal pressure.

Hemodynamic complications due to insufflation are well documented, some of which may be deleterious and even result in death. Cardiac filling is often reduced, as manifested by lower left ventricular end-diastolic volumes due to increased abdominal pressure and abridged venous forward flow. A decrease in cardiac output is the primary indicator of the decline in right heart filling with the establishment of a pneumoperitoneum, especially in the context of patient positioning with reverse Trendelenburg. Both entities can severely limit venous return and ultimately result in a 20% to 60% reduction in cardiac index. Patients with ventricular systolic dysfunction are especially at risk. Hypotension should prompt pneumoperitoneum reduction and intravenous fluid resuscitation to counter these effects.

The occurrence of cardiac arrhythmias during laparoscopy is well chronicled. The rapid stretching of the peritoneum during initial insufflation often elicits a vagal response that can cause profound bradycardia and decreased inotropy. Prompt release of the pneumoperitoneum usually results in return of a normal rhythm. Likewise, carbon dioxide (CO_2) can be absorbed during laparoscopy and decrease the threshold for arrhythmias by irritating the myocytes and altering the conduction pathways.

The respiratory effects of laparoscopy are also notable, as they are both mechanical and due to the aforementioned gas exchange issues. Specifically, there is a reduction in functional reserve capacity (FRC) and lung compliance during abdominal insufflation. While there is a transient decrease in pulmonary shunt on initial insufflation with a concomitant rise in PaO_2, ultimately the elevated diaphragm and resultant decrease in FRC can cause hypoxemia, especially in obese patients or in patients with preexisting pulmonary disease. Therefore, patients with a larger body habitus, and also those with preexisting pulmonary disease, should be managed with higher positive-pressure ventilation and minute ventilation.

Surgical dissection during laparoscopy can also result in noticeable changes in ventilatory physiology and increase the chance of vascular embolic phenomenon. While the resultant hypercapnia is manageable by increasing the minute ventilation, the potential for symptomatic CO_2 gas embolism must be recognized. CO_2 gas embolism is likely an underrecognized occurrence due to its high solubility and diffusion. However, this risk may be heightened, especially with laparoscopic hepatic parenchymal transection due to exposure of the vast network of cut vessels to the pneumoperitoneum. As such, in the event of a rapidly dropping end-tidal CO_2 (E_TCO_2) and cardiopulmonary instability, evacuation of the pneumoperitoneum, volume resuscitation, and maneuvers to place the patient in left lateral decubitus position should commence.

To guard against such mishaps, it is critical that the patient is monitored with more than the usual array of instruments for general anesthesia. Given the potential for rapidly progressing and deleterious events, the patient should have, at a minimum, a radial or femoral arterial line placed. More often than not, it is also recommended to have central venous access should the patient need emergent blood volume replacement. Central venous pressure (CVP) monitoring is also of utmost importance. Blood loss is markedly limited if the liver transection is performed with a low CVP (<5 mm Hg). Secondarily, a central line allows the anesthesiologist to perform an acute normovolemic hemodilution (ANH). In our institution, routine use of a low CVP and ANH for hepatic resection has limited blood loss and reduced the need for allogeneic blood transfusion in patients undergoing major hepatic resections.

OPERATIVE TECHNIQUES

Numerous methods of laparoscopic resection have gained popularity with increased sharing and collaboration in the surgical community. Recognizing the diversity of these laparoscopic techniques used for liver resection, a panel of 45 well-known hepatobiliary surgeons worked to establish a standard classification system and summarize a unified position statement on safety and efficacy of laparoscopic liver resection. This panel of experts agreed on the terms *pure laparoscopy, hand-assisted,* and *hybrid technique* to describe the various approaches.

Pure Laparoscopy

Pure laparoscopy is usually used for wedge resections of anterior lesions of the liver or masses located in the left lateral segment, but it has been used for major lobe resections as well. Access is gained into the abdomen, depending on the surgeon's preference, and an umbilical 10-mm trocar is placed. Safe trocar insertion is of paramount importance. Viscus perforation and vasculature laceration can occur as a result of unintended and uncontrolled insertion. Although these injuries happen infrequently, significant morbidity, including death, can result. As such, the most reliable way of preventing trocar placement injury is macrobracing. This technique involves the use of the nondominant hand to counter the loss of resistance as the trocar tip penetrates the fascia and peritoneum.

After insufflation, the patient is moved into the reverse Trendelenburg position to enable sighting of the hilar structure and to position the small bowel in the lower abdomen and pelvis. Two to three trocars are placed under direct visualization to facilitate triangulation of the intended surgery site. Here, laparoscopic ultrasound is of great use to determine the depth of the mass and its juxtaposition to vasculature. Lesions on the liver surface may be wedged out with the use of laparoscopic adaptations of the Harmonic scalpel (Ethicon Endo-Surgery, Blue Ash, Ohio), LigaSure (Covidien, Boulder, Colo), Enseal (Ethicon Endo-Surgery, Blue Ash, Ohio), or any other bipolar energy device.

More formal laparoscopic liver resection requires far more expertise and level of comfort when dissecting the liver. Although bleeding is not unusual during hepatic parenchymal division, the potential lack of expedient vascular control during life-threatening hemorrhage with minimal access is worrisome. As such, we take a far more conservative approach with anatomic liver resection, opting for use of the hybrid technique. Nevertheless, the literature is replete with examples of pure laparoscopic liver formal resection.

Generally, the hilum is dissected and the respective hepatic artery ligated and divided. The portal vein to the affected side is then clamped. Transection then begins in the usual fashion, and major vasculature is controlled with laparoscopic stapling devices. The major bile ducts are also stapled, and the specimen is extirpated through an extended umbilical incision. For this reason, it is more prudent to attempt larger resections with the alternative hand-assisted and hybrid techniques, given the similarity in the incision size.

Hand-Assisted Technique and the Hybrid Technique

Whereas the incision that accommodates the hand port is the same for the hand-assisted and the hybrid techniques, there are some definitive differences. Both operative procedures employ the hand as a retractor, but hand-assisted liver resection implies that the resection is performed entirely intracorporeally. Conversely, the hybrid technique is a practice of using the hand to mobilize the liver with subsequent removal of the hand port so as to perform the liver transection in an open fashion without extending the incision. Our institution

favors the hybrid approach because we intuitively feel that this technique provides a more expeditious and practical manner for mobilization, parenchymal dissection, and removal of the liver specimen. Nevertheless, because surgeons of great skill have been trained in both methods, the optimum procedure is the one that favors the comfort level of the practitioner. Here we will describe the hybrid approach to liver resection, but the details are applicable to any system of laparoscopy using the hand.

A 7.5-cm subxiphoid incision is made, and a hand port (GelPort Laparoscopic System, Applied Medical, Rancho Santa Margarita, Calif) is inserted for hand assistance (Figure 1). A pneumoperitoneum is established after a standard Hassan trocar insertion periumbilically, and a 5-mm trocar is placed obliquely in the right or left subcostal margin depending on the location of the target lobe. As described earlier, great care must be taken when inserting trocars intraabdominally because of the inherent potential for vascular or viscus injury. The periumbilical trocar placement can be particularly risky because of its larger size and the relatively blind nature of insertion. This possibility can be minimized by introducing the trocar using the Hassan cut-down technique. One hand should be placed into the abdomen through the subxiphoid incision to receive the trocar as the other is used to gently advance the port-system through the fascia. Alternatively, a malleable retractor can be used to displace the bowel and to minimize the consequences of inadvertent and uncontrolled thrusting.

After safe insufflation of the abdomen, the operation begins with mobilization of the liver after positioning the patient in reverse Trendelenburg. Laparoscopic diathermic energy-based devices are used to divide the visceral attachments and triangular and coronary ligaments. The side of hepatic pathology dictates right or left hand insertion for hepatic lobe retraction.

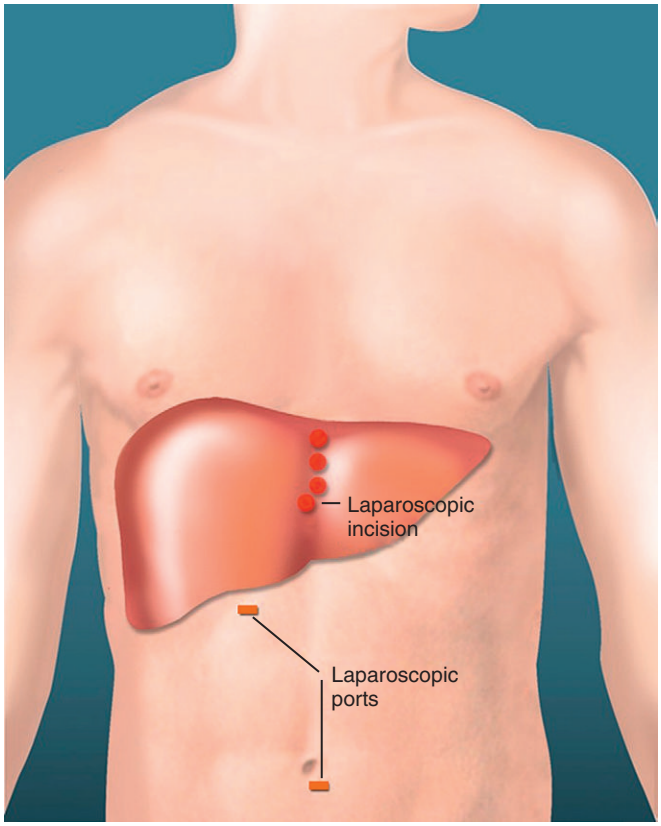

FIGURE 1 A 7.5-cm subxiphoid incision is made, and a hand port (GelPort Laparoscopic System, Applied Medical, Rancho Santa Margarita, Calif) is inserted for hand assistance.

The hand is an optimal retractor because of its ability to conform to the contours of the liver and displace pressure to the entire organ, preventing possible parenchymal injury. Moreover, intracorporeal hand insertion during laparoscopic assisted resection gives the surgeon enhanced tactile stabilization of the liver; this allows for more precise mobilization and dissection of the target lobe. Hand assistance also promotes safety in affording the surgeon with an expedient method of manual control of hemorrhage during a potential vascular mishap.

Furthermore, the laparoscopic camera aids in the operative procedure by enhancing acuity and magnification. Optic capture offered by laparoscopy can secondarily facilitate the identification and division of tangential structures. Angled lenses can offer an even greater advantage through visualization and ligation of the posterior medial vessels such as the retrocaval short hepatic veins during a right hepatectomy. These retroperitoneal short vessels can be divided in the aforementioned fashion or through the hand port after exsufflation.

Once the target liver lobe has been mobilized by division of all peritoneal reflections, the abdomen is exsufflated and the hand port is removed. Because exposure is of paramount importance, we recommend the use of a retractor system. We prefer the BOOKWALTER retractor system (Codman and Shurtleff, Raynham, Mass), but any variation will do. With adequate and uncompromised retraction, extrahepatic hilar vasculature ligation and division then ensue to lessen blood loss during liver transection. Of note, vascular anomalies are far from unusual, and the surgeon must be mindful to assess for aberrant right and left hepatic arteries. Next, the parenchymal dissection through the hard port incision is accomplished with the aid of ultrasonography and ultrasonic surgical aspirators (CUSA, Integra Lifesciences Corp, Plainsboro, NJ) to identify the venous entities. During cases of major resection, the hanging maneuver as described by Dr. Belghiti is used, with an umbilical tape passed anterior to the vena cava. We ardently believe the biliary ductal system should be managed during intrahepatic dissection to prevent injury to the contralateral duct.

For living donor hepatectomies, the hepatic artery, portal vein, and hepatic vein branches are kept intact as the parenchymal division is completed. The patient is then heparinized prior to the dissection of the target vascular structures and ultimate division. Subsequently, the specimen is removed through the hand port site.

Right Hepatectomy Using the Hybrid Technique

After mobilization of the right hepatic lobe by division of the falciform and triangular ligaments, we exsufflate the abdomen, remove the hand port, and secure the retractor system to expose the liver through the midline abdominal incision. Next, we place lap pads behind the liver to bring the hilum into better view.

Prior to dissection, we methodically palpate for a replaced right hepatic artery. Hepatic arterial anomalies are so frequent that they are almost the norm; therefore, a clear distinction of lobar inflow should be made prior to ligation. The middle hepatic artery can be easily mistaken for a right hepatic artery, especially in the setting of a replaced artery, and division can have severe implications for segments 4A and 4B. While we do not routinely use a Doppler to map the arterial routes, we completely dissect out the right hepatic artery. Here we ligate and divide the right hepatic artery and dissect posteriorly to delineate the portal vein. The right portal vein is circumferentially mobilized superiorly and divided. This devascularizes the right lobe inflow and results in demarcation of the liver. The right hepatic vein is then identified on the superior aspect of the liver and is divided using an articulating laparoscopic stapling device (Endo-Path ETS, Ethicon Endo-Surgery, Blue Ash, Ohio) to ensure safe control of this very large vessel off of the inferior vena cava.

We routinely use intraoperative ultrasound to characterize and mark the course of the middle hepatic vein, as relying on ischemic

demarcation can result in injury to a slightly laterally positioned vessel. Using the aforementioned hanging maneuver, we proceed with liver division, being mindful to stay to the right of the middle hepatic vein. We opt to ligate the right hepatic duct during intraparenchymal division because contralateral bile duct ischemia can occur if extrahepatic dissection is attempted. The specimen is then removed through this incision.

Left Hepatectomy Using the Hybrid Technique

A left hepatectomy using the hybrid technique follows many of the same steps that were previously discussed. Again, one should be mindful of arterial variances, especially a replaced left hepatic artery coming from the left gastric artery. After correct identification and division of the middle and left hepatic arteries, dissection of the left portal vein begins by working posteriorly to the ligated arterial vasculature. Traditionally, the caudate lobe is spared in formal left hepatic lobe resections, and therefore the surgeon should preserve the portal venous branches from the left portal vein into this segment.

Next, the middle hepatic vein is characterized using intraoperative ultrasound, and its course is marked on the surface of the liver using electrocautery. The middle and left hepatic veins are then divided with a laparoscopic stapling device, and parenchymal transection begins in the standard fashion.

OPERATIVE METRICS

In a recent study, we compared our experience of conventional open liver resection to laparoscopic liver resection. As expectant, the laparoscopic approach with hand assistance and parenchymal dissection through the hand port incision had equivalent operative metrics with shortened length of stay. Reports like those issued by Koffron et al have shown that laparoscopic resection is less expensive because of the shortened hospital stay. This finding reflects what has already been conclusively shown with laparoscopic cholecystectomy, fundoplication, and gastric bypass surgery.

As efficiency pressures continue to rise, the laparoscopic approach for liver resection will likely be further embraced. To this end, we surmise that the hybrid technique will gain favor, as it more closely assimilates the skills that hepatobiliary surgeons already possess. Moreover, this technique offers the most palatable setting of safety with the use of the hand for liver mobilization and prompt control of bleeding vasculature.

Practically, the hand is the best-known liver retractor, as it is atraumatic and offers varying degrees of facile mobility. Moreover, with this approach, we are able to substantially minimize the incision for an open liver resection as the standard subcostal incision can approach 35 cm. Accordingly, we believe that the potential long-term sequelae of the traditional bilateral subcostal incision with midline extension, which include abdominal wall hernias and paresthesias, may be lessened.

CONCLUSION

Since Dr. Jean Louis Lortat Jacob detailed the first published hepatectomy using the roadmap map laid out by Claude Couinaud, the field of liver surgery has seen a celebrated rise in the capability to offer resection with lower rates of morbidity and mortality. It is evident that with the arrival of the twenty-first century, the emergence of laparoscopy embodies a marriage of uncompromised surgical technique and better outcomes for our patients.

Newer approaches have allowed surgeons to bridge the gap between operative technique and improved outcomes. This occurrence has been largely device-driven, and industry has taken a lead role in these advancements. Laparoscopy has emerged as an advancement that embodies these efforts to improve medical care and represents a significant change to the landscape of surgery. As such, we are in the renaissance of minimally invasive surgery with innovation guiding a renewed operative approach to intraabdominal pathology. Liver surgery, although initially late to embrace laparoscopy, is now gaining momentum in this paradigm shift. The advent of innovative laparoscopic tools that mirror what is used conventionally have facilitated this transition.

Staging Laparoscopy for Gastrointestinal Cancer

Steven D. Wexner, MD, PhD (Hon), FACS, FASCRS, FRCS (Ed), and Elisabeth C. McLemore, MD, FACS, FASCRS

OVERVIEW

Staging laparoscopy can detect radiographically occult metastases and lead to changes in the therapeutic plan for a significant number of patients. Compared with staging laparotomy, staging laparoscopy is associated with a shorter hospital length of stay, reduced pain, lower morbidity, shorter recovery time, and reduced cost. In addition, staging laparoscopy can minimize potential delays in patient access to chemotherapy and radiation therapy and facilitates appropriate selection of patients for palliative therapy.

The improvement in laparoscopic instrumentation and technical ability over the past few decades has resulted in a sensitivity of laparoscopic metastatic detection equivalent to that achieved during open exploration. Intraoperative laparoscopic ultrasound scan can be more sensitive than either preoperative computed tomographic (CT) scan or magnetic resonance imaging (MRI). The concern for the risk of port-site metastasis and peritoneal carcinomatosis as a result of laparoscopic assessment of an abdominal malignant process has abated. However, controversy regarding selective versus routine use of staging laparoscopy has yet to be settled for a subset of patients with cancer.

GENERAL TECHNIQUE

A proposed assessment of the indications and contraindications for staging laparoscopy for specific tumor types is listed in Table 1. Contraindications include severe adhesive disease, intolerance to the establishment of pneumoperitoneum, poor cardiovascular or pulmonary reserve that precludes operative intervention, and uncorrectable coagulopathy. Before a diagnostic or staging laparoscopic procedure is started for a gastrointestinal malignancy, the surgeon must ensure that adequate pathologic expertise is available. Most operations require several frozen-section analyses of biopsy specimens. A phone call from the operating room to the pathologist at the beginning of the case frequently facilitates and hastens the diagnosis, thereby shortening the overall operative time.

With a 30-degree or 45-degree laparoscope, a thorough inspection of the suprahepatic and infrahepatic spaces, diaphragm, surface of the bowel, lesser sac, root of the transverse mesocolon and small bowel, ligament of Treitz, paracolic gutters, and pelvis should be performed. In the case of pancreatic cancer, the lesser sac is opened, and the pancreas and posterior aspect of the stomach are examined. During the inspection, any intraperitoneal fluid or ascites should be aspirated for cytology if suspicious, or as directed per institutional protocol. A biopsy of the abdominal wall, diaphragm, mesentery, or other implants should be taken and assessed with fresh frozen techniques. Peritoneal lavage is performed according to protocol or surgeon preference. Subsequently, the primary tumor can be assessed for possible node involvement that may preclude surgical resection, extraserosal invasion, and infiltration into surrounding structures.

Laparoscopic ultrasound scan is often performed if inspection is uninformative, or if a significant chance of a liver metastasis is present. Intraoperative ultrasound scan has an obvious and important role in surgical decision making for hepatobiliary and pancreatic malignancies. With use of a multifrequency laparoscopic ultrasound probe with a flexible transducer tip, sonographic evaluation should include the deep hepatic parenchyma, portal vein, and mesenteric vessels, and assessment of the involved organ with the primary tumor and its associated nodes. In general, with the probe frequency set to 5 MHz, the liver parenchyma can be systematically assessed, starting from right to left anteriorly then posteriorly. Increasing the probe frequency to 7 MHz allows for further evaluation of the extrahepatic bile ducts and associated nodes, and the long axis in a relatively transverse plane, either directly or through the overlying omentum. For metastatic and primary liver malignancies, an ultrasound scan–guided core biopsy should be taken for suspicious lesions that preclude curative resection. Color-flow Doppler imaging can be used to assess portal and hepatic vasculature and the relationship of these structures to any tumors visualized. For visualization and inspection of the areas listed previously, the patient should be securely positioned with appropriate padding to prevent intraoperative patient position migration or soft tissue damage during liberal adjustment of the operating room table position.

ESOPHAGEAL CANCER

Combined thoracoscopy and laparoscopy for esophageal cancer has been reported to achieve nearly 90% accuracy in documentation of locally advanced disease with nodal involvement. The addition of laparoscopic ultrasound scan during staging has been reported to increase the detection rate for metastasis by 8% with little impact on the false-negative rate. Laparoscopic evaluation allows for assessment of liver and peritoneal metastasis and celiac nodal involvement. Staging laparoscopy results in more significant changes to the treatment plan for patients with lower esophageal and proximal gastric tumors when compared with patients with mid to upper esophageal lesions. At the time of diagnostic laparoscopy, enteral feeding access can be established as necessary to proceed with palliative or neoadjuvant therapy. Thoracoscopic evaluation is performed in the right chest cavity with the patient in left lateral decubitus position with table splitting. Mobilization of the inferior pulmonary ligament allows for assessment of the intrathoracic esophagus, paraesophageal tissues, and subcarinal lymph nodes. Major complications related to laparoscopic staging for esophageal cancer are rare.

GASTRIC ADENOCARCINOMA

Currently, routine preoperative staging for gastric adenocarcinoma in the United States includes esophagogastroduodenoscopy (EGD) with endoscopic ultrasound scan, high-quality cross-sectional imaging, positron emission tomography (PET), and staging laparoscopy. Multiple studies have documented the value of staging laparoscopy. When lymph node–positive disease is discovered at the time of diagnostic laparoscopy in patients without obstructive symptoms, most patients can proceed with systemic chemotherapy without obstruction or bleeding developing. Multidisciplinary clinical staging and medical therapy at high-volume medical centers has been associated with improved oncologic outcomes.

In an attempt to better define those patients who may benefit from staging laparoscopy, Sarela and colleagues from Memorial Sloan Kettering Cancer Center reviewed 657 gastric cancer patients with minimal symptoms and no clinical evidence of metastatic disease on clinical staging spiral CT cross-sectional imaging. Metastatic disease was detected in 31% of patients. Multivariate analysis revealed that radiographically occult metastatic disease was more prevalent in patients with gastroesophageal junction lesions, diffuse gastric

TABLE 1: Indications and contradictions for staging laparoscopy for specific tumor types

Tumor type	Indications	Contradictions
Pancreatic adenocarcinoma	Detection of unsuspected locally advanced disease in patients with resectable disease based on preoperative imaging Consideration of peritoneal lavage before definitive surgery per individual protocol Selection of palliative treatment with locally advanced disease without evidence of metastatic disease Assessment before planned neoadjuvant chemoradiation	Metastatic disease that is evident on CT scan
Gastric adenocarcinoma	T3 or T4 disease without evidence of nodal and distal metastasis Gastroesophageal junction tumors Questionable lymph nodes on imaging	Need for palliative procedures for obstruction, hemorrhage, or perforation; proceed with surgery T1 or T2 disease can proceed with resection without diagnostic laparoscopy
Esophageal tumors	Candidates for neoadjuvant chemotherapy Candidates for curative resection and negative preoperative imaging	
Colorectal cancer	Patients with resectable liver metastases without evidence of extrahepatic metastasis	Unresectable, nonablatable hepatic disease
Primary hepatic tumors	Candidates for curative resection based on size and location with adequate hepatic reserve	Tumors with major vessel or organ invasion
Biliary tract tumors	Known or suspected gallbladder cancer without unresectable or metastatic disease T2 or T3 hilar cholangiocarcinoma	T1 gallbladder cancer incidentally found during cholecystectomy
Lymphoma	Need for tissue diagnosis in the absence of peripheral lymphadenopathy	

CT, Computed tomographic.
Modified from Hori Y: Restaging after treatment or when recurrence is suspected: SAGES Guidelines Committee: diagnostic laparoscopy guidelines, Surg Endosc *22(5):1353-1382, 2008.*

tumors, poor differentiation, and age less than 70 years. In patients with preoperative imaging that revealed lymphadenopathy greater than 1 cm (49%) in diameter and T3 or T4 tumors (63%), a higher incidence of radiographically occult metastatic disease was found.

COLORECTAL LIVER METASTASIS AND HEPATOBILIARY PRIMARY TUMORS

Staging laparoscopy is seldom used in the primary treatment of colorectal cancer. Furthermore, the combination of PET, CT scan, and MRI has decreased the need for diagnostic laparoscopy for colorectal liver metastasis. However, diagnostic laparoscopy used in conjunction with laparoscopic ultrasound scan as a prelude to liver resection can identify factors that preclude curative resection in up to 25% of cases. The overall benefit of diagnostic laparoscopy for the determination of a nonresection candidate is nearly 40% for primary liver tumors and 12% for colorectal liver metastasis. The largest study of staging laparoscopy for hepatocellular carcinoma was notable for avoidance of a nontherapeutic laparotomy in 16% of patients. Routine staging laparoscopy for intrahepatic cholangiocarcinomas has resulted in avoidance of unnecessary operative intervention in 27% of patients treated at Memorial Sloan-Kettering Cancer Center. In patients with hilar cholangiocarcinomas, the addition of intraoperative ultrasound scan increased the yield for detection of tumors not amenable to surgical resection by nearly 20%.

Many patients undergo percutaneous ablative procedures for malignant hepatic lesions. Although these procedures can sometimes be performed in radiology suites, most surgeons believe strongly that these patients are best served in a setting in which staging laparoscopy and laparoscopic ultrasound scan–guided ablation can also be performed. Nearly 40% of patients with unresectable disease have either extrahepatic disease or additional, small-volume disease in the liver that is not detected on preablative imaging. Therefore, patients undergoing percutaneous liver ablative procedures are at risk for undertreatment or overtreatment of the true disease burden.

PANCREATIC AND PERIAMPULLARY ADENOCARCINOMAS

Although the first case series of staging laparoscopy for pancreatic cancer was described by Cushchieri in 1978, minimally invasive techniques for the management of pancreatic cancer have been slow to progress and gain national participation. With the evolution of staging to include pancreatic helical CT imaging with fine cuts, the diagnostic yield of staging laparoscopy over the past few decades has

decreased from 35% to approximately 13%. Therefore, some surgeons have argued for the selective use of staging laparoscopy. Evidence suggests that laparoscopy should be reserved for tumors in the body or tail of the pancreas and tumors larger than 3 cm and for cases with preoperative CA 19-9 levels greater than 100 U/mL. With regard to ampullary, duodenal, and distal bile duct tumors, the addition of diagnostic laparoscopy to dynamic CT scanning appears to identify an additional 10% of patients with unresectable disease.

LYMPHOPROLIFERATIVE DISEASES

Staging laparoscopy for lymphoproliferative disorders is similar to traditional staging laparotomy and can include liver biopsy, splenectomy, and lymph node sampling of iliac, celiac, portal, mesenteric, and periaortic nodes and excision of abnormal nodes identified before surgery with marking of the area of excision with clips. Surgeons may elect to perform oophoropexy posterior to the uterus to improve the patient's fertility. The positive diagnostic yield is related to degree of tissue sampling, experience with laparoscopy, and complete mobilization of the colon, duodenum, and pancreas. Surgeons are most often requested to biopsy abnormal-appearing lymph nodes in the mesentery detected on cross-sectional imaging. The entire node does not need to be removed in some cases; simply obtaining large biopsies with a cupped biopsy instrument may be adequate. Before leaving the operating room, it is important to receive confirmation from the pathologist regarding the diagnosis and ensure that the amount of tissue collected is adequate for flow cytometry or other pathologic evaluation.

A core needle biopsy obtained by a radiologist is an option in some cases. For example, image-guided core needle biopsy may be preferred in those patients with lymphadenopathy that is difficult to reach surgically, such as enlarged lymph nodes posterior to the renal vessels. In addition, image-guided lymph node biopsy is also an attractive alternative in patients who are at high risk or cannot tolerate anesthesia. Although percutaneous biopsy is less invasive, percutaneous biopsy remains inferior to the diagnostic accuracy of laparoscopic biopsy, which has been shown to be greater than 90%.

NATURAL ORIFICE TRANSLUMINAL ENDOSCOPIC SURGERY

Staging peritoneoscopy with natural orifice transluminal endoscopic surgery (NOTES) is a novel diagnostic approach that is currently undergoing evaluation. The methodology of NOTES has been validated in human and animal models. Transvaginal, transgastric, and transcolonic techniques have been described in the literature. In the Netherlands, Voermans and colleagues showed that transcolonic peritoneoscopy was inferior to standard laparoscopy in detection of peritoneal metastases in an animal model (53% vs 95%). Conversely, diagnostic transgastric endoscopic peritoneoscopy was found to have a 95% concordance with laparoscopic exploration for assessment of peritoneal metastasis with no infectious complications at The Ohio State University. Further research and development continue to evolve the means to endoscopically close the natural orifice entry site. At this time, diagnostic natural orifice endoscopic peritoneoscopy is considered an investigative technique and should only be performed with Institutional Review Board (IRB) approval and participation in Natural Orifice Surgery Consortium for Assessment and Research (NOSCAR).

SUMMARY

Advances in preoperative CT scan, endoscopic ultrasound scan, MRI, and PET cross-sectional imaging, and staging laparoscopy, have given physicians more detailed information with which to tailor oncologic therapies within standard national guidelines. By eliminating the need for laparotomy to assess tumor location and surgical resection candidacy, staging laparoscopy continues to play an important role in defining the next appropriate steps in the management of patients with gastrointestinal, hepatobiliary, pancreatic, and lymphoproliferative malignancies. Although routine use of staging laparoscopy continues for esophageal and bile duct malignancies, some investigators have argued for selective utilization of staging laparoscopy for gastric and pancreatic malignancies. As radiographic imaging, endoscopic ultrasound scan, and other staging modalities evolve, clinical trials will continue to further specify the role of laparoscopic investigation of patients with gastrointestinal malignancies.

Laparoscopic Pancreas Surgery

Martin A. Makary, MD, MPH

Laparoscopic pancreas surgery can be difficult to learn, but once mastered and applied appropriately, the approach yields clinical benefits for patients: namely, reduced wound complications and decreased postoperative pain. In the author's experience in performing 270 laparoscopic pancreas operations at Johns Hopkins Hospital, the wound infection rate is 1%, in comparison with 11% for open pancreas surgery. In addition, the laparoscopic approach is associated with decreased postoperative narcotic utilization, decreased time to ambulation, and increased activity level at discharge: patient-centered outcomes that are improved over those of open surgery. These benefits have implications for other outcomes because wound complications and decreased activity are risk factors for secondary complications and increased costs. Infection is an independent predictor of hospital readmission, and the presence of a wound complication often delays postoperative adjuvant therapy. Furthermore, the decrease in pain is of value, in view of the goal of a good quality of life for many patients with cancer and a poor prognosis. Kendrick

and Cusati (2010), in one series, reported that laparoscopic pancreas surgery was associated with no superficial surgical site infections and a reduced length of stay. Other authors have also reported significantly decreased rates of incisional hernia and postoperative bowel obstruction, complications that occur in as many as 20% of patients after open surgery. Another benefit of laparoscopy may be improved cosmesis, an outcome of particular value in young patients who classically present with a pancreas cyst or neuroendocrine tumor. Many of the outcomes favorably influenced by laparoscopy (surgical infection, pain level, and patient satisfaction) are metrics increasingly being used by both surgical registries and payers to measure quality in surgery. In addition, the author has found that the 12-times magnification of new laparoscopic high-definition cameras allows the surgeon to visualize the anatomy better than does open surgery.

LAPAROSCOPIC WHIPPLE

The percentage of Whipple procedures performed laparoscopically at Johns Hopkins Hospital is increasing, and it is expected that the majority of Whipple operations will be performed laparoscopically by 2025. The laparoscopic approach is offered as the procedure of choice for patients who require a Whipple operation and do not have large (>5 cm) tumors or in whom tumors do not involve the large segment of the portal vein. Although other authorities have described laparoscopic resection of a long segment of the portal vein, the author's experience has been limited to partial vein resections managed with a laparoscopic side-biting vascular clamp.

The steps of a laparoscopic Whipple procedure (in order) are listed here and described afterwards:

1. Perform staging laparoscopy
2. Open the lesser sac
3. Resect a common hepatic artery lymph node
4. Divide the gastroduodenal artery
5. Divide the distal stomach
6. Dissect the portal structures
7. Perform cholecystectomy, and divide common bile duct
8. Divide the pancreas after separation from superior mesenteric vein
9. Perform Kocher maneuver
10. Divide jejunum
11. Mobilize the ligament of Treitz
12. Identify the superior mesenteric artery
13. Divide the uncinate/retroperitoneal attachments, and extract specimen
14. Extract jejunum through ligament of Treitz defect
15. Perform retrocolic pancreaticojejunostomy and hepaticojejunostomy
16. Perform antecolic (retrogastric) gastrojejunostomy
17. Drain placement

Technique

Peritoneal access is achieved through the caudal aspect of the umbilicus in a Hassan technique. Once the abdomen is distended, a left subcostal 12-mm bladeless VersaStep port (Covidien, Mansfield, Mass) is placed followed by a 5-mm bladeless VersaStep port left of the umbilicus so that there are two working ports on the patient's left side. The right-sided abdominal ports are then placed by insertion of a 5-mm port at the right subcostal region along the midclavicular line. Caudal to this port, two additional 12-mm ports are inserted so that there are two working ports on each side of the patient, as well as a port for a fan retractor to retract the duodenum and pylorus. A 10-mm, 45-degree laparoscope is used for visualization. The abdomen is explored for metastatic disease.

The lesser sac is accessed through the gastrocolic ligament to the second part of the duodenum. The right colon, including hepatic flexure, is sometimes mobilized. The gastroduodenal artery is then skeletonized, and a silk suture and one or two 10-mm clips are used on the proximal side. The artery is divided with a sealant device. The stomach is then divided just proximal to the pylorus with an Endo GIA stapling device (Covidien) with green or black loads (at least 4.8-mm size) for a classic-type Whipple procedure. A cholecystectomy is then performed, and the common bile duct is divided proximal to the entry site of the cystic duct, which enables the gallbladder to remain with the specimen for subsequent extraction.

The portal vein is then dissected from above the pancreas, and the superior mesenteric vein is dissected from below. A tunnel behind the pancreatic neck is created.

The transverse mesocolon is then raised cephalad to identify the ligament of Treitz. At approximately 15 cm distal to the ligament of Treitz, the small bowel is divided with an Endo GIA stapling device (Covidien) with a white load (2.5 mm). Each stapled end of the jejunum is sewn together with a 10-cm air knot so that the distal segment can later be pulled through the ligament of Treitz defect for the eventual reconstruction. The small bowel mesentery is also divided proximally to the ligament of Treitz, which is mobilized. Turning attention to the patient's right side, the surgeon then identifies the superior mesenteric artery, and the branches of the artery and vein going into the Whipple specimen are divided with the LigaSure (Figure 1) (Covidien); clips are used as needed on larger branches. The Whipple specimen is then extracted out in a 15-mm bag through the umbilicus. The jejunum is extracted intact initially. The fascia and skin defects are extended to approximately 3 to 4 cm for the extraction.

The small bowel is passed through the ligament of Treitz in order to perform an end-to-side pancreaticojejunostomy. This is performed in a handsewn manner over a pancreatic duct stent with the use of a 3F, 5F, or 8F pediatric feeding tube placed into the duct (Figure 2) and into a 2-mm to 3-mm opening in the side of the jejunum. Two running 3-0 barbed stitches (V-Loc sutures; Covidien) are used for the front and back side of the pancreaticojejunostomy. The hepaticojejunostomy is then performed with placement of a single layer of 4-0 Vicryl stitches handsewn in an interrupted manner. The gastrojejunostomy is then performed in an antecolic retrogastric manner along the posterior wall of the stomach in a stapled side-to-side technique with an Endo GIA 60 stapler. The resulting defect is then closed with interrupted stitches.

In patients in whom the pancreas is soft, a surgical drain is then placed near the anastomoses. All 12-mm port sites are closed at the level of the fascia.

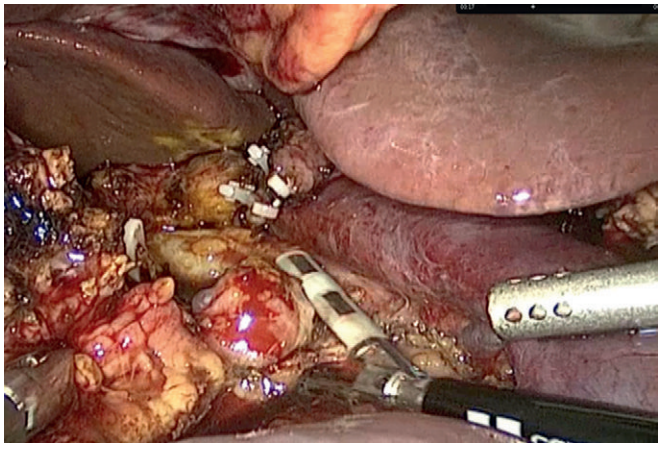

FIGURE 1 Uncinate dissection: division of the pancreas along the portal vein and superior mesenteric artery. (Gastroduodenal artery is clipped with the white clips above.)

Of note, for all of the author's advanced laparoscopic pancreas procedures, a No. 10 blade scalpel and Mayo scissors are always kept on the Mayo stand in case a rapid conversion to open procedure is necessary. Unlike other laparoscopic procedures, laparoscopic pancreas surgery may have to be converted expeditiously to an open approach because of the intimate proximity of the large vessels in the region. The author also makes sure that no pop-off stitches are used because these can easily pop off inadvertently while in the insufflated field. Care is taken to make sure hypercarbia is managed appropriately if it is noted from an elevated end-tidal CO_2 level.

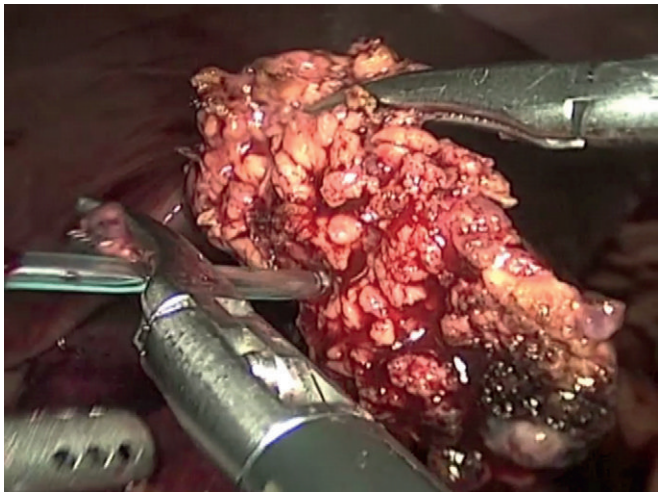

FIGURE 2 Placing a pancreatic duct stent into the divided pancreas.

The author does not use the robot for the laparoscopic Whipple procedure because of the longer operative time currently associated with robotic surgery; however, it may be a useful tool for performing the reconstruction, and future generations of robotic devices may yield advantages not yet realized. In the author's most recent 50 laparoscopic Whipple procedures, mean operative time was 5 hours, 25 minutes. Postoperative management follows a similar pathway as for the open Whipple procedure, although narcotic utilization and activity level during the inpatient recovery are noticeably improved with the laparoscopic approach.

LAPAROSCOPIC DISTAL PANCREATECTOMY

Most distal pancreas tumors are ideal candidates for laparoscopic resection. The author offers a laparoscopic distal pancreatectomy to patients who have lesions that do not involve the celiac or mesenteric vessels and are less than 6 or 7 cm in size. The author routinely attempts spleen preservation when there is no suspicion of malignancy, and the spleen can be spared in 70% of distal pancreatectomies in this setting (Figure 3 and 4). Of importance is that in cases in which malignancy is suspected on the basis of imaging studies or a family history of pancreas cancer, the author removes the spleen with the tail of the pancreas en bloc to achieve a wide resection of

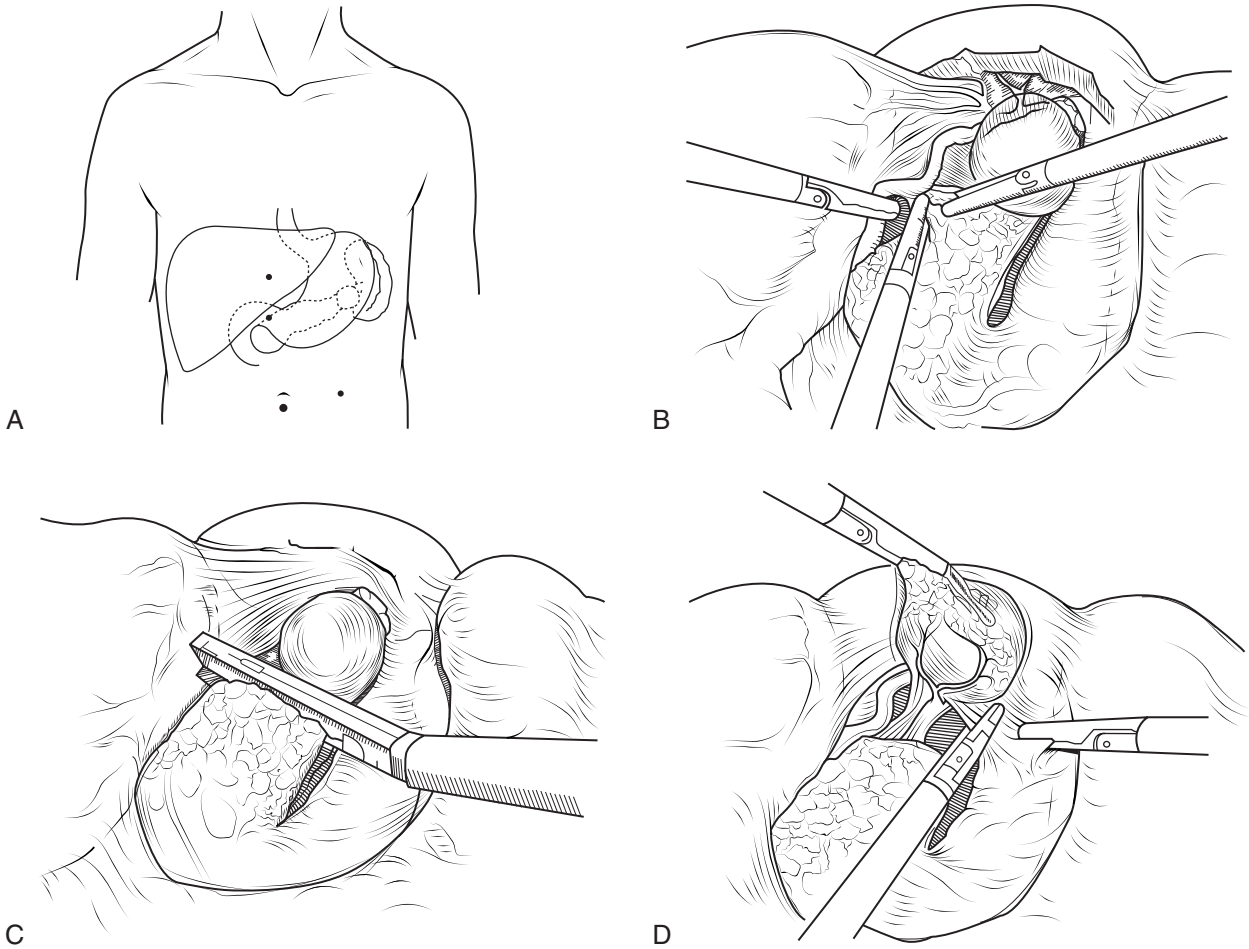

FIGURE 3 Spleen preserving distal pancreactomy: port site placement and vessel-preserving technique.

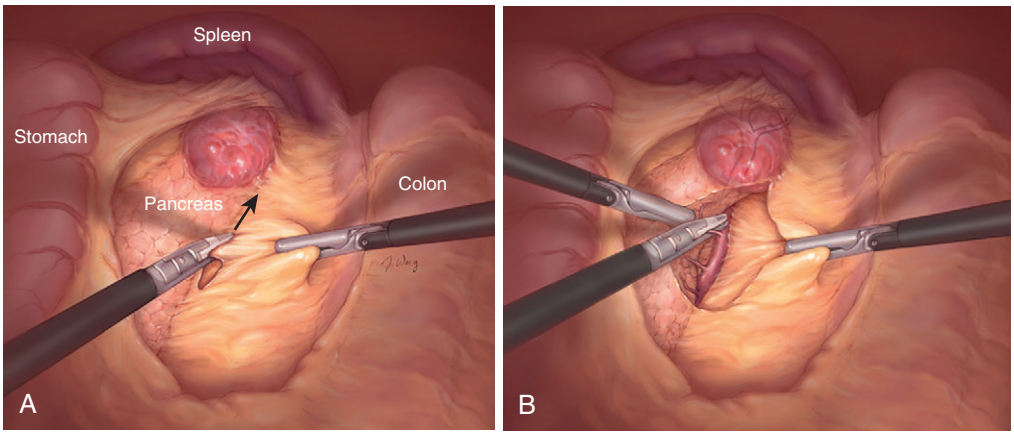

FIGURE 4 **A** and **B,** Laparoscopic distal pancreatectomy. *(© Jenny Wang, 2008.)*

the lymph node basin in the area of the splenic vessels and splenic hilum. In the author's experience, laparoscopic distal pancreatectomy can result in improved patient outcomes and an increased likelihood for splenic preservation in appropriate situations.

Preoperative Tattooing

For small lesions of the pancreatic neck, body, and tail, particularly those that are posterior, the author uses a novel technique to tattoo pancreatic lesions to facilitate identification at the time of laparoscopic surgery. In each patient scheduled for a laparoscopic distal pancreatectomy, the pancreatic lesion is tattooed via an endoscopic transgastric technique under endoscopic ultrasound guidance before surgery (Figure 5). Using an endoscopic 22-gauge needle, the surgeon injects a total of 5 mL of concentrated purified carbon particles (GI Spot dye; GI Supply, Camp Hill, Pa) are injected into the pancreatic parenchyma immediately proximal to the tumor. The dye is injected to create a vertical line deep in the pancreas parenchyma because the dye may need to be identified from the posterior aspect of the gland during the dissection.

Preoperative marking enables the surgeon to quickly identify the location of the tumor at the time of laparoscopy and guides the decision of where to divide the gland. The author has found that tattooing significantly decreases the author's operative time for distal pancreatectomy. Furthermore, it helps avoid the awkward situation of missing a subtle tumor in the resected specimen—a hazard of the decreased tactile sense in laparoscopic palpation with long instruments. Even large tumors detected on computed tomography, which a surgeon can anticipate identifying easily, can be surprisingly difficult to find because of the homogeneous color of the pancreas and its retroperitoneal bed.

Technique

The laparoscopic distal pancreatectomy steps (in order) are listed as follows and described afterwards:

- Perform staging laparoscopy
- Open the lesser sac
- Perform takedown of the splenic flexure of the colon
- Distinguish the splenic vessels from the hepatic vessels
- Divide splenic artery unless the spleen is preserved
- Mobilize the distal pancreas, and divide splenic vein if splenectomy is performed
- Extract specimen
- Place a drain in the divided stapled pancreas

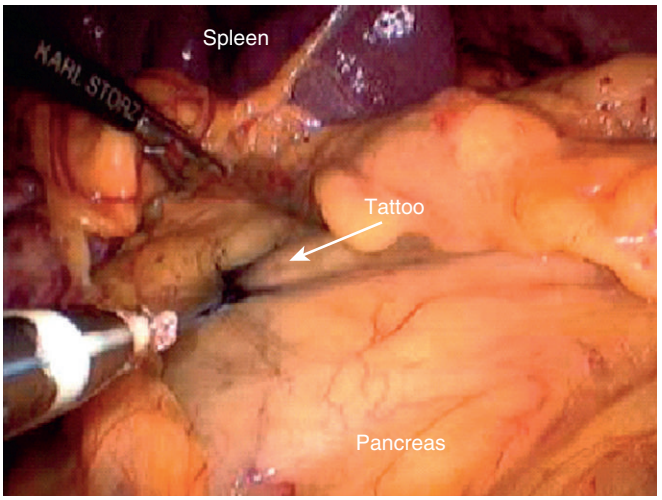

FIGURE 5 **A** and **B,** Tail of pancreas with tattoo and spleen in background. *(© Jenny Wang, 2008.)*

The author places an infraumbilical port with a Hassan method. Two ports placed in the upper midline (or right of midline) and one port in the left lower quadrant are inserted under direct visualization (see Figure 4). The precise locations of these ports depend on the location of the tumor, the intention to preserve the spleen, and the patient's body habitus. Once local landmarks are identified, the gastrocolic omentum and short gastric vessels are divided, followed by takedown of the splenic flexure of the colon to achieve wide visualization of the lesser sac. Mobilization of the gland is easiest from the inferior border of the gland (see Figure 5). Thus, beginning with the inferior approach facilitates dissection of the posterior aspect of the gland from the retroperitoneal bed. The splenic artery and vein branches can be visualized from underneath the pancreas, and the author alternates dissection of the splenic vessels from above and below the gland according to which exposure best offers visualization.

Once the pancreas is clear from the splenic vessels to allow for division of the gland, the author attempts to dissect as much of the tail as possible, freeing the entire tail when feasible. The gland is divided with a stapler with a size chosen on the basis of the pancreas thickness. On occasion, the author has used a reticulating stapler reinforced with a bioabsorbable staple line material (GORE SEAMGUARD, Gore Medical, Newark, Del). The specimen is removed with

an Endo Catch bag (Covidien), and a surgical drain is place at the cut end of the pancreas.

Laparoscopic Distal Pancreatectomy With Splenectomy

When a malignancy is suspected or a technical reason necessitates removal of the spleen, the author chooses to mobilize the spleen after individual division of the splenic artery, splenic vein, and gland. Care is taken to ensure that the splenic artery is not confused with the hepatic artery. Dissection of the splenic artery toward the spleen is sometimes necessary to ensure that the splenic artery is not mistaken for the hepatic artery. The splenic artery and the vein, respectively, are each ligated in turn with a vascular stapler; sometimes these vessels are approached from the posterior aspect of the gland. The spleen is mobilized from its attachments as the last step of the operation.

When the spleen is removed for technical or anatomic (noncologic) reasons, the author divides the pancreas from the spleen to morcellate (liquefy) the spleen for easy extraction from the peritoneum. The intact specimen is freely suspended in the insufflated abdomen, and then the spleen is divided from the tail of the pancreas with a series of GIA staplers fired close to the spleen to avoid leaving residual pancreatic tissue or lymph nodes on the spleen side. This intracorporeal separation allows for removal of the pancreas intact and the spleen by the morcellation technique. However, a stitch or orientation via the tattoo is needed to identify the true pancreatic margin. This piecemeal extraction method is not applicable when an oncologic margin could be threatened by the intracorporeal separation of the pancreas and spleen. In this case, the specimen is removed en bloc in an Endo Catch bag, which necessitates a small extension of the midline 12-mm port sites. A frozen-section analysis is performed intraoperatively to confirm a negative and adequate margin of resection before the operation is completed.

At all times, an Endo GIA 2.5-mm (white vascular load) stapler is open, loaded, and ready to use in case of injury to the splenic vessels. Clips are avoided because stapling devices cannot engage on a clip. As a precaution, the author always keeps a fresh 10-blade scalpel and curved heavy Mayo scissors ready at all times in case a rapid conversion to an open operation is needed to control bleeding.

Patient Outcomes

Patients are admitted to the surgical floor for a typical hospital stay of 2 to 4 days after surgery. The author has observed that these patients behave clinically similar to patients who have undergone laparoscopic cholecystectomy and adrenalectomy: they often require little or no narcotic pain medication. Wound complications are rare after the laparoscopic technique; however, the pancreatic leak rate for all types of laparoscopic pancreas surgery is identical to that for the open operation.

LAPAROSCOPIC CENTRAL PANCREATECTOMY

Less common procedures such as a central pancreatectomy entail the same principles and indications as the open procedure. The author has found that these procedures are ideal in patients who are at risk for developing diabetes or worsening insulin dependence after pancreas surgery. To perform central pancreatectomy, central masses are approached in the same way as in a laparoscopic Whipple procedure, whereby the surgeon delineates the vascular anatomy and creates a tunnel behind the neck of the pancreas.

LAPAROSCOPIC TOTAL PANCREATECTOMY WITH ISLET AUTOTRANSPLANTATION

The author has found laparoscopy to be ideal for patients who require a pancreatectomy for chronic pancreatitis because of the decreased pain benefits, inasmuch as the pain is often challenging to manage. During the procedure, after the pancreas is resected with the techniques described previously, the author performs the hepaticojejunostomy and gastrojejunostomy while the islets are being prepared in the laboratory in the operating room. Once the islet solution is ready for autotransplantation into the liver, the author places a metal hollow-bore 16-gauge needle with intravenous tubing attached through a 12-mm port site. From within the peritoneal cavity, the author uses laparoscopic instruments to place the needle into the splenic or portal vein. The islet infusion is then delivered, the needle is subsequently removed, and direct pressure is applied to the puncture site of the vein to achieve hemostasis (Figure 6).

OLDER AND HIGH-RISK PATIENTS

The author has found that frail older patients and other high-risk patients are ideal candidates for the minimally invasive approach. For such patients, the author uses the lowest insufflation pressures (usually 9 to 11 mm Hg), which allows good visualization. Using appropriate monitoring, the author has observed that the recovery benefits of a laparoscopic resection are magnified in octogenarian patients who have undergone the procedure. As is true for young patients, laparoscopic distal pancreatectomy in frail older patients is a shorter procedure and is associated with less physiologic stress to the patient. Moreover, the decreased postoperative pain associated with laparoscopy allows patients to ambulate earlier and more frequently than patients who undergo open surgery, which decreases the risk of thrombosis.

CONCLUSION

The author's technique and experience with laparoscopic pancreas surgery have been described. A strong foundation with open pancreas surgery is an important prerequisite for developing skills in laparoscopic pancreas surgery. In summary, when applied appropriately, laparoscopy is associated with decreased wound complications

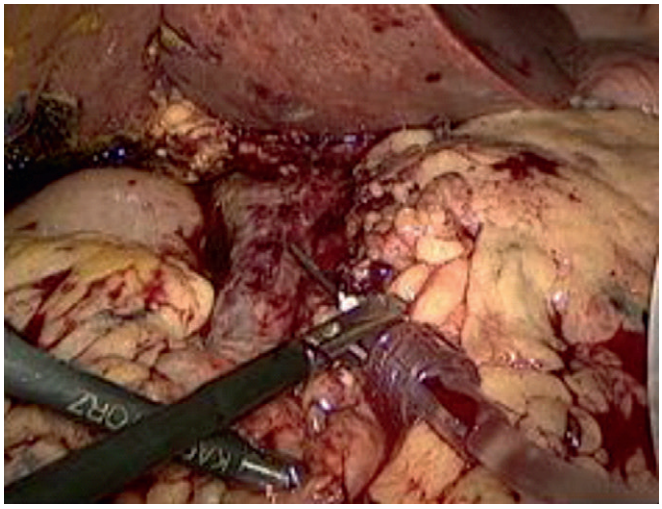

FIGURE 6 Laparoscopic islet autotransplantation infusion into portal vein.

and less pain for patients, and it minimizes the risk for long-term complications such as incisional hernia and small bowel obstruction. In the setting of cancer, an adequate lymphadenectomy with an en bloc resection can be accomplished with a wide resection of the regional lymph nodes. Furthermore, in the absence of a large wound, laparoscopic distal pancreatectomy for cancer allows for a shorter interval to adjuvant therapy when indicated. Laparoscopy is particularly ideal for candidate patients with decreased physiologic reserve or cardiopulmonary risk factors. In the future, improved surgical techniques may decrease the learning curve and enable more patients to benefit from the decreased complications observed.

ACKNOWLEDGMENTS

The author thanks Ms. Jenny Y. Wang of the Johns Hopkins University Graduate School for Art Applied to Medicine, who has demonstrated the procedure through the drawings presented in this chapter. The illustrations are copyrighted to Jenny Wang, 2008.

Laparoscopic Bypass for Pancreatic Cancer

Peter Nau, MD, MS, and Peter Muscarella, MD

BACKGROUND

Pancreatic cancer is the ninth most common cancer in the United States, with approximately 44,030 cases in 2011. Of those, 37,660 will succumb to the disease, making pancreatic cancer the fourth most common cancer causing death. Five-year survival for all stages remains low at 6%. To date, adjuncts to surgical therapy remain inadequate. An R0 resection offers the best chance for cure, but only 10% to 20% of patients will have resectable disease at time of presentation. Consequently, surgical management of pancreatic cancer is often performed for palliation rather than with a curative intent.

Given the high rates of locally invasive and metastatic disease at presentation, many patients are found to have unresectable tumors prior to surgical intervention by evaluation with radiographic and endoscopic staging modalities. With the sensitivity of high-resolution multidetector computed tomography for predicting resectability as high as 96%, this has become increasingly common. In these clinical scenarios there is an opportunity to palliate the patient outside of the operating suite.

The use of endoscopically placed stents for palliation of biliary obstruction has been shown to be a successful modality for patients who are not surgical candidates. The use of metallic stents in these cases is preferred because they are associated with a lower risk of recurrent biliary obstructions. Endoscopic palliation of gastric outlet obstruction (GOO) is also well described. In the multicenter, randomized SUSTENT trial, endoscopic palliation was compared to surgical bypass for the treatment of malignant GOO. In this study, stent placement proved to be a superior treatment for patients with a life expectancy of 2 months or less. However, in those with increased predicted survival, endoscopic palliation was associated with more major complications at a higher mean hospital cost. Furthermore, in the patients who had a longer anticipated life expectancy there were statistically significant increases in food intake, fewer recurrent obstructive symptoms, and a decreased necessity for reinterventions in those who underwent a surgical gastrojejunostomy. It should not go unnoticed that this study was limited by a low patient accrual. This is not unexpected given patient preference for a minimally invasive procedure, thus complicating the extrapolation of the data to a wider population. That being said, current literature supports the use of metallic stents for the endoscopic palliation of biliary obstruction. Additionally, in those with GOO and an estimated life expectancy of 2 months or less, an endoscopic approach is reasonable. Outside of that time frame, the procedure is fraught with complications and increased costs, and it should not be included in the physician's therapeutic armamentarium.

There is little debate that the palliation of GOO secondary to locally invasive disease is associated with an improved quality of life. However, given that as few as 10% of patients with unresectable periampullary malignancies progress to a GOO, the concept of addressing gastric drainage prophylactically is more controversial. In an effort to address this issue, the group at Johns Hopkins Medical Institution completed a prospective, randomized study for prophylactic retrocolic gastrojejunostomy versus no intervention in patients found intraoperatively to have unresectable periampullary carcinomas. They noted that the addition of the prophylactic procedure decreased the incidence of late GOO without a concomitant increase in morbidity or length of stay. A review of the Cochrane Database further clarified the issue, confirming that a prophylactic gastrojejunostomy is indicated in all patients with unresectable periampullary carcinoma already undergoing surgical exploration. Whether the prophylactic procedure should be completed outside of the situation where the abdomen is already open remains controversial.

GASTRIC OUTLET OBSTRUCTION

Laparoscopic Gastrojejunostomy

Technical considerations for laparoscopic gastrojejunostomy begin with appropriate thrombotic and antibiotic prophylaxis. Following placement of an indwelling Foley catheter and temporary orogastric

tube, positioning of the patient is completed. At our institution we prefer the split leg position with the arms abducted and foot boards in place. All pressure points are protected, and the patient is secured to the bed to allow for deep Trendelenberg positioning. This positioning places the operative surgeon on the patient's right with the assistant on the left and a camera holder between the patient's legs.

Accessing the abdomen can be accomplished via an open, cutdown or closed technique. It is our preference to use a veress needle placed in the left upper quadrant to establish pneumoperitoneum. We find that placement of the camera port in the periumbilical position is more consistent when performed following distention of the abdominal wall. Generally, the periumbilical port is placed cephalad to the umbilicus, approximately 15 to 17 cm caudal to the xyphoid process. For this operation, a 10-mm, 30-degree scope is used due to the associated increased illumination and better optics, necessitating a 10-mm supraumbilical port. In total, three additional ports are placed. These are placed with a gentle curve or U-shape conformation with the apex at the midline port. Two ports are placed in the left abdomen. These are placed no less than 1 handbreadth apart to optimize ergonomics and minimize crossing of instruments. The trocars can be 5 mm in size to minimize pain and potential postoperative morbidity. The right-sided trocar should be placed to mirror the medial port on the left, with an option for a fifth port placed more laterally if necessary for bowel manipulation or when it is elected to close the common defect in the gastrojejunostomy via intracorporal suturing techniques. A 12-mm trocar is placed at the more medial right sided port to facilitate stapling and/or intracorporal suturing. In the event that a robotic-assisted procedure is chosen, trocar placement must be more spread out to prevent the arms from colliding with one another.

The operation is begun by examining the small bowel mesentery and the omentum. A foreshortened mesentery or one that is infiltrated with tumor is not amenable to a bypass procedure. Further, the inability to reflect the omentum cephalad may make a laparoscopic procedure prohibitively difficult. In these situations the minimally invasive approach may not be feasible and an open technique should be considered.

Next, the transverse colon is elevated using atraumatic bowel graspers, and the ligament of Treitz is identified. The small intestine is elevated and oriented in an antecolic, isoperistaltic position adjacent to the greater curvature of the stomach. Having verified that the small intestine reaches without undue tension, the lesser sac is entered and the short gastric vessels are ligated with a laparoscopic energy device. It may be unnecessary to ligate all vessels high up on the greater curvature. The goal of this maneuver is to mobilize and expose the greater curvature of the stomach to allow for the creation of a retrogastric anastomosis. This does necessitate the division of any retrogastric attachments to the retroperitoneum. For the most part, this is an avascular dissection. However, it is best completed with a laparoscopic energy device to secure hemostasis. Pancreatitis related to the underlying disease process and associated obstruction may complicate this task. Attention should be paid to the transverse colon and its associated mesentery because injury to these structures can complicate the operation and postoperative hospital course. Placing the patient in reverse Trendelenburg position following mobilization of the stomach will facilitate visualization by allowing the colon to fall out of the operative field. Prior to creation of the anastomosis, a single proximal tacking stitch between the jejunum and stomach is placed to orient the specimens. Next, using electrocautery, enterotomies are made in the antimesenteric border of the jejunum and the posterior wall of the stomach adjacent to the greater curvature. The anastomosis is created using a laparoscopic stapling device (Figure 1). We use staplers with a 60-mm staple length and a depth of no less than 3.5 mm. Staple depth may be increased at the discretion of the operative surgeon based on the thickness of the stomach wall.

Closure of the common enterotomy can be accomplished with intracorporal suturing or an additional firing of the laparoscopic stapling device. A hand-sewn closure is completed in two layers. The inner layer is comprised of a running 3-0 absorbable suture, with an outer layer of interrupted 3-0 nonabsorbable suture to imbricate the edges of the anastomosis. We have found that using two running sutures starting at both ends and then tying them together in the middle is preferable for the inner layer and may decrease the risk of leaks at the ends of the closure. In some hands this procedure may be more reliably completed with the use of a laparoscopic suturing device such as the EndoStitch (Covidien, Norwalk, Conn). In the event that a stapled closure is chosen, attention should be paid to the efferent limb, as this lumen can be easily narrowed. Alternatively, a robotically assisted anastomosis can be fashioned (Figure 2). This technology is particularly suited for suturing and can facilitate creation of a hand-sewn gastrojejunostomy. Assessment of the anastomosis is accomplished via endoscopic insufflation of the stomach while submerging under saline to evaluate for air bubbles. All 10-mm fascial defects are closed at our institution. This is accomplished with a standard figure-of-eight stitch of a large-caliber absorbable suture (0-0 or 1-0) after desufflation of the abdomen or with a suture passer under laparoscopic guidance.

Postoperatively, the patients are kept nil per os (NPO) overnight. On the morning of postoperative day 1, the Foley catheter is removed, and a clear liquid diet is initiated. The diet is advanced as tolerated. In the event that postprandial nausea and delayed gastric emptying are encountered, metoclopramide or erythromycin and antiemetics can be administered. Patients are discharged once they are able to tolerate a diet, with return of gastrointestinal tract function.

LAPAROSCOPIC BILIARY BYPASS PROCEDURES

While feasible, a minimally invasive approach to the palliation of a biliary obstruction is more technically demanding. Moreover, given the complexity of the procedure and decreased morbidity of an endoscopically placed stent, it is easy to see why the majority of malignant biliary obstructions are addressed with biliary stenting rather than by surgical bypass. However, in the event that endoscopic

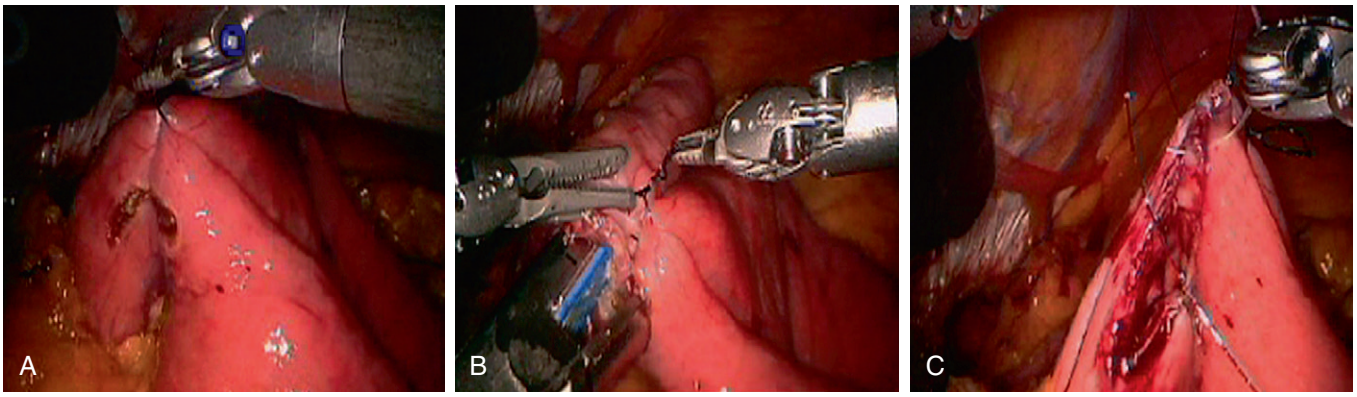

FIGURE 2 Sequential steps illustrating the robotic-assisted gastrojejunostomy. **A,** Tacking the jejunum to the posterior gastric wall, with subsequent creation of enterotomies for staple firing. **B,** Creation of the gastrojejunostomy with a laparoscopic stapling device. **C,** Suture closure of the common enterotomy.

means are not feasible or have failed, the incorporation of this procedure with a gastrojejunostomy to palliate the obstructive symptoms may be necessary.

Laparoscopic Cholecystojejunostomy

Laparoscopic cholecystojejunostomy is well described in the literature. In this procedure the technical demands of a hand-sewn anastomosis are circumvented with the creation of a stapled anastomosis between a distended gallbladder and the jejunum. This is appealing in that it mirrors the procedure performed with an open approach. Further, it requires only token dissection, minimizing the procedure-related morbidity to which the patient is exposed. It has been recommended that this procedure only be considered in those with a radiographically proven patent hepatocystic junction that is well removed from the malignant obstruction. With that said, this operation has fallen out of favor due to a documented 4.4-fold increase in the necessity for reintervention in the population when compared to those that are palliated with a hepaticojejunostomy. In the setting of a palliative operation, we believe this is prohibitively high, making the cholecystojejunostomy a procedure of historic interest only.

Laparoscopic Choledochoduodenostomy

Given the proximity of the duodenum and the common practice of creating a choledochoduodenostomy for refractory calculous disease, it has been proposed to adopt this technique for the treatment of malignant obstructions. Given the nature of the underlying pathology and the propensity for extension of the malignant process, this may be an inadequate or difficult operation in this patient population. The decision to incorporate this methodology for a biliary bypass should only be made when a thorough inspection of the right upper quadrant has convinced the surgeon that extension of the tumor will not cause a recurrent obstruction. Given the propensity for the development of a GOO, it has been suggested that this procedure should be performed with a concomitant palliative gastrojejunostomy.

Technical considerations that arise with the addition of a biliary anastomosis include the necessity of the fifth, right-sided trocar and the need for effective liver retraction. We prefer to use a self-retaining Nathanson liver retractor placed through a subxiphoid stab incision for hands-free exposure of the hepatoduodenal ligament. Using the aforementioned port configuration, a Cattell-Braasch maneuver is performed so as to obtain enough mobility that a tension-free anastomosis can be created. Next, the common bile duct is dissected out from its lateral position in the hepatoduodenal ligament. This is easiest with laparoscopic Maryland forceps and intermittent application of the cautery using the hook dissector. Finally, prior to completion of the anastomosis, a cholecystectomy is completed using standard surgical techniques.

We use a diamond-shaped anastomosis, employing a 1-cm to 2-cm longitudinal duodenotomy and a 1-cm to 2-cm choledochotomy. The apices of the choledochotomy are secured to the midpoints of the duodenotomy (Figure 3). This is completed with a hand-sewn technique using interrupted stitches of 5-0 or 6-0 absorbable, monofilament suture. Alternatively, the back row of the anastomosis can be created using a running suture. Creation of the anastomosis is a complex procedure, but it may be facilitated by placement of the most lateral stitches first. In this way, the anastomosis is orientated and anchored in place for further stitch placement. It is the standard practice at this institution to leave a single 19F Jackson-Pratt (JP) drain in the dependent portion of the right upper quadrant to drain any potential anastomotic leaks. A nasogastric tube is placed in all cases that involve a biliary anastomosis. Postoperative care includes maintenance of a nasogastric tube to low intermittent suction and NPO status while awaiting return of bowel function. Typically, in the absence of any bilious drainage, the JP drain is removed prior to discharge.

Laparoscopic Choledochojejunostomy

Choledochojejunostomy maximizes symptom resolution while minimizing potential morbidity. This operation is set up similarly to the aforementioned choledochoduodenostomy with a five-port technique. A prophylactic gastrojejunostomy may be created proximal to the choledochojejunostomy, but it requires a diverting entero-enterostomy. This procedure is technically challenging when performed laparoscopically, and the risks may outweigh any potential benefits. We prefer an antecolic, loop choledochojejunostomy to the creation of a Roux-en-Y because it eliminates the potential morbidities of small bowel division and the additional anastomosis. Having completely mobilized the stomach and reflected the colon in a caudal direction, the jejunum is approximated to the hepatoduodenal ligament and stomach to ensure that tension-free anastomoses can be created. The choledochojejunostomy is then fashioned in a manner mirroring the choledochoduodenostomy.

It should be noted that robotic-assisted techniques are uniquely suited for the creation of these difficult biliary anastomoses. The three-dimensional optics and increased degrees of freedom provided by the DaVinci Surgical System (Intuitive Surgical, Inc., Sunnyvale, Calif) facilitate what is otherwise a prohibitively difficult procedure in most surgeons' hands. To incorporate the robot in this operation, complete mobilization of the duodenum and stomach is completed.

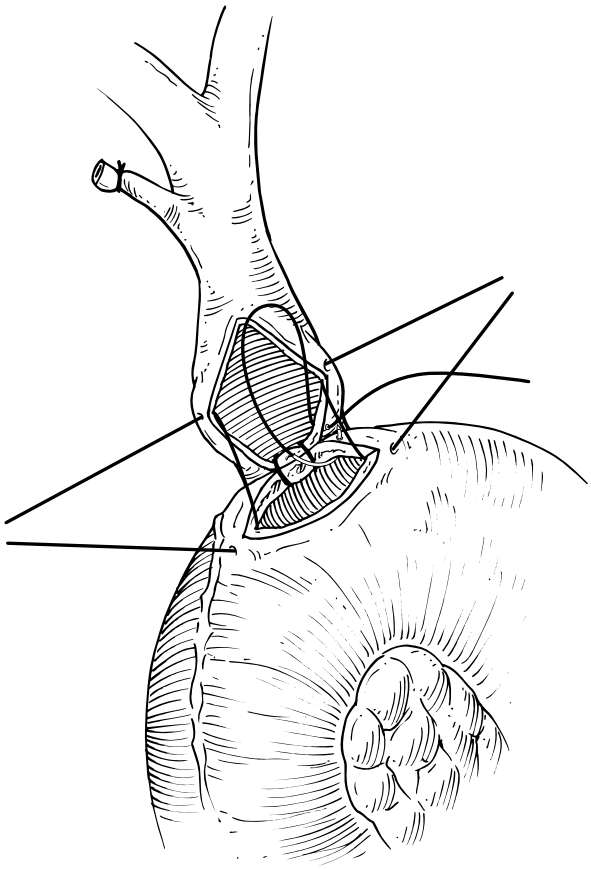

FIGURE 3 Creation of a side-to-side choledochoduodenostomy. Stay sutures aid in orienting the bowel. *(From Riall TS: Choledochoduodenostomy and Hepaticojejunostomy. In Townsend CM, Evers BM, editors:* Atlas of general surgical techniques, *St. Louis, 2010, Saunders.)*

After having oriented the jejunum in position, the robot is docked and the anastomosis completed. The means for completion of the concomitant gastrojejunostomy is left at the discretion of the surgeon. Postoperative care mirrors that for the choledochoduodenostomy.

CONCLUSIONS

Pancreatic cancer is a common cause of cancer death, and most patients present with advanced disease. Palliation of biliary and gastric outlet obstruction is necessary for many of the 80% to 90% of patients in whom cure is not possible due to metastatic or locally advanced disease. Endoscopic stenting may be useful in many patients, but surgery continues to play a role in patients who are found to have unresectable disease at the time of surgical exploration or who have failed or are not candidates for endoscopic therapy. In addition, surgical palliation may have better results for patients whose life expectancies are more than several weeks. The role for palliative gastric bypass is unclear, but the procedure appears to offer benefit for patients who are already undergoing surgery for exploration and/or biliary bypass procedures. Minimally invasive techniques offer the potential benefits of decreased morbidity, pain, and hospital length of stay when performed by experienced surgeons. Robotic-assistance with these procedures may improve outcomes for many surgeons, offering improved visualization and suturing capability for these sometimes difficult anastomoses.

Laparoscopic Management of Pancreatic Pseudocyst

Andre Ilbawi, MD, and
Karen D. Horvath, MD, FACS

OVERVIEW

With the improved understanding of the complications of acute pancreatitis in the last half century, more precise morphologic terms have evolved. The most recent revision of the 1992 Atlanta Symposium terms should be used for all clinical and research communications (Table 1). With use of these descriptors, a pancreatic pseudocyst is a fluid-filled collection with minimal or no necrosis. It forms after disruption of the pancreatic duct leaking activated pancreatic enzymes into the peripancreatic tissues. The resultant inflammatory reaction stimulates a fibrous pseudocapsule to form after about 4 weeks. Pseudocysts can form after an episode of acute pancreatitis (2% to 10%) or after an acute exacerbation of chronic pancreatitis (20% to 40%). In contrast, patients who have development of necrotizing pancreatitis, with resulting necrosis of the pancreatic gland or peripancreatic tissues, do not present with a pseudocyst but instead with a walled-off necrosis (WON). These two entities are often confused in clinical and research communications, and each carries a different management algorithm and prognosis. At its most fundamental level, appropriate management depends first on accurate diagnosis: does this patient have a pancreatic pseudocyst or WON? This is followed by the characterization of the process as sterile or infected, which also informs decision making.

Once the diagnosis of a pseudocyst is established, the next step is to decide if, when, and how to intervene. Minimally invasive approaches are now considered standard of care, so optimal management necessitates a multidisciplinary approach.

CLINICAL FEATURES

Pseudocysts develop from acute fluid collections that persist for more than 4 weeks after an episode of acute interstitial edematous pancreatitis. Spontaneous resolution may occur after sealing of the ductal leak with reabsorption of the fluid. The most common symptom is abdominal pain, which is present in 80% to 90% of patients. Nausea, emesis, early satiety, or weight loss can also be presenting symptoms. On examination, an epigastric mass is found in 50% of patients. General tenderness may be present on physical examination. Rarely, patients may also have signs that result from an obstructive process such as jaundice. A mildly elevated amylase may be present in up to 76% of patients.

PREOPERATIVE WORKUP

Preoperative radiographic studies establish the diagnosis and help guide therapy. A contrast-enhanced computed tomographic (CT) scan (CECT) should be performed in all patients. Radiographically, pseudocysts are surrounded by a well-defined wall with few to no nonliquid components. High-density material within the fluid collection on CECT of more than 20 Hounsfield units should be suspicious for the presence of WON. The CECT should be reviewed with an eye towards establishing the proximity to adjacent structures and cyst wall thickness; identifying any sequelae of portal hypertension or venous thrombosis, such gastric varices lying in the path of the planned operation; and revealing an infectious process (i.e., presence of gas) or a pseudoaneurysm.

An ultrasound scan of the gallbladder should be performed in all patients, and a cholecystectomy should be planned if gallstones or sludge are present. The utility of preoperative endoscopic retrograde cholangiopancreatography (ERCP) in patients with a pseudocyst is debated, but the procedure does offer information regarding ductal anatomy, undetected multiplicity, and areas of disruption or stenosis of the duct that should lead away from percutaneous or endoscopic management. Definitive intervention should be done 24 to 48 hours after ERCP because manipulation carries a high incidence of introducing infection. Other imaging modalities such as transabdominal ultrasound scan, magnetic resonance cholangiopancreatography (MRCP), and endoscopic ultrasound scan are useful adjuncts in select patients.

A cystic neoplasm of the pancreas must be distinguished from a pseudocyst. Approximately 20% of lesions originally thought to be pseudocysts are estimated to eventually be found to be cystic neoplasms. Suspicion for a cystic neoplasm should be heightened in patients with no history of acute pancreatitis and no risk factors for chronic pancreatitis. Prior imaging should be obtained, with a focus on interval changes and associated radiographic findings that would indicate a recent history of acute pancreatitis, such as peripancreatic inflammation, pancreatic ascites, pleural effusions, and absence of septa within the pseudocyst. Aspiration with evaluation of fluid content can be helpful. Pseudocysts usually contain an elevated amylase value of more than 5000 IU/mL, whereas elevated carbohydrate antigen 19-9 (CA19-9) and carcinoembryonic antigen (CEA) values are concerning for a cystic neoplasm.

A related pathologic entity in the differential diagnosis is a delayed postnecronectomy pseudocyst that occurs after endoscopic drainage or necronectomy of a WON. This unusual pseudocyst occurs in the recovery phase of a patient with necrotizing pancreatitis and is the result of disconnected pancreatic tail syndrome that occurs when a viable but orphaned portion of distal pancreas secretes pancreatic fluid into a cavity forming a pseudocyst.

OPERATIVE INDICATIONS

Pseudocyst drainage is indicated with symptomatic or enlarging conditions or with development of complications, such as infection, bleeding, or rupture. Surgical convention also supports intervention for a pseudocyst size of more than 6 cm that persists beyond 4 to 6 weeks because larger cysts are associated with a higher complication rate. Intrasplenic or perisplenic pseudocysts are thought to have a higher incidence of hemorrhage and are thus also managed operatively.

Relative contraindications to an internal surgical drainage procedure include acute fluid collections with an immature capsule and those that are grossly infected.

PROCEDURE SELECTION

Selection of the best approach for definitive management is complex and depends on many factors. Decisions can be influenced by the local anatomy, presence of sinistral hypertension, and communication with the pancreatic duct; presence of infection; suspicion of a cystic neoplasm; the size, number, and location of pseudocysts; the presence of chronic pancreatitis; and the medical status of the patient. Management of a pancreatic pseudocyst should be customized for each patient and is best decided in consultation with a

TABLE 1: Revised Atlanta classification terms

	Interstitial edematous pancreatitis Acute inflammation of the pancreatic parenchyma and peripancreatic tissues, but without recognizable necrosis of pancreatic parenchyma or peripancreatic tissues.	Necrotizing pancreatitis Inflammation associated with pancreatic parenchymal necrosis or peripancreatic necrosis.
Early (1st 4 wk after onset of pancreatitis)	Acute fluid collection Peripancreatic fluid associated with IEP with no associated peripancreatic necrosis. This term applies only to areas of peripancreatic fluid seen within the first 4 wk after onset of IEP.	Acute necrotic collection A collection containing variable amounts of both fluid and necrosis associated with necrotizing pancreatitis; the necrosis can involve the pancreatic parenchyma or the peripancreatic tissues.
Late (≥4 wk after onset of pancreatitis)	Pancreatic pseudocyst A complete encapsulated collection of fluid outside the pancreas with minimal (<5%) or no necrosis usually requires more than 4 wk after onset of IEP to mature and has a well-defined inflammatory wall; rarely, a pancreatic pseudocyst may develop in a patient with necrotizing pancreatitis after treatment with necronectomy, usually related to disconnected duct syndrome.	Walled-off necrosis An encapsulated collection of pancreatic or peripancreatic necrosis that persists for >4 wk after onset of necrotizing pancreatitis and has a well-defined inflammatory wall.

IEP, Interstitial edematous pancreatitis.

multidisciplinary team composed of an interventional radiologist, an endoscopist, and a surgeon.

Pseudocysts are treated most effectively with internal drainage, which is done through the surgical or endoscopic creation of a cystenterostomy. Endoscopic transmural cystenterostomy with the use of endoscopic ultrasound scan (EUS) and color Doppler offers a less invasive option when the pseudocyst is mature and has a favorable anatomy and location. However, accumulating evidence suggests that endoscopic drainage may have higher rates of failure, sepsis, and bleeding. Still, it is the most common form of drainage procedure used in the United States, which leaves the surgeon for the most difficult cases.

Surgical intervention is the standard when endoscopy is not a viable option, when concern exists for a cystic neoplasm, and when complications related to chronic pancreatitis are present, such as pancreatic duct strictures and stones. Operative internal drainage can be accomplished with cystenterostomy, usually cystgastrostomy or cystjejunostomy. In general, cystgastrostomy has a decreased operative time and faster recovery. The two laparoscopic cystgastrostomy approaches are the anterior approach and the posterior approach. The anterior approach is technically less demanding but requires that the stomach be widely adherent to the cyst. The posterior approach avoids an additional gastrotomy and is thought to allow more precise cyst visualization and dissection. It also provides a greater tissue yield for histopathology and is associated with a lower risk of recurrence from occlusion. A transgastric approach has also been described but requires specialized equipment (e.g., intraluminal trocars) and can be technically challenging. Multiple pseudocysts and giant pseudocysts (>10 cm) are best managed with cystjejunostomy. This approach minimizes the formation of dependent residual pockets, which are prone to infection. Finally, the presence of common duct stenosis or pancreatic duct dilation favors cystjejunostomy that can drain both the pseudocyst and the dilated ductal system. Cystduodenostomy has very few indications.

Pseudocyst resection is an alternative to surgical cystenterostomy for moderately sized chronic pseudocysts and for a pseudoaneurysm in close association with the pseudocyst. Most resections for pseudocysts involve a distal pancreatectomy with or without concomitant splenectomy. Roux-en-Y pancreaticojejunostomy can be used if a distal pancreatic stump remains in situ.

Percutaneous catheter drainage should be reserved for either poor operative candidates or infected pseudocysts because of the risk of persistent pancreaticocutaneous fistula. Early recurrence is high, approaching 80%. Transpapillary stenting is effective when used with a communicating pseudocyst, particularly if it is solitary, smaller than 6 cm, and remote from the gastric or duodenal wall.

PREOPERATIVE PLANNING

Preoperative planning should include a gastroduodenoscopy to exclude gastric or duodenal pathology. It is also important to ensure that surgical pathology is available for frozen-section analysis of the pseudocyst wall before cystenteric drainage. The patient is placed in the supine position with the surgeon to the patient's left. A nasogastric tube and Foley catheter should be placed. A first generation cephalosporin is administered before surgery. Port placement may be modified if laparoscopic cholecystectomy is also planned. Critical surgical principles for laparoscopic cystenterostomy are listed in Box 1.

LAPAROSCOPIC CYSTGASTROSTOMY

Anterior Approach

Hasson's technique is used to gain access to the peritoneal cavity at the umbilicus. Three additional ports are placed (Figure 1). The left lobe of the liver is retracted cephalad, exposing the entire anterior gastric wall. An anterior gastrotomy (extending 4 to 5 cm) is made with ultrasonic shears or Harmonic scalpel (Ethicon Endosurgery, Cincinnati, Ohio) to expose the posterior gastric wall.

The pseudocyst is identified by visualizing a bulge on the posterior wall of the stomach. Laparoscopic ultrasound scan should be used to verify the location, map out the planned cystogastrostomy, and define the presence of large interposing blood vessels. The pseudocyst should be aspirated to assist in localization, obtain sample for gram stain, and establish the thickness of the common wall. The pseudocyst is then entered with an incision on the posterior wall of the stomach with a Ligasure device (Covidien, Boulder, Colo) or ultrasonic shears for an incision length of 4 to 6 cm (Figure 2). Simple electrocautery alone is insufficient because of concern for postoperative hemorrhage. A biopsy of the pseudocyst wall is sent. The interior of the pseudocyst is examined with the laparoscope, then the cavity is aggressively irrigated and debris removed with a blunt grasper. The cavity is inspected for hemostasis.

The cystgastrostomy can be created with an endoscopic linear 45-mm stapler, and a wedge or diamond-shaped cystgastrostomy is made (Figure 3). An alternate approach to ensure apposition and control hemostasis is to create the cystgastrostomy with running, locked full-thickness sutures. The anterior gastrotomy is closed with a running, continuous suture or linear stapler (Figure 4).

BOX 1: Critical surgical principles

1. Place the patient on a padded bean bag if patient position is to be changed during the procedure.
2. Be prepared to perform a splenectomy if a distal pancreatectomy is planned.
3. Use of intraoperative ultrasound scan is a critical adjunct in defining anatomic relationships, the presence of multiple cysts, and the location of the common bile duct and pancreatic duct.
4. Rule out pseudoaneurysm with Doppler-guided ultrasound scan.
5. Consider use of a hand-assist device if the dissection is difficult.
6. Access the cyst in a dependent location to optimize pseudocyst drainage. Aspirate first, then create cystotomy with electrocautery alongside the needle.
7. Biopsy cyst wall to rule out cystic neoplasm.
8. Débride content of the pseudocyst thoroughly but with caution to avoid bleeding.
9. Cystenteric anastomosis should be 3 to 5 cm to prevent premature closure and recurrence.
10. Ensure hemostasis of friable pseudocyst wall with either an endoscopic stapler or a suture ligation with a continuous, locking closure.
11. Interrogate the cystgastrostomy with submersion in saline solution as the stomach is insufflated via the nasogastric tube.
12. Consider placing omentum over cystenterostomy.
13. Place a closed suction drain to identify and control potential postoperative fistulae.

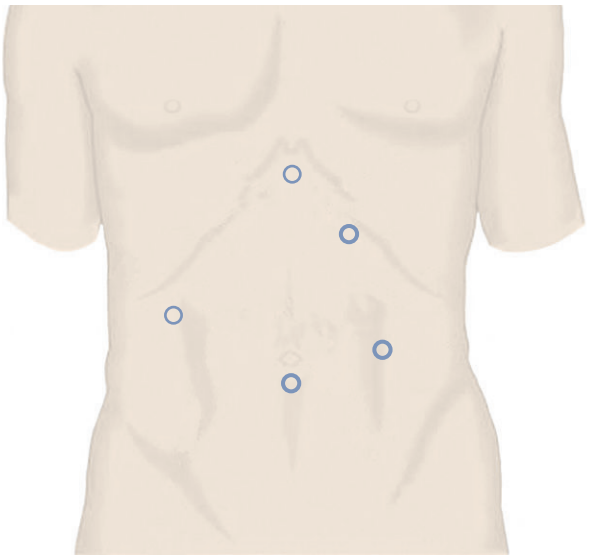

FIGURE 1 General port placement for cystenterostomy. For anterior cystgastrostomy, the epigastric port is often not needed. *(From Kaban GK, Perugini RA, Czerniach DR, et al: Pancreatic pseudocyst drainage,* Op Tech Gen Surg *6(1):55-62, 2004.)*

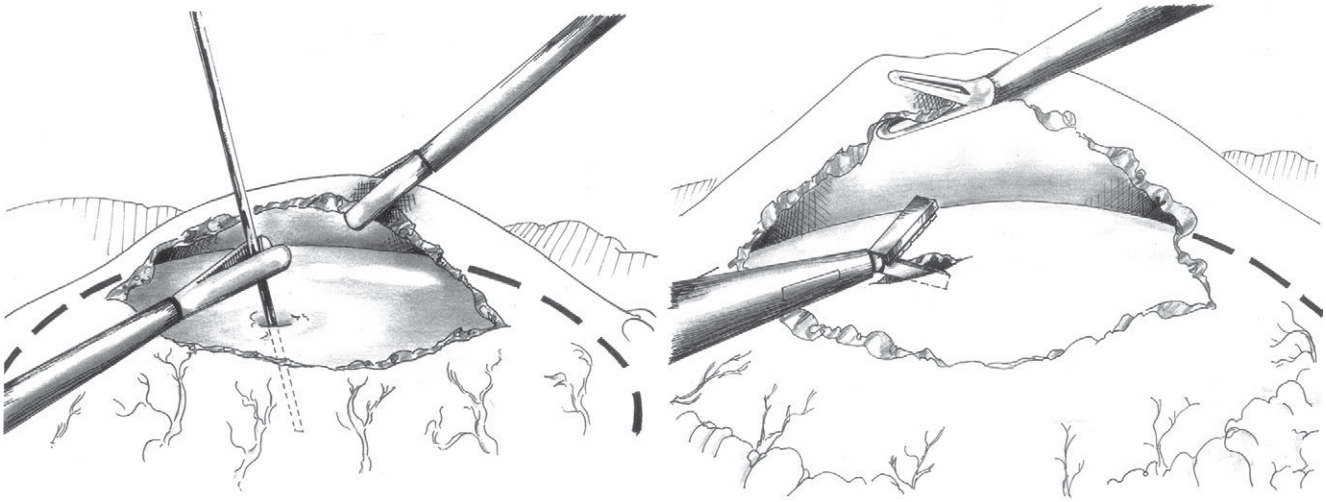

FIGURE 2 Anterior approach. After anterior gastrotomy, the cyst is aspirated in a dependent position to confirm its location and to prepare for a cystotomy to be made transversely along the access site. *(From Kaban GK, Perugini RA, Czerniach DR, et al: Pancreatic pseudocyst drainage,* Op Tech Gen Surg *6(1):55-62, 2004.)*

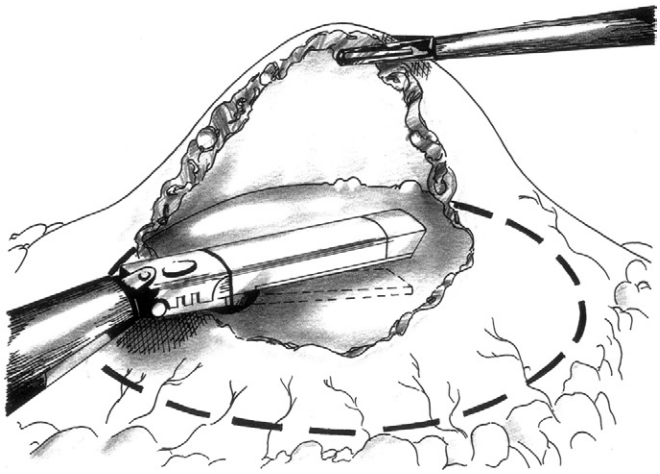

FIGURE 3 Anterior approach. A stapling device can be used to extend the cystgastrostomy, usually with 2.5-mm staples. Thicker walled pseudocysts require staples of 3.5 mm of larger. Intracorporeal suturing may be necessary. *(From Kaban GK, Perugini RA, Czerniach DR, et al: Pancreatic pseudocyst drainage,* Op Tech Gen Surg *6(1):55-62, 2004.)*

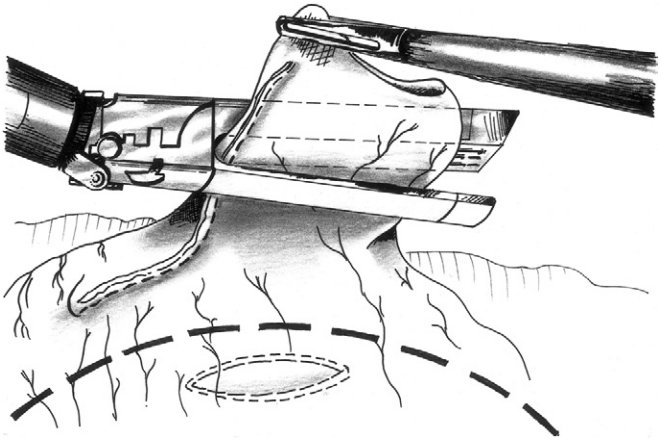

FIGURE 4 Anterior approach. The anterior gastrotomy is closed with an endoscopic linear stapler or running suture. *(From Kaban GK, Perugini RA, Czerniach DR, et al: Pancreatic pseudocyst drainage,* Op Tech Gen Surg *6(1):55-62, 2004.)*

Posterior Approach

The posterior, or lesser sac, approach can be used when the pseudocyst resides close to the inferior edge of the stomach. The posterior gastric wall is directly accessed for the cystgastrostomy through one gastrotomy.

Standard laparoscopic access is obtained, and the left lobe of the liver retracted as described previously. The lesser sac is entered by dividing the gastrocolic ligament; this is often tedious and challenging given the prior inflammatory process, distorted anatomy, and adhesions. The anterior gastric wall is retracted cephalad. The pseudocyst is exposed and skeletonized to the area where it is closely adherent to the posterior gastric wall. A needle is passed to aspirate the cyst fluid for analysis as described previously. A biopsy of the cyst wall is sent. A cystotomy is made to accommodate the linear stapler. The optimal position of the gastrotomy can be confirmed with simultaneous introduction of a gastric endoscope. A gastrotomy is created about 3 to 5 cm along the posterior gastric wall directly opposite the cystotomy. A linear staple is used to create the cystogastrostomy. The common defect is closed with interrupted or running sutures or an additional laparoscopic stapler.

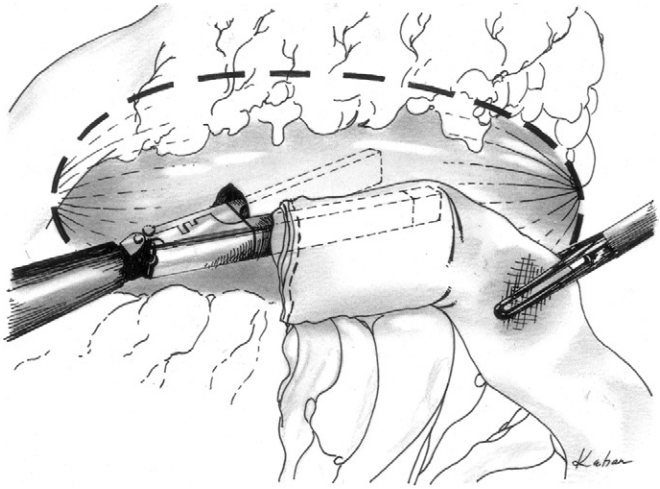

FIGURE 5 Laparoscopic cystjejunostomy. The cystjejunostomy is created in the most dependent portion of the cyst, oriented in an antimesenteric fashion. *(From Kaban GK, Perugini RA, Czerniach DR, et al: Pancreatic pseudocyst drainage,* Op Tech Gen Surg *6(1):55-62, 2004.)*

LAPAROSCOPIC CYSTJEJUNOSTOMY

Access to the peritoneal cavity is achieved through an initial 10-mm periumbilical port, and pneumoperitoneum is established. Three additional ports are placed in the bilateral upper abdomen. If a linear stapler will be used, a 12-mm port is also placed in the left lower quadrant. The transverse colon and omentum are retracted cephalad. The pseudocyst often bulges through the transverse mesocolon just to the left of the middle colic vessels. If not, it can be accessed through the lesser sac. Careful attention must be paid to the central middle colic pedicle, which can be obscured by thickened overlying peritoneum and saponified adipose tissue from prior inflammation. The preferred site of access is just superior and lateral to the ligament of Treitz. The most dependent portion of the pseudocyst is identified with ultrasound scan assistance and aspirated as described previously. The cystotomy is created with the Ligasure or Harmonic scalpel, and a biopsy of the cyst wall is performed. Inspection and débridement of the pseudocyst are performed before proceeding with the Roux-en-Y reconstruction.

The ligament of Treitz is identified, and the jejunum is transected 20 cm distal to this point with a linear stapler. The mesentery is divided in the direction of the root of the mesentery in a way to ensure adequate blood flow to the Roux limb. The jejunojejunostomy is created approximately 40 cm distal to the transection site. The mesenteric defect should be closed. The Roux limb is brought up to the pseudocyst either directly opposed to the mesocolon or through a window in the transverse mesocolon to which it is later secured. It is then tacked to the pseudocyst to achieve optimal orientation for linear stapling, ensuring the distal loop of bowel is approximated to the pseudocyst in the longitudinal plane and is antimesenteric (Figure 5). A small incision is made in the jejunum opposite to the one previously made in the pseudocyst. Hemostasis is ensured through direct inspection. The cystjejunostomy is fashioned to a total length of 5 cm or greater. This is done either with a laparoscopic linear stapler or a running or interrupted suture. The cystenterotomy is closed with a single layer of interrupted suture. A closed suction drain should be left. The abdomen is inspected and irrigated followed by fascial closure of any port 10 mm or more.

A lateral, side-to-side pancreaticojejunostomy may be necessary in patients with chronic pancreatitis and a dilated pancreatic duct. Additional pseudocysts can be incorporated into the laterally positioned Roux limb.

POSTOPERATIVE CARE

Enteral feeding can begin usually at about 48 hours after laparoscopic cystenterostomy. This is the case even with Roux-en-Y reconstruction as reflux into the cyst is minimal and prolonged ileus is rare. Postoperative bleeding from the pseudocyst capsule or anastomosis should be managed with endoscopic electrocoagulation, laparoscopy, or laparotomy. Bleeding may also arise from avulsion or laceration of peripancreatic arteries or veins during cyst débridement and may require emergent coil embolization. Drain fluid may be assayed for amylase if there is a concern for anastomotic dehiscence. Persistent postoperative fever of unclear etiology should be worked up with an abdominal CT scan with oral contrast to rule out premature closure of the cystenterostomy or formation of an abscess.

OUTCOMES AND COMPLICATIONS

Limited reports exist that compare laparoscopic and open cystenterostomy, and no comparative studies are found for the different laparoscopic approaches to cystgastrostomy or cystjejunostomy. Given the low prevalence of true pseudocysts, these studies are unlikely to become available. The proposed advantages of a laparoscopic approach are less postoperative pain, smaller scar, shortened stay, and more rapid return to activities. Recurrence rates on published series of laparoscopic management of pseudocysts range from 0 to 2%, with a morbidity rate of 3% to 33%. Use of a laparoscopic stapler is thought to possibly carry a lower bleeding risk.

BRIEF COMMENT ON WALLED-OFF NECROSIS

WON occurs at a much greater frequency than pseudocyst formation. If a patient is determined to have WON and not a pancreatic pseudocyst, the options for effective drainage are different. There now exist prospective safety and efficacy and randomized controlled trial data to support superior short-term and long-term clinical outcomes and cost benefits with a step-up approach to WON. The step-up approach involves initial percutaneous drainage of a symptomatic WON followed by a more invasive drainage procedure when necessary. Classically, the step-up approach was described with the videoscopic-assisted retroperitoneal débridement technique, although any endoscopic, laparoscopic, or open approach can be substituted.

VIDEO-ASSISTED THORACIC SURGERY

Christopher M. Sciortino, MD, PhD, Benedetto Mungo, MD, and Daniela Molena, MD

INTRODUCTION

Video-assisted thoracic surgery (VATS) is the minimally invasive alternative to open thoracotomy for thoracic procedures. It has become an invaluable technique for the diagnosis and treatment of thoracic disease. Thoracoscopy was first described in 1910 by a Swedish internist, Hans Christian Jacobaeus, who used a rigid cystoscope to perform pleural inspection and adhesiolysis for tuberculosis. Today, VATS is used for a wide spectrum of diseases by both thoracic and general surgeons. This chapter outlines the indications and the general technique of VATS.

INDICATIONS FOR VIDEO-ASSISTED THORACIC SURGERY AND PATIENT SELECTION

The indications for the VATS approach are nearly identical to those for open thoracotomy. Box 1 lists the surgical applications for VATS. Relative contraindications to VATS are listed in Box 2. The contraindications would be similar to the relative contraindications to open thoracotomy with the possible exception of fused pleural space and tumor involvement of the chest wall.

Advantages of VATS over the open thoracotomy approach include less pain, lower rates of postoperative pneumonia, and shorter hospital stays. Disadvantages of VATS include limited exposure, inability to palpate all but superficial structures, the need for specialty equipment, two-dimensional view of the operative field, and the potential need for emergency conversion to open thoracotomy if major airway or vascular disruption should occur.

No matter which technique is utilized, careful preoperative workup must be performed to ensure that the patient is a suitable candidate for the planned thoracic procedure. The workup includes a general medical evaluation, preoperative imaging, laboratory tests, pulmonary function testing, and cardiac evaluation if applicable.

BOX 1: Common applications for video-assisted thoracic surgery approach to the thorax

Diagnostic thoracoscopy
Pleural biopsy
Lymph node biopsy
Decortication
Pleurodesis
Wedge resection
Lobectomy
Pneumonectomy
Mediastinal tumor excision
Thymectomy
Pericardial window
Resection of benign esophageal tumors
Esophageal diverticulectomy
Esophageal myotomy
Paraesophageal hernia repair
Minimally invasive esophagectomy
Sympathectomy
Pulmonary vein isolation
Lung volume reduction surgery
Diaphragm plication

BOX 2: Relative contraindications to VATS

Dense pleural adhesion (obliterated pleural space)*
Pulmonary hilar lesion*
Superior sulcus tumor*
Small (<1 cm), deeply located pulmonary nodule*
Extensive tumor involvement of the chest wall*
Severe hemorrhage*
Inability to achieve ipsilateral lung isolation
Hemodynamic instability
Ventilator dependency
Coagulopathy
Inadequate visualization
Severe thoracic or spinal deformities (e.g., scoliosis or pectus excavatum)
Inability to tolerate single lung ventilation
Noncompliant lung
Severe emphysema

*Specific to video-assisted thoracic surgery (VATS) in comparison with open thoracotomy.

Pulmonary function tests are used to help predict (1) whether the patient can tolerate one lung ventilation for the proposed procedure and (2) whether the patient has the physiologic reserve to tolerate any planned pulmonary resection. Figure 1 is a useful algorithm to assess patient's eligibility for lung resection on the basis of preoperative lung function.

SURGICAL SETUP AND EQUIPMENT

Anesthesia

Thoracic surgical procedures require an experienced anesthesia team familiar with single-lung ventilation. The expertise includes the ability to place and troubleshoot double-lumen tubes or bronchial blockers, as well as the ability to manage hemodynamic shifts that result from single-lung ventilation (e.g., shunt physiology).

The majority of patients who undergo a thoracic surgical procedure have an epidural catheter placed before the procedure for intraoperative and postoperative analgesia management. Routine use of epidural analgesia significantly decreases postoperative pain and respiratory complications. All patients undergoing major lung resection should have an arterial cannula placed for hemodynamic monitoring and frequent blood gas analysis. Central venous access is utilized on a case-by-case basis.

Patient Positioning

Figure 2 illustrates the basic positioning for most VATS procedures. The patient is placed in the lateral decubitus position, with an axillary roll. The bed is flexed all the way to help separate the ribs and open the intercostal spaces, but, of most importance, to allow the hip to descend below the line of the chest wall to avoid interference with instruments manipulation. The neck is supported to keep the spine straight. The lower arm is placed on an arm board with copious padding to minimize the risk of neuropraxia, and the upper arm is either rested on pillows or preferably supported by commercially available arm holders or retractors in a manner that gives access to the entire chest and axilla. The patient is supported on each side either with a bean bag or rolled sheets. Broad silk tape is used to stabilize the hips. The legs are well padded, especially on the knees and ankles; the inferior leg is bent to approximately 90 degrees; and the superior leg is straight.

Equipment

The basic VATS imaging equipment is similar to that for laparoscopy and consists of a fiber optic light source and an imaging system linked to the operative camera. For most adult procedures, the authors use a 10-mm scope (30 or 45 degrees) attached to the camera head. The current generation of cameras offers high-definition resolution with the capacity for continuous recording of procedures. Carbon dioxide insufflation is not routinely used in VATS; however, it is occasionally used to help compress the isolated lung when endoluminal suction is insufficient, to increase the intrathoracic volume by pushing the diaphragm down, and to stabilize the mediastinum by decreasing contralateral respiratory excursions. The insufflation pressure should be kept low (the authors recommend not exceeding 8 mm Hg), and attention to hemodynamic changes is imperative because the lack of compliance of the chest wall (in relation to the abdomen) can result in a rapid decrease in venous return or mediastinal shift, both of which could cause a profound drop in blood pressure.

Surgical instruments for VATS procedures are also similar to those for laparoscopy. Long channel graspers, dissectors, and scissors are utilized for their designed purpose. Instruments unique to VATS include specially designed lung graspers (Figure 3) with a broad-based shape to minimize tissue trauma and tearing during lung manipulation. Monopolar electrocautery is used for dissection and hemostasis and can be engaged either through the connection on endothoracic instruments or through the use of an extended-length electrocautery pen. Ultrasonic dissector–coagulator (Harmonic scalpel; Ethicon, Bridgewater, NJ) systems are often utilized in VATS procedures and have less heat dispersion and a protected jaw arm, which can be important during dissection in the region of delicate structures such as nerves and thin vessels. A bendable argon beam (Bend-A-Beam; ConMed, Utica, NY) can be useful for overcoming the limitations of a rigid chest cavity and allows reaching around the lungs or the convexity of the chest wall.

Endoscopic staplers are the modern mainstay of resections by VATS (Figure 4). Most staplers used in VATS are capable of simultaneously stapling and cutting. Characteristics of currently available staplers include a variety of lengths (from 30 to 60 mm), varying staple heights, and the ability to roticulate. The length of stapler should be carefully chosen according to amount of tissue that must

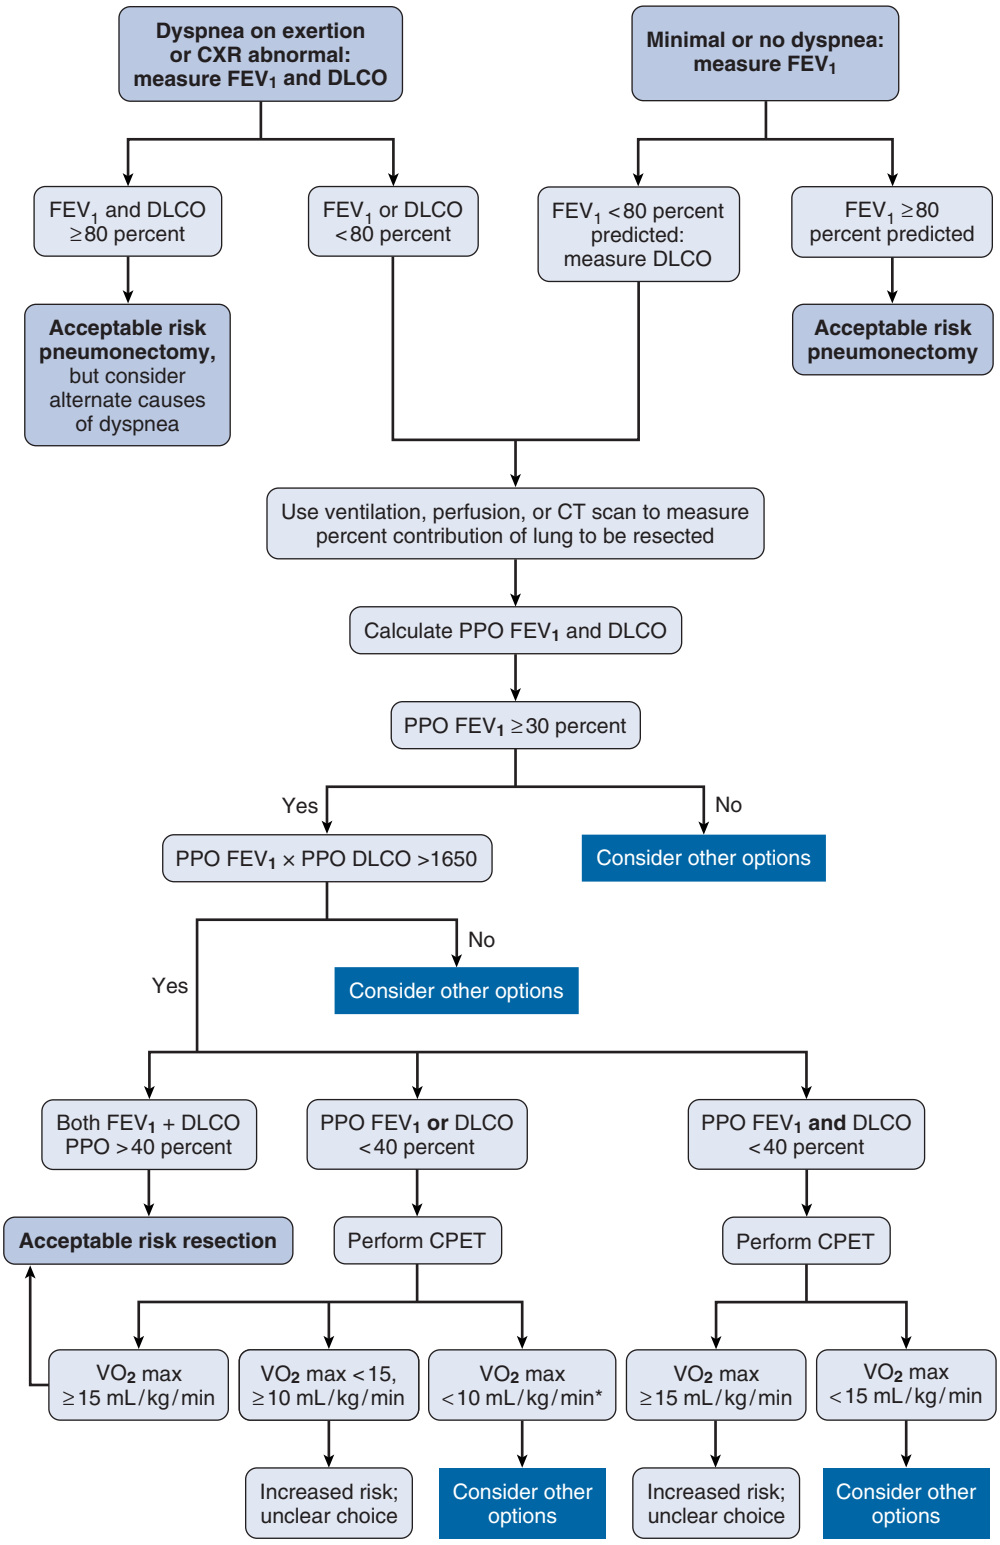

FIGURE 1 Evaluation for lung resection. *VO_2 max <10 mL/kg/min is approximately equivalent to walking less than 25 shuttles on two shuttle walks or less than 1 flight of stairs. *CPET,* Cardiopulmonary exercise test; *CT,* computed tomographic; *CXR,* chest radiograph; *DLCO,* diffusion capacity of carbon monoxide; *FEV_1,* forced expiratory volume in 1 second; *PPO,* predicted postoperative; *VO_2,* oxygen consumption. *(Data from Colice GL, Shafazand S, Griffin JP, et al: Physiologic evaluation of the patient with lung cancer being considered for resectional surgery,* Chest *132:161S, 2007.)*

FIGURE 2 Patient positioning for video-assisted thoracic surgery (VATS). The patient is placed in the lateral decubitus position with axillary roll. Padding is placed under the neck to ensure alignment of cervical spine. Rolls are placed on either side of the patient to stabilize the torso. Silk tape is used to secure the position of the hips. Padding is placed around arms and between legs to minimize the risk of neuropraxia.

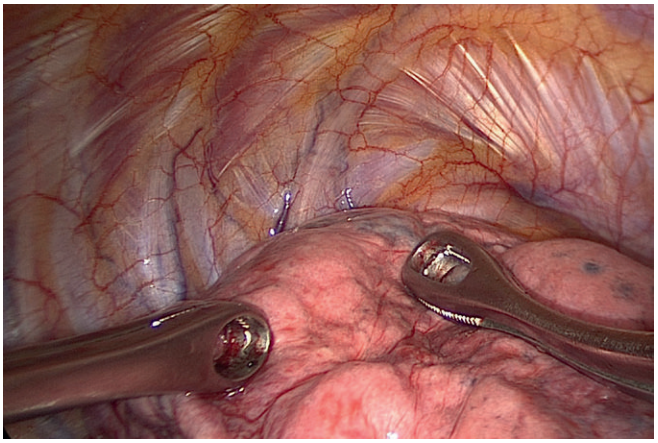

FIGURE 3 Intraoperative view of a video-assisted thoracic surgery (VATS) procedure. Note the peculiar shape of the atraumatic tissue graspers, specifically designed for the lung parenchyma.

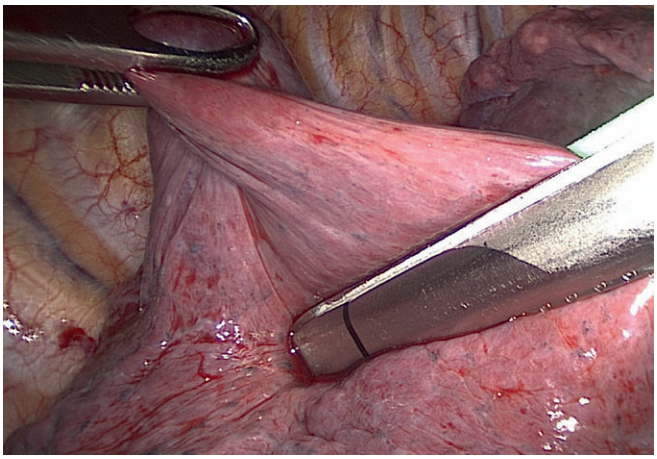

FIGURE 4 Intraoperative view of a video-assisted thoracic surgery (VATS) procedure. In a pulmonary resection, the surgeon uses an endoscopic stapling device to quickly divide both pulmonary parenchyma and vessels, while excellent pneumostasis and hemostasis is maintained.

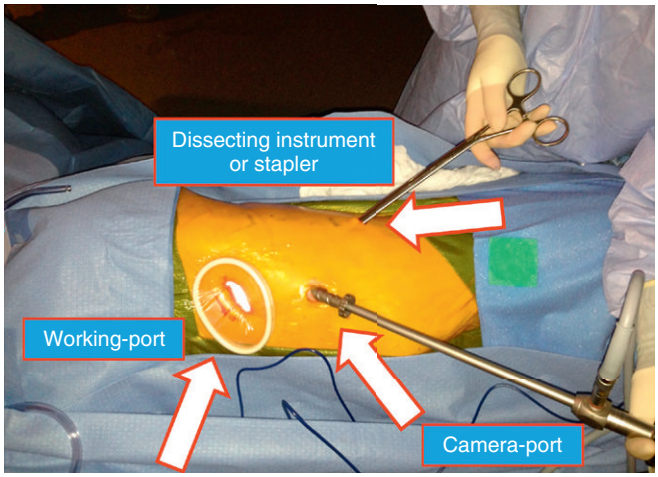

FIGURE 5 The triangulation principle of thoracoscopic port placement. The optic channel is often placed centrally and should maintain an angle of 30 to 60 degrees between it and any other instruments. A wound retractor is useful to separate the soft tissues and allow easy introduction of instruments through the working port.

be resected, the location in relation to the chest wall and mediastinum, and the patient's chest cavity volume. Because of the closed and fixed confines of the chest cavity, longer staplers are difficult to manipulate in small patients or for lung resections close to the chest wall. The staples' height is chosen on the basis of the thickness of the tissue that needs to be sealed; for example, 2-mm to 2.5-mm staples are used for blood vessels and very thin lung parenchyma, whereas 4.8-mm staples are used for thick lung parenchyma or a lobar bronchus.

Several products exist to reinforce staple lines and are compatible with most staplers. They are marketed as a means to decrease air leaks at staple lines, decrease the duration of chest tube drainage, and potentially decrease the length of hospital stay. Only one biologic glue (Progel; Neomend, Irvine, Calif) has been approved by the U.S. Food and Drug Administration for application to the lung, and it is specifically designed for sealing small tears on the surface of the lung and at staple sites to decrease air leaks. The added cost of these materials limits their routine use; therefore, the authors utilize them selectively in patients at high risk for prolonged air leaks.

Port Site Placement

Port site placement is the most important factor for the successful performance of thoracic procedure by VATS. Triangulation to the desired intrathoracic target is hindered by the rigidity of the chest wall, limited intercostal space, the diaphragm, the heart, and the scapula. Typically, for a three-port technique, one port is placed in the seventh or eight intercostal space along the posterior axillary line, and it is used to introduce the camera. The second port site is usually placed in the eight intercostal space in line with the tip of the scapula, and it is used for retraction or stapling, or both. A third port is positioned in the fourth or fifth intercostal space in the midaxillary line (Figure 5). This affords enough port separation at the skin level to

allow for adequate instrument spacing in the chest to work without crossing instruments. However, the placements of these ports can be modified after initial thoracoscopy to optimize instruments' position. Minor procedures such as pleural inspection and biopsy can be performed with a single port. In most procedures, two to four ports are used, and in some instances, the more proximal port may be lengthened to allow multiple instruments to be placed through it ("working port").

BASIC TECHNIQUE AND EMERGENCY CONVERSION TO THORACOTOMY

Basic Technique of Video-Assisted Thoracic Surgery

After induction of anesthesia and endotracheal intubation, a diagnostic bronchoscopy is performed to evaluate the airways, clear any secretions, and ensure proper position of the double-lumen endotracheal tube. The patient is then carefully positioned, prepared, and draped. The desired lung is isolated to allow adequate time for collapse. The port sites are marked and, after the skin is incised, electrocautery is used to dissect to the level of the rib space. The chest is entered by electrocautery dissection on the superior aspect of the rib to avoid the intercostal bundle. The authors utilize short metal bullet-tipped trocars for the camera port to keep the track open and protect the camera during entry. If insufflation is used, thoracoscopic trocars with a unidirectional valve should be placed through each incision, to avoid air leakage. The camera is coated with antifog solution and carefully placed in to the thoracic cavity for initial inspection and evaluation of lung isolation. Adhesions are taken down either with the Harmonic scalpel or with electrocautery. Excessive torque should be avoided while the VATS instrument is manipulated to avoid postoperative intercostal neuritis. Vascular structures are circumferentially dissected before stapler engagement to ensure that the stapler can be placed with minimal tension on the vessel. Once the desired specimen is dissected free, it is retrieved from the chest via a specimen bag to prevent chest wall seeding. After the specimen is removed, the surgical site is inspected and then irrigated and cleared of any fluid and clot. Chest tubes are placed under direct vision through port sites before lung reexpansion. The lung is reinflated under direct vision to assess for areas of persistent atelectasis, to ensure adequate filling of the chest cavity, and to evaluate all staple lines for leaks. The chest wall muscles are approximated with absorbable suture to avoid lung herniation, and a subcuticular suture is used to close the skin.

Conversion to Thoracotomy

The need for conversion from VATS to open thoracotomy is always a possibility, and the operating room should be prepared for this event. This typically occurs in the situation in which there is unexpected bleeding or airway disruption or if it is unsafe or impractical to proceed by VATS (e.g., tumor extends to the hilum). In the nonemergency setting, a muscle-sparing thoracotomy can be considered. However, in the urgent/emergency conversion, a non–muscle-sparing thoracotomy can be performed. Bleeding can occasionally be controlled by compression with a sponge stick while the thoracotomy is opened. It is important to have proper retractors and other equipment readily available when VATS is performed, in case there is a need to quickly convert to thoracotomy.

SUMMARY

VATS represents a safe and feasible alternative to thoracotomy for a wide range of surgical procedures. It offers surgical and oncologic outcomes comparable with those of traditional surgery and, moreover, provides some adjunctive benefits, such as less postoperative pain and faster recovery. Future technologic achievements, targeted to overcome the known limitations of this technique, will contribute to further extension of its indications and use.

Laparoscopic Surgery for Morbid Obesity

Kashif A. Zuberi, MD, Thomas Magnuson, MD, and Michael A. Schweitzer, MD

The morbid obesity epidemic continues to spread throughout industrialized nations. It is a condition with a heterogeneous etiology, including genetic, psychosocial, and environmental factors. Prevention methods have currently been unable to halt the further spread of this disease. Obesity has been linked to increased healthcare costs, common physiologic derangements, reduced quality of life, and increased overall mortality. More than one third of adults and almost 17% of children in the United States are obese.

Medical therapy that can cause sustained significant weight loss may be years away. Bariatric surgery, when combined with a multidisciplinary team, continues to be the only proven method to achieve sustained weight loss in most patients. Bariatric procedures modify gastrointestinal anatomy and, in some cases, enteric hormone release to reduce caloric intake, reduce absorption, and alter metabolism to achieve weight loss. Currently, the three most common bariatric operations in the United States are Roux-en-Y gastric bypass,

adjustable gastric band, and the vertical sleeve gastrectomy (Boxes 1, 2, and 3). The sleeve gastrectomy is part of a duodenal switch with biliopancreatic diversion. It has been used in patients at higher risk as a first-staged weight loss procedure, where the plan is to induce a significant weight loss and then offer patients a revision to a gastric bypass or duodenal switch with biliopancreatic diversion when they have achieved a safer weight. It is also now used as a primary bariatric operation with weight loss results that are better than adjustable gastric band but without the intestinal malabsorption issues seen after gastric bypass. Duodenal switch with biliopancreatic diversion has never been a popular weight loss surgery because of the significant malnutrition that accompanies this procedure (Box 4). All four of these operations can be performed laparoscopically in most patients.

PREOPERATIVE EVALUATION

The National Institutes of Health Consensus Development Conference Statement for Gastrointestinal Surgery for Severe Obesity was issued in 1991 and is still regarded as the starting point for criteria to accept patients in a surgical weight loss program. Patients are considered morbidly obese and candidates for surgery if they have a body mass index (BMI) of at least 35 kg/m^2, with an obesity-related comorbidity or greater than 40 kg/m^2. Recommendations are that patients should have tried dieting in the past before surgical therapy is considered as a treatment option (Box 5).

In evaluation of a potential patient for bariatric surgery, a multidisciplinary team should be used. This team should include a dietitian and mental health professional, whose purpose is to obtain dietary and behavioral eating history, discuss postoperative dietary expectations, and decide whether the patient is appropriate for bariatric surgery. Support for the surgery from family members and friends is helpful. If the team believes that the patient is not appropriate for surgery, then consideration should be given to nonoperative medical management with appropriate counseling and surgery should be reconsidered or denied indefinitely.

Patients with severe end organ disease, such as end-stage heart failure or respiratory failure, are at higher risk for morbidity and mortality. Surgery is not necessarily contraindicated for these patients, but weight loss alone may not significantly correct end-stage heart or lung disease. Patients with cirrhosis may be at higher risk

BOX 1: Gastric bypass

Advantages
- Proven weight loss over 5 years
- Better weight loss than restrictive-only operations
- Proven improvement in medical comorbidities
- Mortality rate less than 1% at most centers

Disadvantages
- Malabsorption
- Marginal ulcer
- Stomal stenosis
- Inability to easily access distal stomach
- Internal hernia
- Small bowel obstruction
- Iron deficiency anemia
- Calcium and vitamin B_{12} deficiency

BOX 2: Adjustable gastric band

Advantages
- Reversible
- Least invasive (no stapling of the stomach)
- Lowest risk of death
- No malabsorption

Disadvantages
- Erosion
- Esophageal dilation
- Breakage
- Port problems
- Slippage or prolapse
- May worsen GERD
- Failure to lose weight
- Lower average weight loss

GERD, Gastroesophageal reflux disease.

BOX 3: Sleeve gastrectomy

Advantages
- Better weight loss than with adjustable gastric band
- Proven improvement in medical comorbidities
- Easier to perform than gastric bypass, especially if BMI is high
- No intestinal malabsorption
- No risk of marginal ulcers
- Preserved pylorus means less risk of dumping
- Ability to convert to gastric bypass or DS-BPD
- Mortality rate less than 1% at most centers

Disadvantages
- Not reversible
- Large portion of stomach removed
- A proximal leak is difficult to treat
- Stricture (incisura angularis)

BMI, Body mass index; *DS-BPD,* duodenal switch with biliopancreatic diversion.

BOX 4: Duodenal switch with biliopancreatic diversion

Advantages
- Excellent weight loss
- Proven improvement in medical comorbidities
- Preserved pylorus means less risk of dumping
- Less risk of marginal ulcers

Disadvantages
- Increased risk of protein malabsorption
- Increased risk of fat-soluble vitamin malabsorption (A, D, E, and K)
- Iron deficiency anemia
- Diarrhea and excess gas more common
- Internal hernia
- Higher complication rate
- Higher risk of osteoporosis

BOX 5: Patient requirements for bariatric surgery

1. Patients with a BMI of 40 kg/m^2 or greater are potential candidates for bariatric surgery.
2. Patients with a BMI of 35 to 40 kg/m^2 with significant obesity-related comorbidity are also potential candidates for bariatric surgery.
3. Patients with a history of dieting.
4. Patients with no recent substance abuse.
5. Patients should be evaluated by a multidisciplinary team that includes a dietitian and psychologic evaluation before surgery.

BMI, Body mass index.

for surgery but certainly may benefit from weight loss. Patients who are morbidly obese may be rejected for heart, lung, liver, or kidney transplant and, therefore, may benefit from bariatric surgery-induced weight loss. Patients who are nonambulating or bedridden should also be considered at high risk for postoperative complications.

Currently, patients with type 2 diabetes with a BMI of 30 to 35 kg/m^2 are being studied for whether they would benefit from bariatric surgery. The U.S. Food and Drug Administration (FDA) has approved the adjustable gastric band for this subgroup of patients.

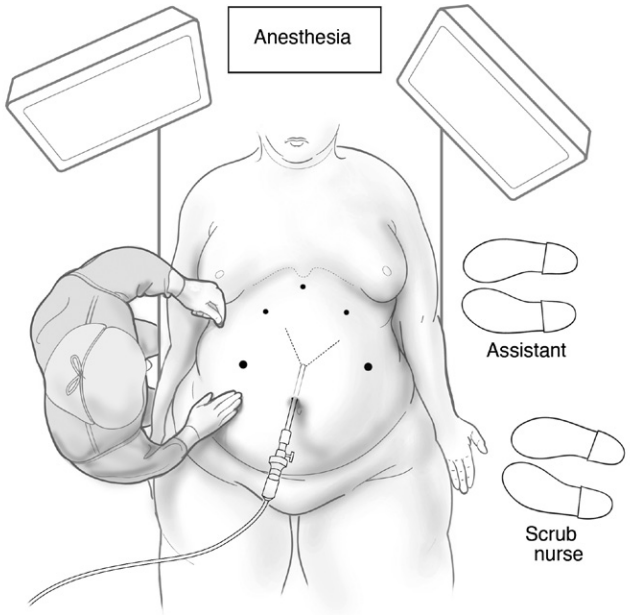

FIGURE 1 Positioning for laparoscopic gastric bypass. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

PREPARING THE PATIENT IN THE OPERATING ROOM

On the morning of surgery, the patient is injected subcutaneously with low molecular-weight heparin to prevent venous thromboembolic complications. A peripheral intravenous (IV) line is placed, and an appropriate antibiotic is administered intravenously. The patient is placed on the operating room table in the supine position with a footboard. Appropriate padding of the patient is important because these particular patients are at increased risk for compression-related injuries. Sequential compression devices are placed on the lower extremities if they fit. General anesthesia is performed, and then a urinary catheter is inserted. The anesthetist inserts, applies suction to, and then immediately removes the oral-gastric tube before starting the operation. Esophageal temperature probes are not recommended because these can migrate into the stomach during stapling. The operating surgeon stands on the patient's right side, and the assistant on the left (Figure 1). Entering the abdomen in morbidly obese patients is safe with direct vision with a device that allows visualization of the abdominal wall layers sequentially with a 0-degree laparoscope inserted inside of it. Initial access in each procedure is through a left upper quadrant 12-mm incision.

TECHNIQUES

Laparoscopic Antecolic Antegastric Roux-en-Y Gastric Bypass Operative Technique

The abdomen is then insufflated with carbon dioxide to a pressure of 15 mm Hg, a 45-degree angled laparoscope is inserted, and an additional four ports are placed (a 5-mm trocar at the right subcostal margin, a 5-mm inferior to the left upper quadrant 12-mm trocar, a 12-mm trocar in the right upper quadrant, and a 12-mm trocar in the upper abdominal midline). The omentum and transverse colon are retracted cephalad until the transverse colon mesentery is visualized. Anterior retraction of the mesentery allows visualization of the jejunum at the ligament of Trietz. The jejunum is then transected with a linear stapler loaded with a 60-mm–length cartridge containing variable staple sizes from 2.0 to 3.0 mm for medium-thickness tissue, approximately 40 cm to 75 cm distal to the ligament of Trietz. A long enough section of mesentery is usually found here so that the Roux limb can be placed in the antecolic antegastric position and safely reach the gastric pouch without any significant tension. The mesentery is divided with a linear stapler loaded with a 2.0-mm staple cartridge, and then the ultrasonic shears are used to extend this division as much as necessary so that the proximal Roux limb is able to safely reach the gastric pouch. A stay suture is placed on the proximal Roux limb, and then the bowel is run approximately 60 to 100 cm distal to the stapled off end. A stay suture is placed here to mark where the stapled side-to-side jejunojejunostomy will be constructed with the end of the biliopancreatic limb. The anastomosis is performed with a linear stapler loaded with a 60-mm–length cartridge containing variable staple sizes from 2.0 to 3.0 mm that is inserted through small enterotomies made with the ultrasonic shears below the stay suture (Figure 2). The enterotomy opening is then closed with firing of a similar linear stapler that has been placed under two stay sutures at each end of the opening (Figure 3). An unzippering stitch is placed in the crotch of the stapled anastomosis, and an antiobstruction stitch is placed to keep the Roux limb from kinking at the jejunojejunostomy. The mesenteric defect is then closed with a running suture. Clips or sutures are placed on the staple line if there is any bleeding. The greater omentum is divided in half with an ultrasonic dissector or vessel-sealing device along its entire length up to the border of the transverse colon.

Next, the patient is placed into steep reverse Trendelenburg's position. The legs and feet are then checked to ensure they are still straight and on the footboard. The left lateral segment of the liver is retracted with a Nathanson's retractor through a subxiphoid 4-mm puncture, which is then held in position with a movable arm that attaches to the operating room table (Iron Intern with Nathanson's liver retractors, Automated Medical Products Corp., Edison, NJ). The procedure then begins with dissecting the peritoneal attachments at the angle of His to expose the left crus, followed by the bare area of the gastrohepatic omentum to enter the lesser sac. Division of the neurovascular bundle on the lesser curvature side of the stomach just distal to the left gastric vein is done with a linear stapler with a

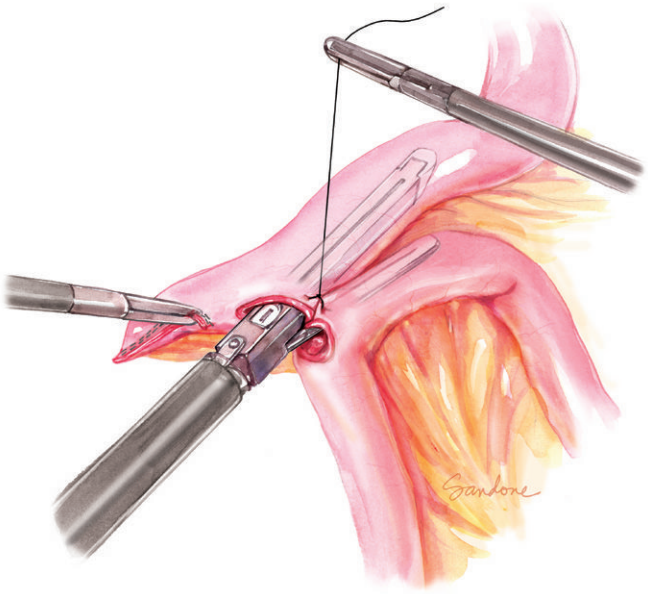

FIGURE 2 A linear stapler is used to create the jejunojejunostomy. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

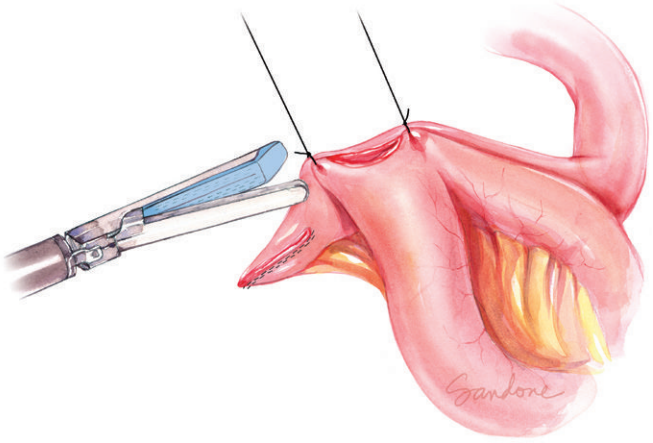

FIGURE 3 Closure of jejunojejunostomy opening. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

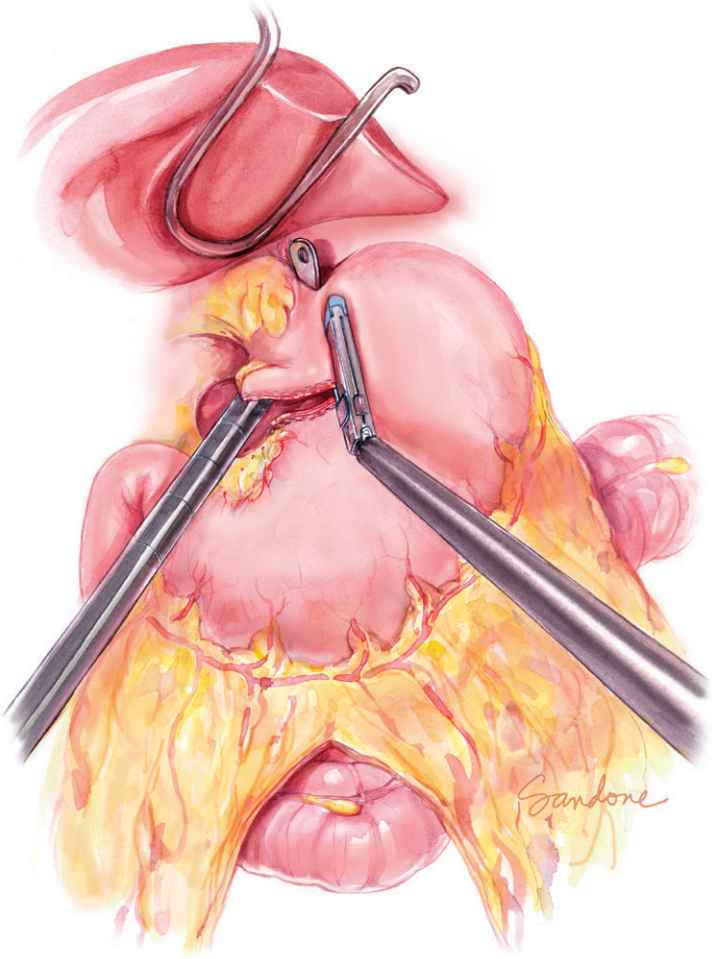

FIGURE 4 Stapled division of stomach. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

2.0-mm staple cartridge. Next, a linear stapler loaded with a 60-mm–length cartridge containing variable staple sizes from 3.0 to 4.0 mm is first used to divide the stomach, followed by successive firings of a linear stapler containing 60-mm–length cartridges with variable staple sizes from 2.0 to 3.0 mm. The first gastric staple transection is started on the lesser curve side just below the left gastric vein and is then followed by sequential stapling until completion at the angle of His so that the proximal gastric pouch created is 15 to 20 mL in size (Figure 4). It is important to retract the posterior fundus downward and bring the stapler around the tissue at the angle of His to avoid making a large fundal pouch. This is prevented by entering the open space of the lesser sac after the first stapled division of the stomach and then dissecting through to the angle of His with an articulating dissector instrument that can then lock in place after forming a right angle. The articulating dissector can then be used to retract the fundus inferiorly while stapling sequentially to the angle of His. The stomach staple lines on both sides should be inspected for adequate staple formation, bleeding, and ischemia. Bleeding staple lines are usually easily taken care of with a clip or direct suture ligation.

The Roux limb is brought up antecolic antegastric with care to avoid a twist in the mesentery. The Roux limb is then sutured to the gastric pouch staple line approximately where the first and second gastric staple lines intersect. A small enterotomy is made below the stay suture in the Roux limb and a similar size gastrotomy in the pouch to place the linear stapler loaded with a 45-mm–length cartridge containing variable staple sizes from 3.0 to 4.0 mm to create the gastrojejunostomy where only the first 30-mm of the staple cartridge are used (Figure 5). A stay suture is placed on the lesser curve (right) side of the opening; it is then used to retract the posterior part of the anastomosis to the left and anterior, thereby exposing the entire posterior side. A running 2-0 suture is then placed starting posterior on the left side and continuously run to the stay suture on the right side, which it is tied too (Figure 6). The anesthesia team carefully passes a 32F blunt round-end bougie from the mouth and then through the gastrojejunal anastomosis and into the Roux limb. A stay suture is placed at the halfway point of the opening between the end stay sutures. This stay suture and the stay suture on the left (angle of His side) are used to elevate the tissue so that the linear stapler loaded with a 60-mm–length cartridge containing variable staple sizes from 3.0 to 4.0 mm can be used to close the openings. The stapler is brought down on top of the bougie while retracting the tissue to be transected. This firing then closes most of the opening,

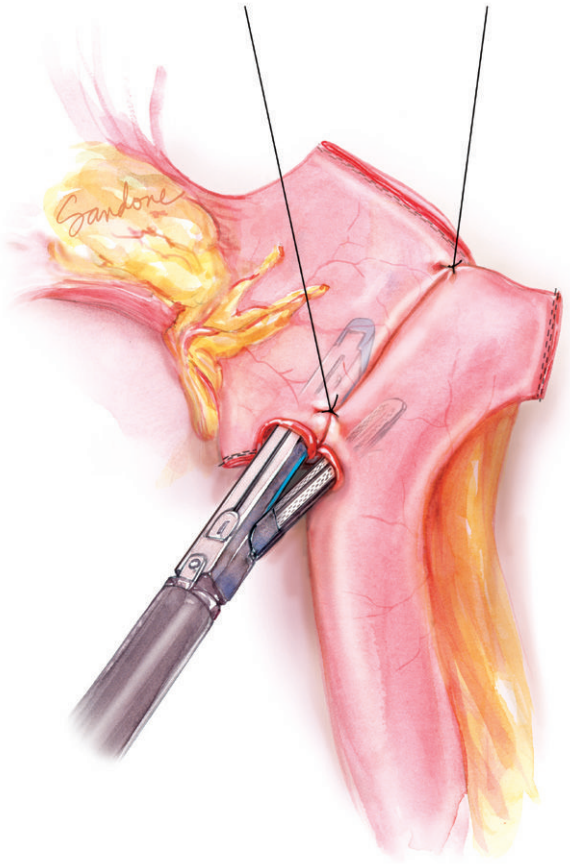

FIGURE 5 A linear stapler is used to create the gastrojejunostomy. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

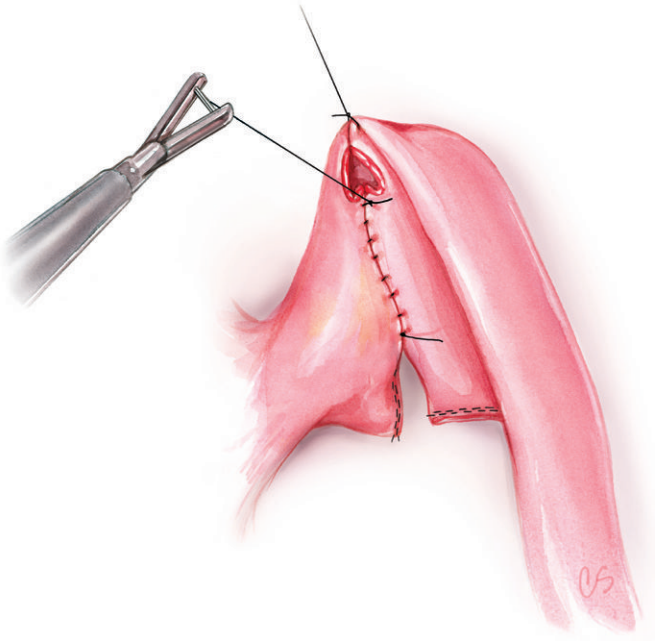

FIGURE 6 Reinforcing the posterior staple line of the gastrojejunostomy. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

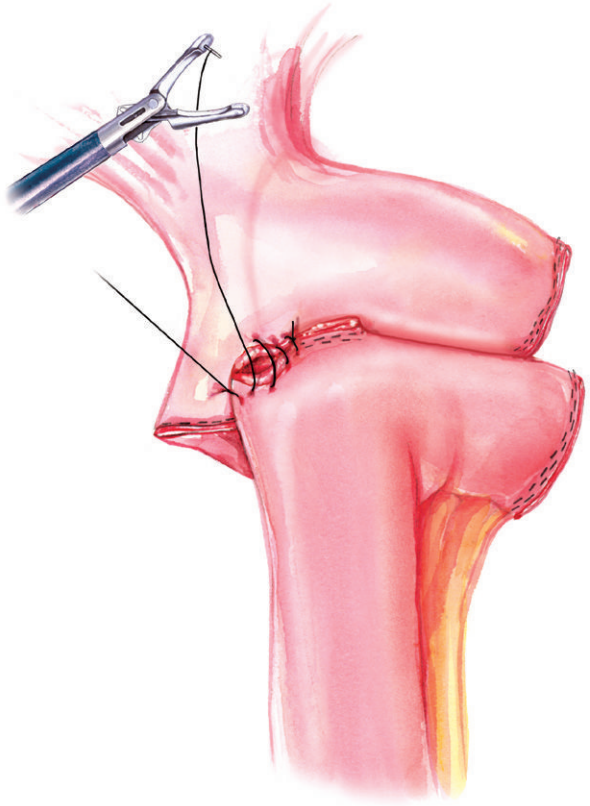

FIGURE 7 The opening used for the linear stapler is then closed with a running suture. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

and the small remaining defect on the right side is easily closed with a 2-0 suture (Figure 7). Alternatively, the entire opening could be closed with a running 2-0 suture. The gastrojejunal anastomosis is then completed by running a 2-0 suture to cover the entire anterior and lateral sides in a second layer. The resultant anastomosis is approximately 12 mm in diameter and has been completely encircled by multiple continuous running 2-0 suture. An air leak test can be performed if desired to test the gastrojejunal anastomosis.

The operating room table is taken out of steep reverse Trendelenburg's position, and the mesenteric defect is then closed between the Roux limb mesentery and the transverse mesocolon, up to the transverse colon with running 2-0 suture. This is to help prevent an internal hernia through Peterson's defect. The remaining jejunojejunostomy mesenteric defect is then closed with a running suture. A drain is placed in the left upper quadrant by the anastomosis, and the trocars are removed with direct vision. Long-acting local anesthetic is placed in the wound, and the sites are closed with an absorbable subcuticular suture and glue (Figure 8).

Laparoscopic Adjustable Gastric Band

The 45-degree angled viewing laparoscope is inserted, and an additional three trocars (a 12-mm trocar in the upper abdominal midline and two right upper quadrant 5-mm trocars) are placed with direct vision. The angle of His attachments are taken down with blunt dissection, and the gastrohepatic omentum in the bare area is divided with a hook electrocautery. The right crus is identified. After the hook cautery is used to divide peritoneal tissue, an articulating dissector is then placed from the right crus side to the angle of His, with gentle rotating side-to-side motion as it is advanced forward; it is then

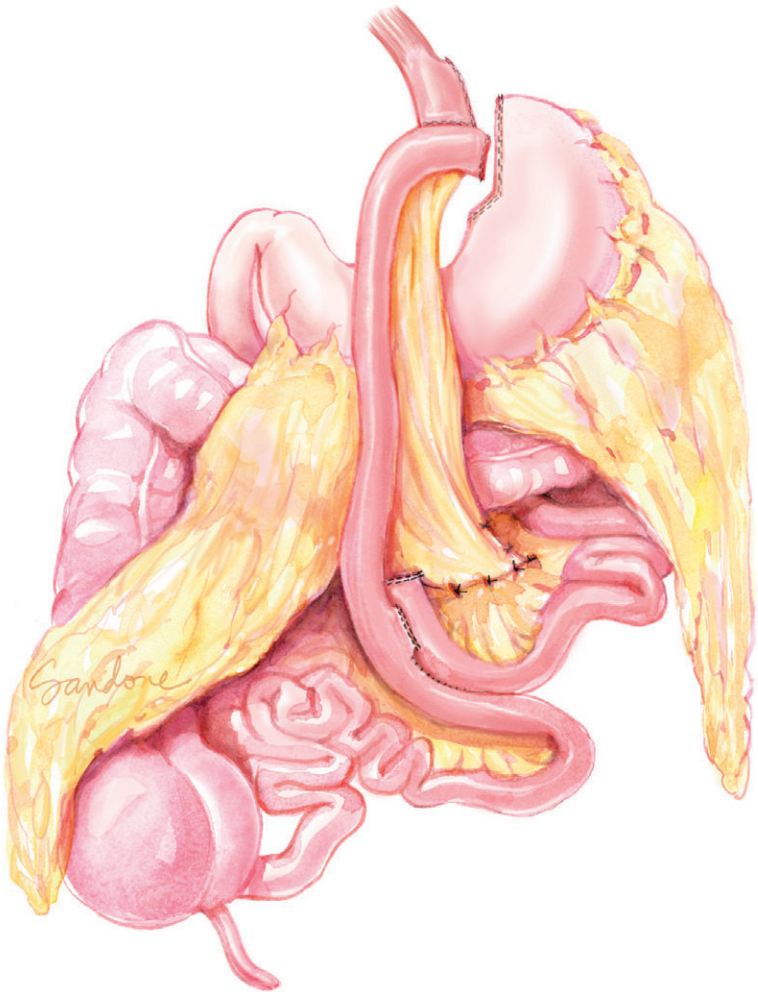

FIGURE 8 Antecolic antegastric Roux-en-Y gastric bypass. *(Illustration used with permission from Cameron JL, Sandone C: Atlas of gastrointestinal surgery, ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

flexed into a right angle and locked. The 12-mm left upper quadrant trocar is removed, and a 15-mm trocar is placed. The adjustable band is placed into the abdomen through the 15-mm trocar. The band tubing is then placed through the opening in the articulating dissector and then brought over to the right crus side (Figure 9). The tubing is removed from the dissector and then placed through the buckle of the band. The buckle is then locked. Next, one to four interrupted 2-0 nonabsorble sutures are placed from the fundus to the proximal stomach (superior to the band). It is easier to work closer to the angle of His side of the stomach and then sew towards the patient's right side (Figure 10). The buckle of the band should not be covered because of increased risk of erosion. The anterior fundal wrap over the band should be without tension. The tubing of the band is grasped and removed through the left upper quadrant trocar site. The trocars are then removed. A subcutaneous pocket is formed on the anterior side of the fascia, and the port is connected to the band tubing and then secured to the fascia. It is important to check the tubing and ensure it has no kinks as it enters the fascia. The site is irrigated, and then all the trocar sites are closed with subcuticular suture and glue (Figure 11).

Laparoscopic Vertical Sleeve Gastrectomy

Laparoscopic vertical sleeve gastrectomy was initially used as a first-stage operation in patients at high risk or in patients whose super morbid obesity made a laparoscopic-only approach difficult. After 12 to 24 months of weight loss, a second-stage operation could be used in those who were still at a high BMI and wanted to be revised to a laparoscopic Roux-en-Y gastric bypass or a laparoscopic duodenal switch with biliopancreatic diversion. This staged approach is designed to reduce operative risk by improving comorbidities and reducing the technical challenges associated with super morbidly obese patients. Recent data has shown that sleeve gastrectomy is an effective operation for weight loss, resulting in 40% to 60% excess body weight loss as the primary treatment alone. It is easier to perform and has less complications then a Roux-en-Y gastric bypass or duodenal switch with biliopancreatic diversion. It does not involve a large foreign body that can be at risk to erode or slip as with an adjustable gastric band. It also avoids the intestinal malabsorption and small bowel obstruction risks seen with gastric bypass or duodenal switch with biliopancreatic diversion.

As previously described, entry to the abdominal cavity starts with a 12-mm trocar placed with direct vision through a left upper quadrant incision. The abdomen is then insufflated with carbon dioxide to a pressure of 15 mm Hg, a 45-degree angled laparoscope is inserted and an additional three ports (a 5-mm trocar at the right subcostal margin, a 15-mm trocar in the right upper quadrant, and a 12-mm trocar just to the left of the upper abdominal midline) and a subxiphoid liver retractor are placed with direct vision. The operation starts with division of the stomach's greater curvature blood supply with a vessel-sealing device to divide the gastrocolic and gastrosplenic

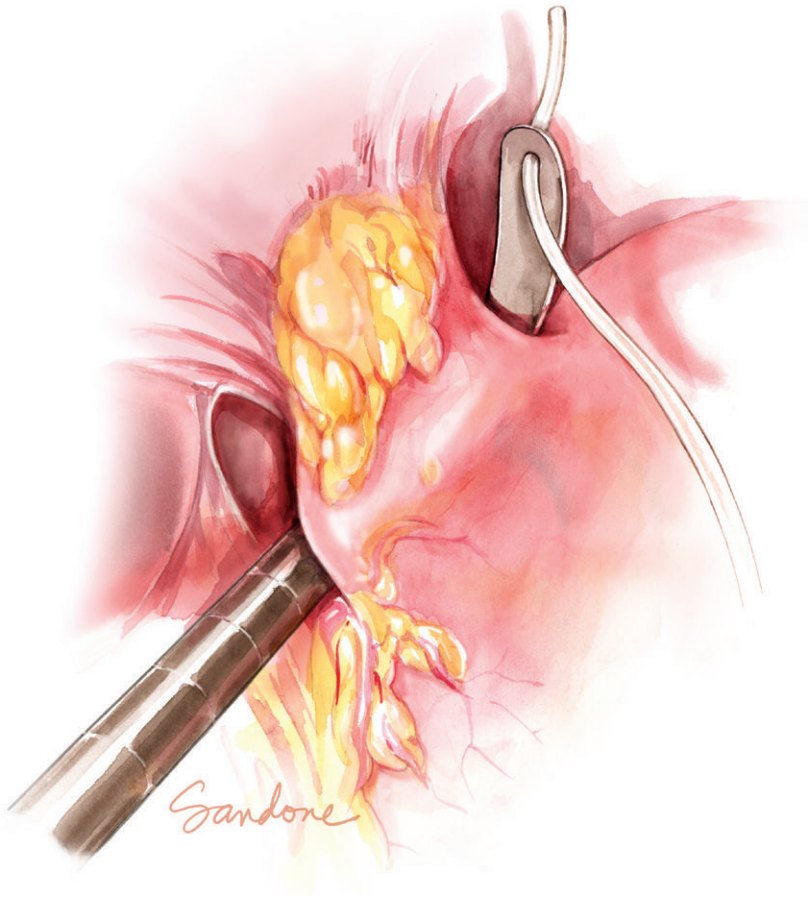

FIGURE 9 The band tubing attached to the articulating dissector is then brought around the posterior stomach, from patient's left to right side. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

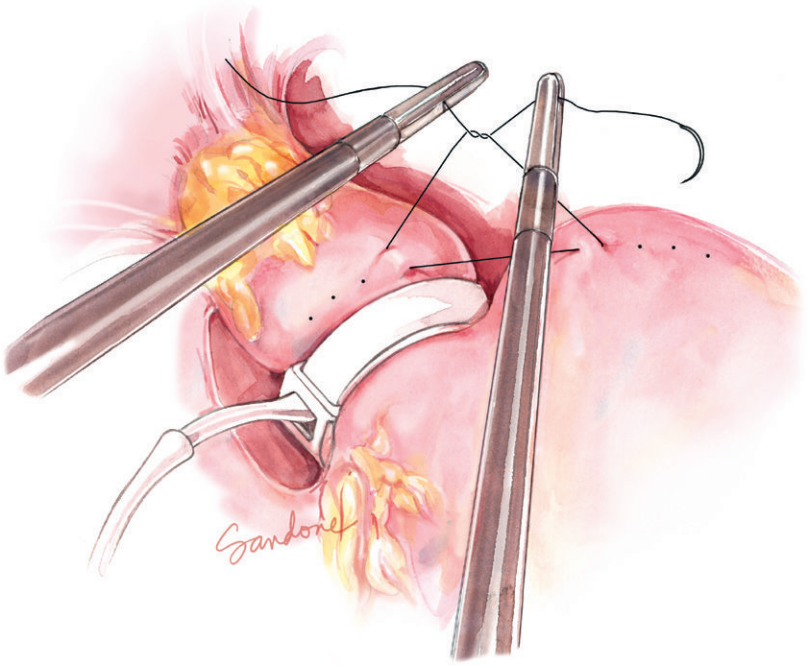

FIGURE 10 An anterior gastric wrap is performed with interrupted nonabsorbable sutures. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

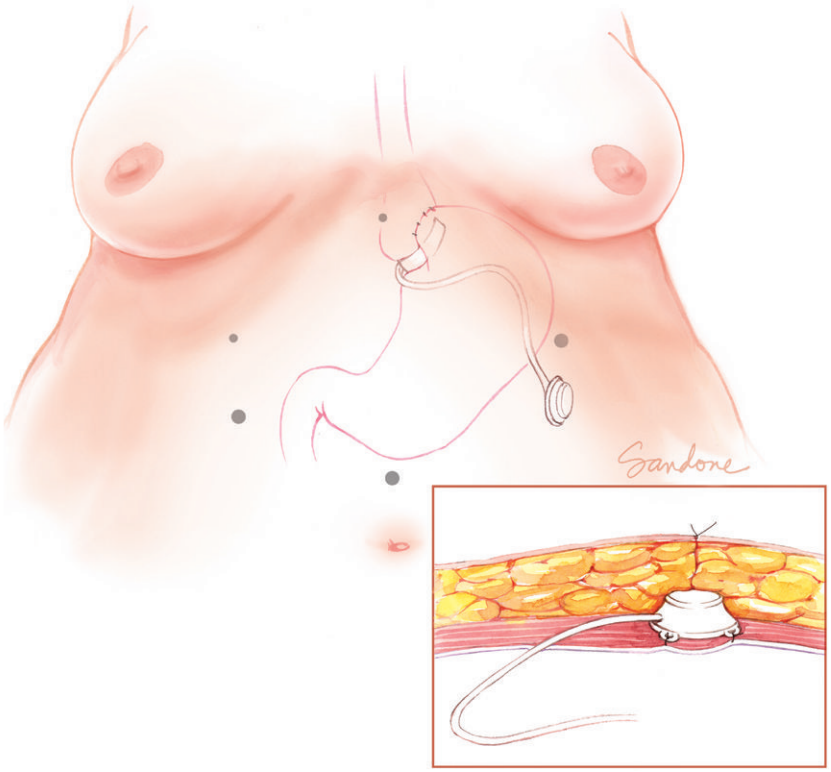

FIGURE 11 Adjustable gastric band with port placement in the left upper quadrant. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

ligaments close to the stomach (Figure 12). A stay suture is placed 6 to 7 cm from the pylorus-duodenal junction. A 40F bougie is inserted transorally and brought down alongside the lesser curve until it lays against the stomach wall to the patient's right of the stay suture. Next, a narrow gastric tube is created with a linear cutting stapler starting on the patient's right side of the stay suture and sequentially stapling towards the angle of His alongside a 40F bougie. The surgeons should confirm that the bougie is on the lesser curve side of the stapler.

The stomach is first divided with two firings of the linear stapler loaded with 60-mm–length cartridges containing variable staple sizes from 4.0 to 5.0 mm for extra thick tissue. The stomach is continued to be divided with a linear stapler loaded with 60-mm–length cartridges containing variable staple sizes from 3.0 to 4.0 mm. The stomach is divided next to the bougie all the way up to the angle of His where the lateral stomach is separated (Figure 13). Care is taken not to leave any fundus behind and not to apply the stapler too close to the gastroesophageal junction. Hemostasis of the gastric staple line can be secured with running sutures or clips. The resected stomach is extracted intact through the 15-mm trocar site, after widening the fascial opening with a clamp device. If the surgeon desires, the staple line can be evaluated with an underwater leak test either with an orogastric tube or an endoscope. A drain is placed in the left upper quadrant and brought out through the 5-mm trocar site. The ports are removed with direct vision after first closing the 15-mm port site suture passing device. Long-acting local anesthetic is placed in the wounds, and the sites are closed with subcuticular sutures (Figure 14).

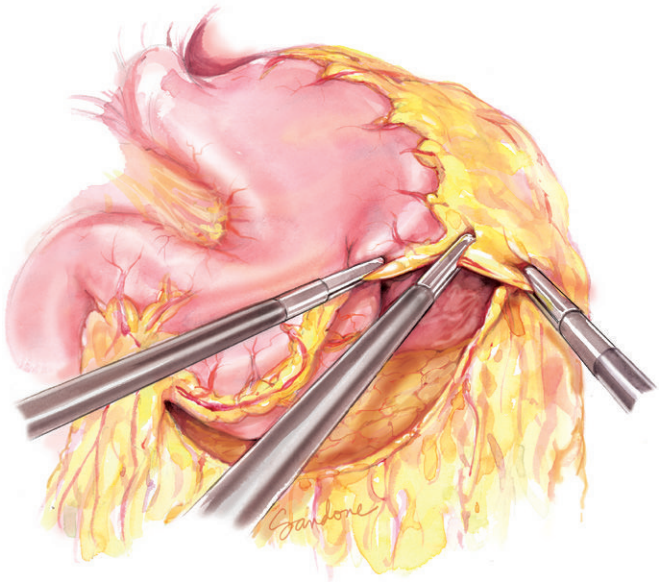

FIGURE 12 Division of the vascular supply next to the greater curvature of the stomach. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

Laparoscopic Biliopancreatic Diversion With Duodenal Switch

The laparoscopic duodenal switch with biliopancreatic diversion (DS-BPD) is primarily a malabsorptive operation that involves preservation of the gastric pylorus and creation of a short, 100-cm ileal "common channel," where food and biliopancreatic enzymes are allowed to mix. Because of the potential for malabsorption-related nutritional deficiencies and the complexity of the operation, DS-BPD is the least common bariatric operation performed in the United States when compared with gastric bypass, sleeve gastrectomy, and adjustable gastric banding.

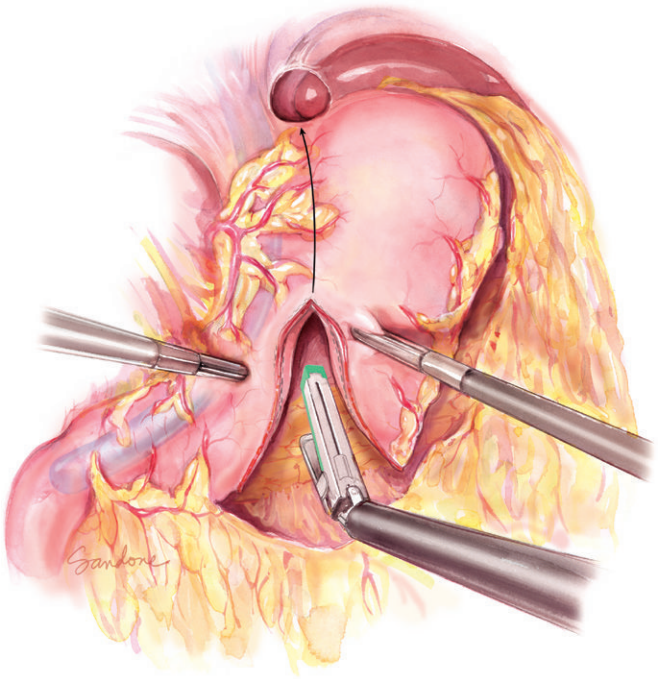

FIGURE 13 Linear stapler used to vertically divide the stomach close to the lesser curve. A 40F bougie is used to calibrate the size of the remaining stomach. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

FIGURE 14 Vertical sleeve gastrectomy. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

As previously described, entry to the abdominal cavity starts with a 12-mm trocar placed with direct vision through a left upper quadrant incision. The abdomen is then insufflated with carbon dioxide to a pressure of 15 mm Hg, a 45-degree angled laparoscope is inserted, and an additional four ports (a 5-mm trocar at the right subcostal margin, a 5-mm inferior to the left upper quadrant 12-mm trocar, a 15-mm trocar in the right upper quadrant, and a 12-mm trocar in the upper abdominal) and a subxiphoid liver retractor are placed with direct vision. The operating surgeon stands on the patient's left side for the small intestinal part of the operation, and the assistant on the right. The left-sided ports are the surgeon's operating ports for the ileoileostomy part of the procedure. The operating room table is then placed flat, and the omentum and transverse colon are retracted cephalad. The cecum and ileocecal valve are then identified, and the ileum is measured back 100 cm proximal to the cecum. A stay suture is placed, and then another 150 cm of ileum is measured proximal from the suture. This is where the ileum is transected with a linear stapler loaded with a 60-mm–length cartridge containing variable staple sizes from 2.0 to 3.0 mm. The mesentery is divided with the ultrasonic shears, and a stay suture is placed on the distal transected bowel to mark the Roux end that will connect to the duodenum. The proximal divided bowel is the biliopancreatic limb, which is brought down to the previous stay suture marking the ileum at 100 cm from the cecum. A stapled side-to-side ileoileostomy is then constructed. Care should be taken to avoid a twist or misalignment of the bowel at this point. The anastomosis is performed as the previously described enteroenterostomy in the gastric bypass section.

Next, the patient is placed in steep reverse Trendelenburg's position, and a liver retractor is placed in the subxiphoid position to retract the left lateral segment of the liver. As previously described, a sleeve gastrectomy is then performed, with a 48F instead of a 40F bougie, and then it is removed after completion. Attention is then turned toward the duodenum, which is freed from its lateral attachments, with great care taken to not injure any of the structures in the hepatoduodenal ligament. The duodenum is divided approximately 2 to 4 cm distal to the pylorus with a linear stapler loaded with a 60-mm–length cartridge containing variable staple sizes from 3.0 to 4.0 mm (Figure 15). The omentum is split, and the Roux limb is brought antecolic up to the proximal duodenal end. Two stay sutures are placed for a side-to-side anastomosis. Under the inferior stay suture, both ends are opened and a linear stapler loaded with a 45-mm–length cartridge containing variable staple sizes from 3.0 to 4.0 mm is placed for 2.5 to 3 cm and fired (Figure 16). A 40F bougie is placed through the anastomosis. The opening is now closed with a running suture. Multiple seromuscular interrupted sutures are placed circumferentially. The mesenteric defect is then closed between the Roux limb mesentery and the transverse mesocolon, up to the transverse colon. A drain is left by the stomach, and another drain is left by the ileoduodenal anastomosis. The trocars are removed, and local anesthetic is injected, followed by a subcuticular closure of the trocar sites (Figure 17).

Laparoscopic Gastric Plication

Laparoscopic gastric greater curvature plication is an emerging restrictive bariatric procedure that successfully reduces the gastric volume with plication of the gastric greater curvature. Its main advantages are the reversibility of the technique, no staple line needed, and no foreign body. Currently, it is under investigational protocol at several institutions in the United States. The procedure consists of separating the greater omentum and attachments of the spleen from the greater curvature of the stomach. The anesthesiologist places a bougie into the stomach or a flexible endoscope may be used in its place. The surgeon then starts inverting the stomach 2 cm from the angle of His on the greater curvature side with either running or interrupted sutures to approximately 5 to 6 cm from the pylorus. A second row of sutures are usually placed to further fold the stomach inward and create more restriction. Current studies have shown short-term efficacy in weight reduction. However, further studies are needed to determine long-term efficacy and safety because the rates of complications may increase over time along with weight regain. Acute gastric perforation, leak at the suture line, obstruction, and intussusception are all possible complications.

POSTOPERATIVE MANAGEMENT

Most patients are transferred after routine monitoring in the recovery room. Patients with moderate to severe obstructive sleep apnea are prescribed (CPAP [continuous positive airway pressure]) during

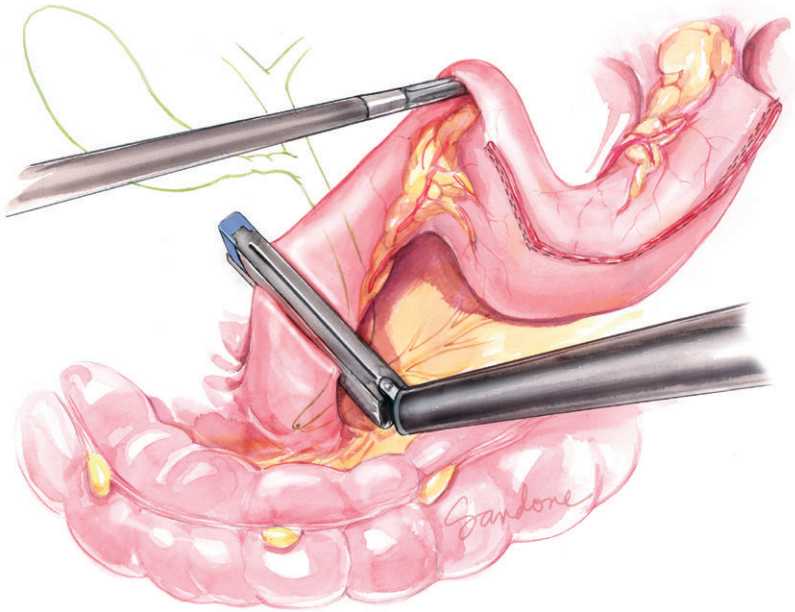

FIGURE 15 The duodenum is divided with a linear stapler. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

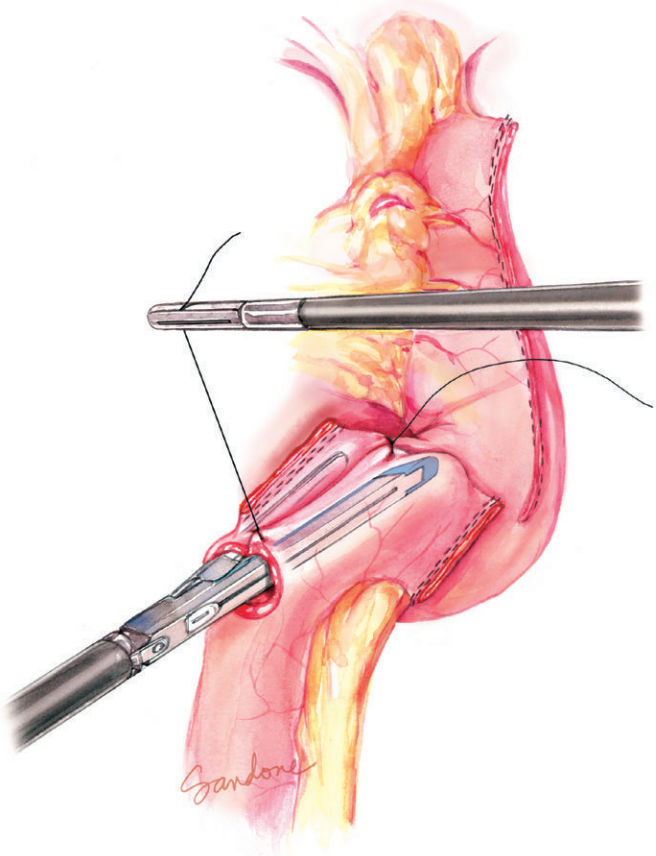

FIGURE 16 The duodenoileostomy is created with a linear stapler. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

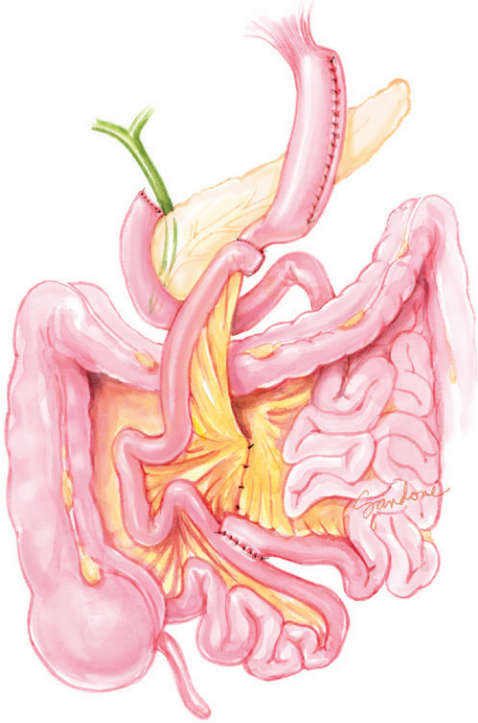

FIGURE 17 Antecolic duodenal switch with biliopancreatic diversion. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, Shelton, CT, in press, PMPH-USA.)*

sleep, if they are able to tolerate it or use it routinely at home. Low molecular-weight heparin is continued during hospitalization for most patients, and some patients who are at higher risk for venous thromboembolism may be treated at home for an entire month after surgery. The patient is usually in a chair or ambulating within the first 12 hours. Pain is managed with a patient-controlled analgesia delivery device for the first evening, and the patient is encouraged to use the incentive spirometer while awake.

Patients for adjustable gastric band are given a liquid diet the following morning and then discharged to home. Patients for gastric bypass and duodenal switch are started on a limited liquid diet on postoperative day 1, and then the quantity of liquids is advanced as tolerated on day 2 with discharge planned that day. Patients for sleeve gastrectomy are given a nonsugar liquid diet on postoperative day 1

and usually advanced over the course of the day, with an aim to discharge that day or the following morning. Patients after all four operations remain on a nonsugar noncarbonated liquid diet that includes protein drinks for the first week after surgery. They are then advanced to a puree diet that still includes protein drinks for the following 3 weeks, at which time they start to introduce solid foods. Selective upper gastrointestinal series radiography is used in patients who have a sustained heart rate over 120 bpm, respiratory distress, fever, increasing abdominal pain or chest pain. The drain is removed before discharge.

Follow-up is in 2 weeks for all patients. Patients are highly encouraged to go to monthly support group meeting and see the dietitian on a routine basis, along with a mental health professional if needed or requested.

Patients for adjustable gastric band are evaluated for their first fill at the 6-week postoperative appointment. Patients who, despite making healthy food choices, have stopped losing weight, who report no "restriction" with solid foods, and who are consistently hungry in between meals get a fill. Patients are then asked to follow-up in 2 months. Band position and tightness can be assessed with fluoroscopy if necessary in patients who, despite repeated fills, continue to have no restriction. Patients who report continued vomiting, abdominal pain, or severe gastroesophageal reflux disease (GERD)–like symptoms should also be evaluated with an upper gastrointestinal fluoroscopic study.

All patients are placed on a multivitamin and calcium after surgery. Menstruating women are placed on iron to prevent anemia. Patients for gastric bypass are recommended to take vitamin B_{12}, and patients for duodenal switch with biliopancreatic diversion are advised to take supplements that include the fat-soluble vitamins A, D, E, and K. Patients who have not had their gallbladder previously removed are placed on ursodiol 300 mg twice a day for 6 months to reduce the risk of symptomatic cholelithiasis during the rapid weight loss phase after gastric bypass, sleeve gastrectomy, or DS-BPD surgery. Follow-up is usually around 3, 6, 12, 18, and 24 months, followed by every year thereafter. An iron panel and hematologic, electrolyte, and liver function laboratory tests are obtained at 3 months, and vitamin B_{12} 25-hydroxy vitamin D and PTH levels, are added at 1-year visits. Patients who are not taking in enough protein by diet history may need prealbumin checked along with nutritional counseling. Patients for DS-BPD may also need the additional vitamins A, E, and K tested for after surgery.

OUTCOMES AND COMPLICATIONS

Buchwald and colleagues conducted a meta-analysis of the bariatric literature in 2003. They found that mean excess weight losses for adjustable gastric band, Roux-en-Y gastric bypass, and biliopancreatic diversion with or without duodenal switch were 48%, 62%, and 70%, respectively. Mortality rates were 0.1%, 0.5%, and 1.1%, respectively, for the three operations. Type II diabetes was found overall to be completely resolved in 77% of patients and improved in an additional 9% of patients. Hyperlipidemia, hypertension, and obstructive sleep apnea were improved in 70%, 79%, and 84%, respectively. Schauer and associates showed in a randomized prospective trial that obese patients with uncontrolled type II diabetes had significant improvement in glycemic control after both Roux-en-Y gastric bypass and sleeve gastrectomy compared with medical therapy alone. The mean glycated hemoglobin was 9.2% before the study; after 12 months, the mean decreased to 7.5% in the medical therapy alone group, 6.4% in the gastric bypass group ($P < 0.001$), and 6.6% in the sleeve gastrectomy group ($P = 0.003$). Patient weight loss was only −5.4 kg in the medical therapy group as compared with the gastric bypass and sleeve gastrectomy groups (−29.4 kg and −25.1 kg, respectively; $P < 0.001$) at 12 months follow-up. In a large retrospective cohort study comparing bariatric surgery patients matched with morbidly obese patients who did not undergo surgery, Adams and colleagues found a 40% reduction in mortality rate after 7.1 years with the surgery group. The significant decrease in the long-term mortality rate was attributed to a decrease in coronary artery disease, type II diabetes, and cancer-related deaths.

Pulmonary embolism and sepsis from an anastomotic leak are the two leading causes of death in the postoperative period after bariatric surgery. Both complications are less than 1% at most bariatric surgery centers that are part of the American College of Surgeons Bariatric Surgery Center Network Accreditation program. Perioperative measures to reduce the risk include: chemoprophylaxis, sequential compression devices (if they can safely fit the patient's lower extremity), and early ambulation. Some centers go beyond the routine in-hospital prophylaxis by placing patients who may be at higher risk for venous thromboembolism on low molecular-weight heparin anywhere from 10 days to a month after discharge from the hospital. These patients may include those who have a history of pulmonary embolism or deep venous thrombosis, poor ambulation, severe venous stasis disease, and possibly a BMI of more than 70 kg/m^2. Inferior vena cava filters are also used in some select patients who may be at higher risk for death from pulmonary embolism. It is unclear to date whether these extra measures used to prevent venous thromboembolism (VTE) are helpful because no randomized trials specifically address the morbid obese patient population that undergoes bariatric surgery.

Prevention of a leak is one of the primary ways to decrease mortality after bariatric surgery. The most common area for a leak to occur after gastric bypass is at the gastrojejunostomy. However, a leak may also occur at the distal stomach staple line or the jejunojejunostomy. There are several ways of performing the upper anastomosis of a GBP or DS-BPD that include circular stapler, linear stapler, hand-sewn, and a combination of stapling with an outer layer of suturing. This may account for variation in the reported rates of a leak, stomal stenosis, and marginal ulcer. At Johns Hopkins, the laparoscopic Roux-en-Y gastric bypass leak rate is less than 0.3% with the previously described technique that has an inner stapled layer and essentially an outer layer consisting of multiple running sutures.

Box 6 shows the published complication rate after laparoscopic gastric bypass. The authors have used an antecolic antegastric technique for more than 7 years, which has reduced the internal hernia rates to less than 2%. The authors continue to close the defect between the transverse mesocolon and the Roux limb mesentery up to the transverse colon along with the enteroenterostomy defect in both the gastric bypass and the DS-BPD operations. Stomal stenosis after gastric bypass most commonly occurs between 2 to 6 weeks after surgery but occasionally may be seen later in conjunction with a marginal ulcer. Greater than 90% of these patients respond to balloon dilation; however, late-occurring strictures are less likely to heal and may require revision of the gastrojejunostomy with or without a truncal vagotomy. A marginal ulcer after gastric bypass can occur on the jejunal side of the gastrojejunal anastomosis, and again, greater than 90% heal with proton pump inhibitor therapy. Patients should

BOX 6: Complications for 251 cases

Stomal stenosis: 10 (4%)
Marginal ulcer: 11 (4%)
Symptomatic gallstones: 8 (3%)
Internal hernia: 4 (2%)
Postoperative bleeding: 5 (2%)
Stroke (minor): 1 (0.4%)
Trocar hernia: 0 (0)
Deep venous thrombosis: 0 (0)
Pulmonary emboli: 0(0)
Wound infection: 0 (0)
Leaks: 0 (0%)
Death: 1 (0.4%)

be asked if they are smoking, using nonsteroidal antiinflammatory drugs (NSAIDs), or drinking large quantities of caffeinated drinks (coffee, tea, etc.) because these have all been attributed with marginal ulceration. The most common location of a stricture seen after sleeve gastrectomy is at the incisura angularis. These strictures may respond to balloon dilation, otherwise a revision to a gastrojejunostomy proximal to the stricture may be needed.

The laparoscopic adjustable gastric band (LAGB) operation has a lower 30-day major complication rate when compared with gastric bypass, sleeve gastrectomy, and DS-BPD. However, long-term complications after LAGB appear to be higher, with rates above 20%. Cottam and colleagues in a case-controlled matched-pair cohort study showed excess weight loss is greater after gastric bypass when compared with LAGB (74% vs 51%, respectively; $P < 0.001$) at 3 years. Type II diabetes resolved more frequently after gastric bypass (78% vs 50%, respectively; $P = 0.01$). The most common complications after LAGB are port/tubing breakage, flipped port, gastric prolapse or band slippage, and GERD. Gastric prolapse or band slippage entails cephalad herniation of the stomach through the band, resulting in a larger pouch and, in some cases, near or total gastric outlet obstruction. Erosion of the band into the stomach lumen is a complication reported in ~1% of cases and requires removal of the band. Infection of the band system is also seen in ~1% of cases and again requires removal. GERD symptoms that develop when inflating the band with saline solution to increase restriction may require removal of the some or all of the fluid. Patients who have an obvious hiatal hernia at the time of surgery may benefit from a crural repair at the time of gastric band placement.

ENDOSCOPIC APPROACHES TO THE MANAGEMENT OF OBESITY

Transoral endoluminal interventions performed entirely through the gastrointestinal tract with flexible endoscopy offer the potential for an ambulatory weight loss procedure without any incisions on the abdominal wall. The restrictive procedures include intragastric balloon treatment, endoluminal sutured gastroplasty, and transoral stapled gastroplasty. The malabsorptive procedures include duodenojejunal bypass sleeve and gastroduodenojejunal bypass sleeve. Other procedures that have been performed with varying degrees of short-term success include intragastric injection of botulinum toxin type A and gastric electrical stimulation.

The most widely studied of these therapies is the intragastric balloon. Although this device is currently not FDA approved for use in the United States, it has been used in Europe, Canada, Mexico, India, and South America with adequate short-term results. The most common complication is nausea and vomiting, but more serious complications, such as gastric erosions, ulcerations, and bowel obstructions, have been noted. There are ongoing trials looking at the use of flexible endoscopically guided staplers or suture devices to create a gastric sleeve along the lesser curvature of the stomach. Flexible endoscopic suturing devices have also been used to reduce the size of the stoma and gastric pouch in patients who have had weight regain after gastric bypass. Unfortunately, long-term weight loss has not been proven with these devices.

Malabsorptive procedures, such as the duodenojejunal bypass sleeve, use a prosthetic barrier device that intraluminally bypasses the necessary areas of absorption in the duodenum and the upper part of the jejunum. A gastroduodenojejunal bypass sleeve has also shown promise in very short-term results with regards to weight loss and glycemic control. Long-term results and safety profile studies are needed with these devices.

Endoscopic therapy for weight loss is in its infancy; newer therapies are constantly being introduced and tested. If appropriate efficacy and safety profiles can be established, these products may be introduced into the clinical mainstream practice.

COMMENTS

Bariatric surgery continues to be the only effective means of producing weight loss in most patients. It has been shown to reduce or even eliminate comorbidities associated with a high BMI. Mortality and leak rates less than 1% have been published by several leading surgical centers committed to bariatric surgery. Laparoscopic techniques have been shown in randomized prospective studies over open approaches to significantly reduce perioperative wound complications and incisional hernias. Appropriate attention to the risks and benefits of the procedure along with the individual patient's medical risks requires consultation and joint decision making between the physician and the patient. Center of excellence certification programs are collecting outcome data that will not only help to document in the future the beneficial long-term effects of bariatric surgery but will also define acceptable outcomes and complication rates.

Laparoscopic Donor Nephrectomy

Dorry Segev, MD, PhD

Once the patients and the team decided to proceed with the transplant, an extra professional burden falls on the surgeon performing the donor nephrectomy because his patient is expected to survive normally.

Joseph Murray, MD, Nobel Lecture, December 8, 1990

OVERVIEW

Every year since 2000, approximately 6000 healthy individuals in the United States undergo uninephrectomy for the purposes of kidney donation to a family member, a friend, or even a stranger. This rate has doubled since 1995 (Figure 1), the year the laparoscopic donor nephrectomy was developed and first described by Ratner and colleagues (1995) at Johns Hopkins Medical Center. At this point, nearly all donor nephrectomies in this country are performed laparoscopically, either through traditional (pure) laparoscopy or hand-assisted techniques (Figure 2). Although the significant increase in live donor kidney transplantation between 1995 and 2000 was probably inspired by the decrease in the problems of a minimally invasive approach (pain, scar, duration of convalescence), risks are still associated with this operation, and minimizing and understanding these risks remain high priorities for the transplant community.

To help clinicians better understand the laparoscopic donor nephrectomy, this chapter explores the evaluation of the live kidney donor, contraindications to donation, the intraoperative approach, and postoperative management. Short-term risks are discussed, as are what are known and unknown about long-term risk.

EVALUATION OF THE LIVE KIDNEY DONOR

In general, live kidney donors should be both physically and mentally well, with adequate social and financial support. A thorough, careful medical history is obtained, and donors undergo physical examination, laboratory screening, and radiographic assessment. Creatinine clearance is determined, urinalysis and culture are examined, complete blood cell count and chemistry profiles are obtained, and screening for infectious diseases (including cytomegalovirus [CMV], Epstein-Barr virus [EBV], varicella-zoster virus [VZV], human immunodeficiency virus [HIV], syphilis, hepatitis, and tuberculosis) is performed.

Transplantation centers often conduct the evaluation in various phases to save donor candidates the cost and burden of additional testing if they are excluded in an earlier phase. Donors who pass early screening tests eventually undergo in-person consultation by a nephrologist, a surgeon, a psychologist or psychiatrist, a nurse coordinator, a social worker, and an independent living donor advocate. Later phase screening might include mammography, cardiac evaluation such as echocardiography or stress testing, pulmonary testing, colonoscopy, Papanicolaou smear, or prostate-specific antigen measurement (PSA).

All donors undergo abdominal imaging to confirm the presence of two kidneys and map the hilar anatomy; although it is unusual for a donor to be excluded on the basis of vascular abnormalities, this does occur on occasion, but of more importance is that a preoperative understanding of the vascular anatomy can assist with choice of kidney, as well as of the intraoperative approach. The left kidney is commonly the kidney of choice, because of its longer renal vein and lack of proximity to the liver, unless abnormalities or other inequalities between the kidneys exist.

CONTRAINDICATIONS

Age of younger than 18 years is considered a contraindication to donation in almost all cases. Diabetes mellitus, significant cardiac disease, and vascular disease are also considered absolute contraindications, as are most active malignancies. HIV infection is an exclusion criterion currently dictated by congressional law, in addition to the potential risk of HIV-related renal disease. Active infection is generally a contraindication, particularly if systemic. Untreatable psychiatric illness, active substance abuse, and severe neurologic deficits are also contraindications. Debated contraindications include decreased creatinine clearance, insulin resistance, obesity, and hypertension; the level for exclusion varies among transplantation centers, and some centers have written extensive protocols for evaluating, approving, and monitoring donors with these conditions.

OPERATIVE APPROACH

The patient is positioned in a modified lateral decubitus position, with the ipsilateral side (the side of the kidney intended for donation) upward. A periumbilical camera port, a subxyphoid operating port, and a left lateral operating port are placed. Pfannenstiel's incision, 6 to 8 cm long, is also made for eventual extraction; until then, the fascial incision is limited to a single port, and a retractor is placed through this site for medial retraction of the colon throughout the operation. A left nephrectomy is usually performed inasmuch as the left kidney is preferred (all other things equal) because of its longer vein. The right nephrectomy is performed in a very similar manner, in mirror image; an additional upper-abdominal port is often needed for liver retraction.

Dissection begins with medial reflection of the descending colon to the left margin of the aorta. As this reflection progresses, the elements of the hilum are visualized, including the renal vein, the gonadal vein, and the ureter. Keeping the mesoureter intact, so as to avoid devascularizing the ureter, the surgeon creates a plane between the ureteral pedicle (including the ureter, the mesoureter, and the gonadal vein) and the psoas muscle. This plane proceeds along the lateral margin of the aorta from the caudalmost extent of the dissection, usually where the ureter crosses the psoas muscle, in a cephalad manner towards the hilum; the ureteral pedicle is elevated during this process to assist in defining this plane. As the dissection approaches the renal vessels, small lumbar tributaries to the renal vein are occasionally encountered and must be ligated carefully.

Hilar dissection includes definition of the renal vein, ligation of the adrenal vein, definition of the renal artery to its base, and division of the periaortic tissue between the renal vein and artery (Figure 3). This is usually accomplished as listed, although anatomic variations are common and may require a different order of operations; gentle anterior retraction of the vein is often required to visualize the artery. Once the hilum is carefully dissected, the upper pole of the kidney is separated from the adrenal gland; it is important to carefully define the extrarenal route of the artery to protect it from injury during this upper pole dissection. Continuing cephalad, the surgeon divides the splenorenal ligament, following the plane along the upper pole of the

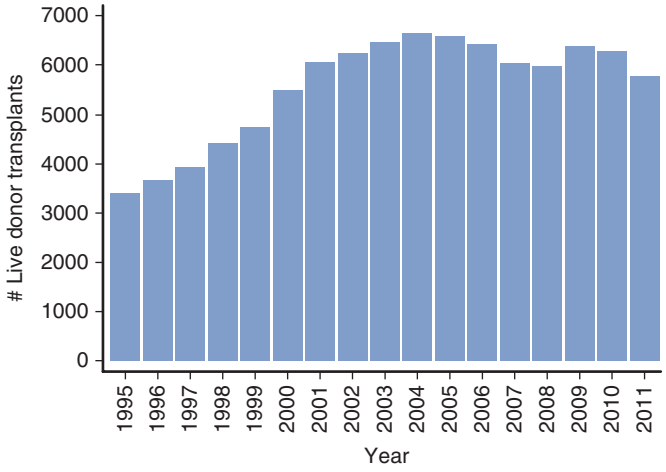

FIGURE 1 Number of live donor kidney transplantations in the United States, by year. *(Data from the Organ Procurement and Transplantation Network.)*

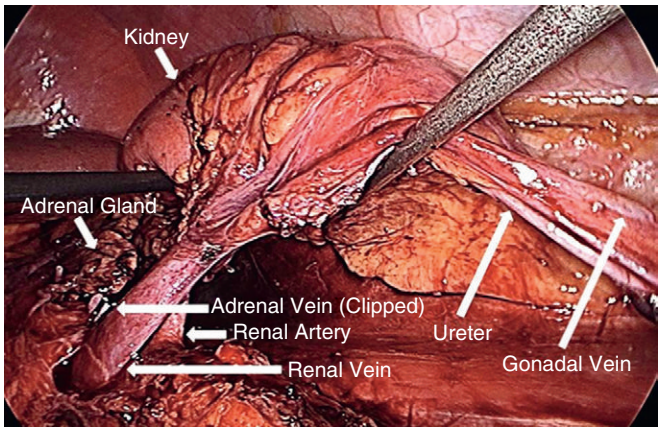

FIGURE 3 Hilar anatomy of the left kidney during a laparoscopic donor nephrectomy.

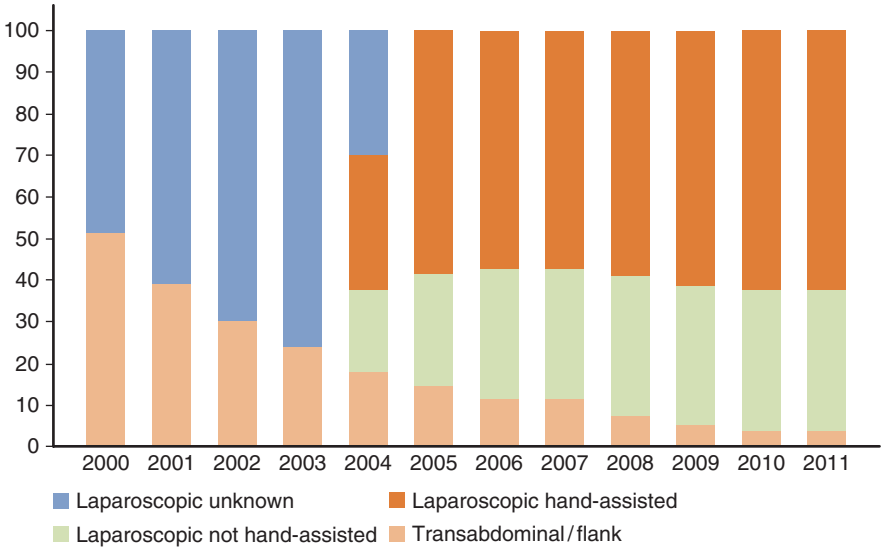

FIGURE 2 Percentage of donor nephrectomies in the United States performed laparoscopically, by year. *(Data from the Organ Procurement and Transplantation Network.)*

kidney to avoid injury to nearby structures such as the pancreas and spleen.

If the donor operation is coordinated with a recipient room, the donor operation typically does not proceed beyond this point until there is confirmation of safe induction of anesthesia in the recipient or identification of appropriate arterial and venous conduits for the allograft. Furosemide and mannitol are administered to the donor, the ureter and gonadal vein are divided distally, and the kidney is separated from its posterolateral attachments. After the surgeon verifies that the kidney remains attached by only the renal artery and vein, heparin is administered to the donor. The Endo Catch bag is placed through Pfannenstiel's incision, and the camera is moved from the periumbilical port to the lateral port to facilitate the appropriate angle for the endovascular stapler. To remove the kidney through Pfannenstiel's incision, the fascia are further opened to accommodate the kidney in the Endo Catch bag. Protamine is administered, and the kidney is removed for backtable flushing. After the fascia are closed, the abdomen is reinsufflated to confirm hemostasis and integrity of nearby structures, including the spleen and mesocolon.

An alternative approach, the Hopkins group has reported vaginal extraction of the kidney for donation. In lieu of extraction through Pfannenstiel's incision, a transverse posterior colpotomy at the apex of the posterior fornix is used, leaving the donor with only port sites.

It is absolutely imperative to control the renal artery by using a tissue transfixion technique such as suture ligation or staples anchored within the vessel wall. The use of nontransfixing devices (such as the Hem-o-lok clip) has been associated with fatal hemorrhagic complications because these devices, not anchored to the vessel wall, can dislodge. In spite of a class II recall by the U.S. Food and Drug Administration, there is evidence that these clips are still in use, which puts live kidney donors, and the entire practice of live donor kidney transplantation, at avoidable and unnecessary risk.

POSTOPERATIVE MANAGEMENT

The usual length of a hospital stay after live donor nephrectomy is approximately 2 days. Most postoperative management is relatively self-evident and consistent with management of other abdominal operations that do not involve entry into a hollow viscus. It is prudent to measure the donor's hemoglobin on the first postoperative day, in view of the location of the dissection and the intraoperative heparinization, as well as the creatinine level, which is expected to rise

about 50%. In general, donors who do not experience complications are seen for one in-person postoperative outpatient visit and are otherwise monitored by phone unless otherwise necessary. Interval reporting of donor follow-up to the Organ Procurement and Transplantation Network is required throughout the first 2 years after donation.

RISKS

The main operative risks arise from the transabdominal nature of the operation, including damage to abdominal viscera, particularly those near the kidney. Because major tributaries of the venae cavae and aorta are dissected and ligated, bleeding can be profuse on rare occasion. In a study of more than 80,000 living kidney donors, (Segev et al., 2010) the risk of perioperative death was estimated to be 3.1 per 10,000 donors (95% confidence interval: 2.0 to 4.6); although this incidence is extremely low, the potential of death from this operation is not treated lightly, inasmuch as the donor undergoing the operation gains no direct medical benefit from doing so.

The greater worry is the long-term risk after kidney donation. The risk of death over the long term does not seem to be higher in persons who donated a kidney than in healthy nondonor controls, regardless of age; however, many questions remain regarding risk of long-term medical sequelae attributable to donation. Unfortunately, most studies lack an appropriate nondonor comparison group, and so most of the available evidence is limited to studies of donors versus other donors. For example, there is strong evidence that African American donors have a higher incidence of postdonation hypertension, diabetes, and kidney disease.

CONCLUSION

On the basis of currently available data, it seems reasonable for a healthy individual to undergo nephrectomy for the purposes of kidney donation, if the individual is carefully screened and approved by a transplantation center. Most donor operations are performed laparoscopically, either with hand assistance or, as described in this chapter, with pure laparoscopic techniques. Risk remains low, although it is not fully quantified because of limitations in research and follow-up of donors, as well as the relatively short history of this operation. Efforts to increase live donation in response to the worsening organ shortage are ongoing, in parallel with efforts to understand and minimize postdonation risk.

Laparoendoscopic Single-Site Surgery as an Evolving Surgical Approach

John C. LaMattina, MD and Rolf N. Barth, MD

The ability to consolidate multiple laparoscopic port and specimen extraction sites within one incision hidden within the umbilicus provides the impetus for utilizing a single-port approach in surgery. The benefits of improved cosmetic outcomes have been tempered by the learning curve and potential risks associated with adopting a new and potentially more difficult technique. Nonetheless, the availability of multiple single-port devices has allowed for application and progressive experience in general surgery, urology, and gynecology (Table 1).

Single-port laparoscopy has been referred to by a number of terms, some of which are proprietary. Current consensus statements have supported preference for the term laparoendoscopic single-site (LESS) surgery. However, other terms are utilized in both academic literature and commercial marketing. These include single-site laparoscopy (SSL), single-port laparoscopy (SPL), single-incision laparoscopic surgery (SILS), and embryonic natural-orifice transumbilical endoscopic surgery (e-NOTES). It is important to recognize that these descriptors refer to a common technical approach. Most single-port procedures are performed through a transumbilical approach.

TRAINING AND LEARNING CURVE

A multidisciplinary international consortium met in 2008 to create recommendations for the emerging technology of single-port laparoscopy. The consortium's statement supported stepwise training for LESS surgery, including inanimate trainers, training on animals, observation, and mentoring/proctoring. The importance of patient safety in applying this technology was highlighted, and a specific statement was included to encourage the use of accessory 2-mm needlescopic ports to assist with the surgical procedure. The accessory needlescopic site is most beneficial during the learning curve in utilizing single-port surgery.

The authors' experience introducing this technique for donor nephrectomy in 2009 followed a similar approach of observation and mentorship, use of animal models, and proctoring. Of importance is that they maintained an extremely low threshold for additional port placement if progress slowed or technical difficulties were encountered. One reasonable approach for learning the single-port technique is progressive port minimization during the learning curve, with decreased use and number of additional ports as expertise with the LESS technique is obtained. The authors utilized the needlescopic ports in the majority of early cases (first 50) and required needlescopic or additional ports in fewer than 10% of subsequent cases. After the initial 25 cases, there was no statistical difference between LESS donor nephrectomy times and the times of historic controls.

TABLE 1: Identified current laparoendoscopic single-site (LESS) procedures in various surgical specialties*

High-volume procedures	Intermediate-volume procedures	Low-volume procedures

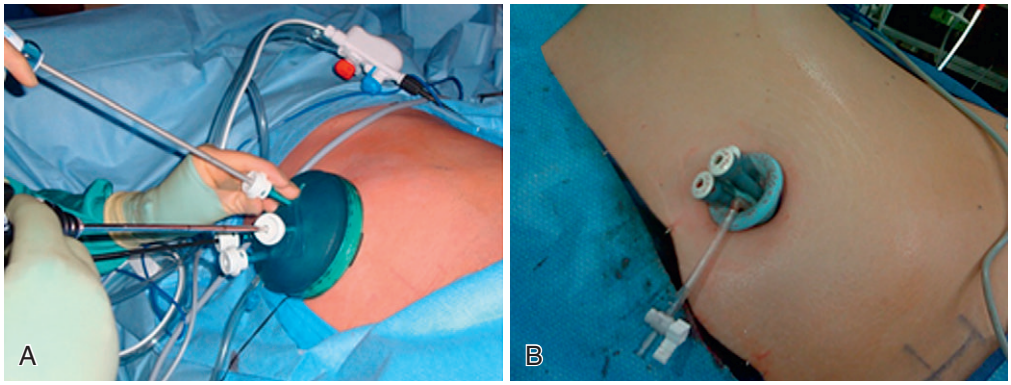

FIGURE 1 Single-port devices available are either **(A)** gel-based devices (Gelpoint, Applied Medical, Rancho Santa Margarita, Calif) or **(B)** more compact solid port designs (SILS Port, Covidien, Mansfield, Mass).

DEVICES AND INSTRUMENTS

Multiple commercial port devices are available for LESS surgery. The predominant difference is between gel-based devices (GelPOINT Advanced Access System and GelPort Laparoscopic System, Applied Medical, Rancho Santa Margarita, Calif), and more compact solid port designs (SILS Port, Covidien, Mansfield, Mass; Quadport, Olympus, Center Valley, Pa; Single Port Access Device, Ethicon, New Brunswick, NJ) (Figure 1). Single-port systems include the required insufflation port and accommodate three, four, or five ports sized between 5 and 15 mm. Ports are placed via open techniques under direct visualization and are either placed directly through the fascia or attached to wound retractor components. The incisions required to accommodate the ports vary from 22 mm to more than 70 mm. Most single-port systems also include a ventilation valve because the accumulation of vapor and aerosolized materials can significantly impair visualization.

Optical laparoscopic equipment need not be specifically modified for single-port surgery. Both 5-mm and 10-mm standard laparoscopic cameras can be utilized. Because of the umbilical port placement and the close proximity of operative instruments, some benefit is obtained from the use of bariatric-length cameras and right-angle light cord adaptors. The 5-mm cameras provide less illumination than do 10-mm systems. Articulating cameras are available and, with experience, provide some benefit in reducing interference with operative instruments (Figure 2, *A*). Depending on the application, experience in using both articulating and standard cameras in a single-port device can be helpful, inasmuch as one or the other could result in less interference between operative instruments and contamination of the camera lens, which would provide a more optimal visualization of the operative field. The ability to navigate the camera to reduce interference with operative instruments is a key component of success with single-port techniques.

No specialized instruments are needed to perform single-port procedures. The use of standard energy devices, clip appliers, and staplers is enabled by all available port devices. Articulating instruments are available for dissection, grasping, and cutting (see Figure 2, *B*). With progressive experience in using articulating instruments, some benefits can be realized with improved mobility that is inherently limited by a single-site approach. Nonetheless, none of the articulating instruments are needed to successfully accomplish the variety of surgical procedures currently being performed. One important concept is the use of instruments of different lengths to separate the surgeon's hands at different distances externally. For instance, combining bariatric-length suction-irrigator devices and Maryland dissectors with standard-length instruments can allow for separation of the surgeon's hands in different planes and reduce external hand conflicts.

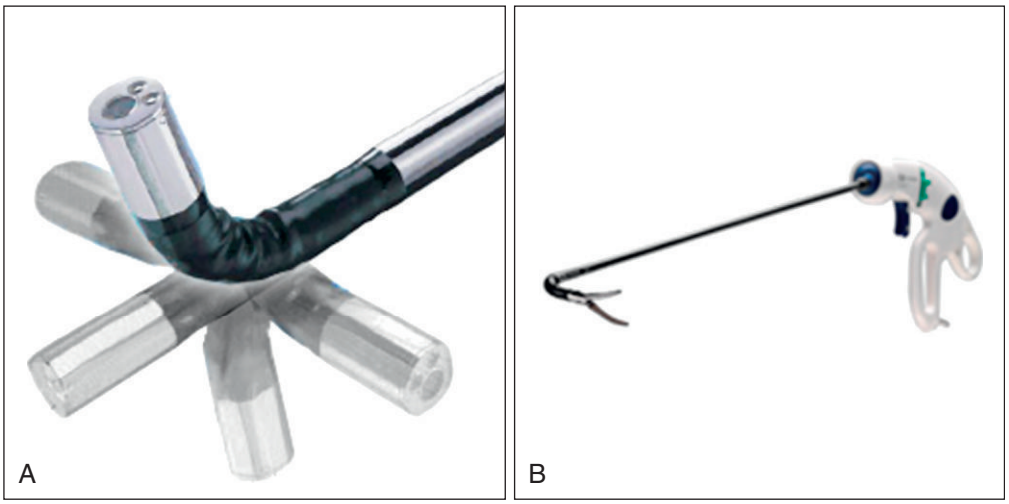

FIGURE 2 Articulating camera and instruments are available for single-port systems. **A,** Articulating 5-mm camera (Olympus LTF-VP Deflectable Tip Video Laparoscope, Center Valley, Pa); **B,** Articulating 5-mm dissecting device (SILSDISSECT36 Single Use Articulating Dissector with Monopolar Cautery, Covidien, Mansfield, Mass).

TRANSUMBILICAL APPROACH

The primary benefit of LESS surgery is improved cosmesis, which is best achieved when the port is inserted transumbilically. Although transumbilical port placement is most common, alternative port site placements have been utilized for other procedures, such as bariatric surgery. Depending on the device utilized and the required length of extraction incision, total incision lengths can vary from 2 to 7 cm (or longer). The invagination of the umbilicus allows for the majority of the incision length to be camouflaged, which results in apparent incision lengths of 3 to 4 cm. Healing and contraction of the umbilical incision over time further minimizes the postoperative scar so that it becomes barely visible (Figure 3). The rationale supporting LESS surgery may be poorer for procedures in which larger incisions are needed for specimen extraction.

One weakness of the transumbilical approach is the potential for umbilical incisional hernias. The presence of incidental umbilical defects has been noted in approximately 25% of potential kidney donors. The fascia incision can be closed by a variety of techniques, and the authors generally perform interrupted closures with No. 1 polydioxanone suture. The authors have observed umbilical hernias in 2% of kidney donors, and although this surgical complication rate is comparable with that in other approaches, the authors do specify this risk in the consent process. For procedures that do not necessitate significant extraction incisions (e.g., gastric bypass), port site hernia rates of less than 1% (similar between single- and multiple-port approaches when a 15-mm port was utilized) have been described. The authors' center experience also suggests that obese patients or patients who engage in extreme physical exertion within months of donation are more susceptible to hernia development. In addition, target operative anatomy may be displaced significantly from the umbilicus in obese patients, in comparison with nonobese patients (Figure 4). Achieving instrument reach may require modification of port placement from the transumbilical site in these patient populations.

NEPHRECTOMY

The availability of kidney transplantation is dependent on substantial numbers of living donors to address the nearly 100,000 patients currently awaiting renal transplantation. Of the approximately 18,000 kidney transplantations performed annually in the United States, approximately 33% involve kidneys from living donors. Nearly all renal donations in the United States are currently performed via laparoscopy (hand-assisted or total laparoscopic approaches). Extensive preoperative imaging is performed to ensure knowledge of vascular anatomy to allow for optimal surgical planning. Kidney donors are typically otherwise in excellent health without comorbid conditions. Thus improved cosmesis could be viewed as one advantage of LESS donor nephrectomy. The potential to attract kidney donors or encourage recipients to ask possible donors is one rationale for this surgical procedure.

The use of LESS approaches in renal surgery and living-donor kidney donation was first reported by Gill and colleagues (2008) at the Cleveland Clinic Foundation. In this initial series, they described technical feasibility, safety, and good outcomes for renal donation. The authors' experience with more than 250 LESS donor nephrectomies has provided evidence of the safe and routine application of this technique. The authors have found equivalent safety, complication rates, and transplantation outcomes in their patients in comparison with historic laparoscopic controls. The authors have additionally noted that kidney donors who donated via LESS donor nephrectomy approaches reported higher satisfaction with the donation process than did donors who donated via a totally laparoscopic multiport approach. Whether this will translate into increased interest and higher numbers of kidney donors has yet to be revealed.

The technical learning curve was overcome after the first 25 cases, with subsequent operative times that were not significantly different from those of totally laparoscopic approaches. Four surgeons at the authors' center have been able to achieve proficiency in the LESS approach and can perform LESS donor nephrectomy independently. In addition, the authors have participated in training surgeons from other centers who have then applied the technique successfully. Two important principles are (1) the addition of laparoscopic ports if the procedure appears to stop making progress and before complications arise and (2) the presence of an additional trained surgeon to help in decision making and expedient extraction of the renal allograft after vascular division. The few other centers in which this approach has been used have reported similar results in regard to donor safety and transplantation outcomes.

CHOLECYSTECTOMY

Cholecystectomy is one of the most common general surgery procedures, and laparoscopy has one of the most extensive applications in this procedure. The moderately sized tissue specimen can be removed through the single-port incision without extension, whereas removal through a 12-mm laparoscopic trocar site occasionally requires extending the incision length. In contrast to donor nephrectomy, inasmuch as cholecystectomy is often performed urgently, the target

anatomy has associated inflammation, and extensive imaging cannot be performed before surgery. Despite these differences, general surgeons have applied LESS cholecystectomy with good outcomes.

Studies performed to address concerns that the single-port approach could result in higher complication rates have yielded conflicting data. It is more technically challenging to demonstrate the "critical view" that can typically be readily achieved with triangulated instrument placement and gallbladder retraction. Multiple approaches to gallbladder retraction via the single-port have been utilized, including accessory needlescopic ports or transabdominal retaining sutures. One randomized study of only 21 patients who underwent LESS cholecystectomy did reveal increased rates of complications, including hernia, bleeding, and a retained stone. Larger series have demonstrated results similar to those of standard multiport approaches without any increase in biliary or other complications. Operative times also appear to normalize to multiport techniques with progressive experience; some centers have reported a learning curve of as few as five patients. One randomized trial of 150 patients assigned to undergo either LESS or conventional laparoscopic cholecystectomy demonstrated (1) that patients who underwent LESS procedures had improved pain scores, decreased analgesic use, and better survey responses for cosmesis and quality of life, and (2) no increase in reported complications. Other trials have confirmed the improved cosmetic appearances but have not demonstrated significant differences with pain or convalescence. Another randomized study determined that although initial pain scores are the same between LESS and multiport approaches, pain scores decreased to a greater degree in the patients who underwent LESS procedures after the first 6 to 12 hours.

The concern for hernia formation has been highlighted by other data. One multicenter randomized trial of 200 patients undergoing either LESS or multiport cholecystectomy revealed a significant difference in rates of hernia formation (8.4% vs 1.2%, $P = 0.03$) after 1 year of follow-up. These results differ from those of other large reviews of LESS cholecystectomy, in which incisional hernia rates were reported to be between 1% and 2%. Unlike extraction incisions for other surgical resections via single-port approaches, the required extraction incision for cholecystectomy does not generally require extension. Longer term follow-up of hernia rates are of significant importance in more accurately defining whether risk is increased with LESS approaches.

BARIATRIC SURGERY

The successful application of single-site approaches in bariatric surgery has been reported for gastric banding, sleeve gastrectomy, and Roux-en-Y gastric bypass procedures. Because gastric banding necessitates an adequate incision length for the implantable band device, this provides a good indication for the LESS approach. The technical feasibility and safety of the LESS approach for gastric banding were first reported in 2010 and confirmed in a larger series in 2012. In one series, additional port placement was required in 6% of patients, and no open conversions or blood transfusions were required. Recommendations were made for additional port placement after increased operative times (>60 minutes) with the single-port device.

Sleeve gastrectomy requires extraction of the resected gastric remnant, which necessitates extension of individual port sites when performed via a multiport approach. On the other hand, the longer incision length required for the single-port device is typically sufficient for specimen extraction. In one small series, sleeve gastrectomy entailed increased operative times with LESS surgery but resulted in decreased pain and analgesic requirements.

Roux-en-Y gastric bypass has also been performed via a single-port technique, with success rates equivalent to those of multiport approaches and with better patient satisfaction scores. The LESS procedures were performed by experienced bariatric surgeons (>400 procedures), but still resulted in longer operative times, with subjective appreciation of increased technical difficulty. Because gastric bypass does not involve specimen extraction or device implantation, the use of a single-port approach is based on the potential for improved cosmesis and decreased pain.

COLECTOMY

Single-port approaches have also been increasingly utilized and explored for both benign and oncologic colonic resections. Although technical considerations in the transition from multiport to single-port approaches in performing a colectomy are similar with regard to triangulation as for other procedures, laparoendoscopic single-site colectomy introduces the additional variable of an increased specimen size.

A meta-analysis of more than 500 patients who underwent LESS colorectal surgical procedures demonstrated equivalent outcomes, with decreased blood loss, hospital stay, and incision size in comparison to an equal cohort of patients undergoing standard laparoscopic procedures. No differences were reported with overall outcomes, rates of conversion to open surgery, or oncologic outcomes for tumor resection. In another large single-center report, researchers described their experience with more than 200 LESS colectomies for predominantly diverticular disease. Patients underwent sigmoid/left colectomy or high anterior resection. Open conversion rates were 6% and were generally attributed to difficulty with laparoscopic dissection in diverticular disease. Right-sided colectomies appear equally feasible. A report in which more than 40 LESS right hemicolectomies were compared with 100 conventional laparoscopic right hemicolectomies performed mostly for oncologic indications revealed equivalent oncologic outcomes and complication rates. LESS approaches resulted in an equal rate of conversion to open surgery (5%) as conventional surgery. Of the patients who underwent LESS surgery, 7.5% required additional port placement.

URGENT INDICATIONS

New technical approaches in laparoscopy may be difficult to use for urgent surgical indications; such cases may occur on nights and weekends when the surgeon is likely to encounter surgical staff who are less familiar with instrumentation and devices. Nonetheless, LESS surgery does not require unique laparoscopic instrumentation outside of the single-port device. Predicted differences in operative time, especially during the learning curve for single-port approaches, may be a driving consideration of which patients are candidates for LESS surgery for more urgent indications. Despite these challenges, LESS surgery is possible for urgent procedures. A trial of nearly 200 patients undergoing urgent appendectomy via either multiport or LESS approaches demonstrated slightly increased operative times (6 minutes) and decreased pain levels postoperatively in the patients who underwent LESS surgery. Appendix extraction was possible via the 12-mm port site in the patients who underwent multiport surgery and via the 2-cm single-port site in those who underwent LESS surgery. In this study, both groups included pediatric patients.

UROLOGIC SURGERY

LESS surgery has been reported for numerous urologic procedures, including pyeloplasty, nephrectomy, adrenalectomy, and prostatectomy. Much of the early experience with LESS procedures and the translation from animal models to human procedures focused on laparoscopic nephrectomy. The technical modifications required for LESS surgery were investigated and evaluated in urologic applications before more widespread marketing and availability of single-port devices. Initial descriptions focused on the feasibility and limitations of the approaches. In later randomized studies, outcomes were compared with those of multiport approaches; patient satisfaction with cosmesis was improved, return to activity was quicker, and postoperative pain was decreased.

A review of more than 1000 LESS urologic procedures from 18 academic institutions around the world demonstrated that nearly 50% of single-port procedures were directed toward renal tumors or cysts. Overall, a 3.3% complication rate was reported (the majority of these were minor), 23% of cases required additional port placement, and fewer than 1% of cases required conversion to open surgery. Of interest is that 13% of cases involved the use of robotic assistance through the existing GelPort platform (Applied Medical, Rancho Santa Margarita, Calif). Robotic-assisted LESS surgery has demonstrated its feasibility but, conversely, also has limitations, which illustrates the continued demand for technical advancements in the available instrumentation and compatible robotic platforms. Robotic surgery has a strong place in the current repertoire of urologic surgery, and thus the combination of single-site approaches and robotic surgery has the potential to drive further innovation in surgery that will enable broader application.

GYNECOLOGIC SURGERY

Gynecologic surgeons have likewise introduced LESS approaches. In an initial report, applications of both manual and robotic single-site approaches were described for such indications as pelvic staging, oophorectomy, hysterectomy, and ovarian cystectomy. As noted in urologic applications, the hybrid approach of utilizing robot-assisted laparoscopy may represent one technique that enables single-site surgery.

ROBOTIC SINGLE-PORT APPROACH

The U.S. Food and Drug Administration (FDA) approved a single-port platform for the robotic da Vinci Surgical System (Intuitive Surgical, Sunnyvale, Calif; Figure 5). In the United States, this device is approved for only cholecystectomy; however, European investigators have used these devices for urologic and gynecologic procedures. Initial reports demonstrate the safety of this platform in robotic

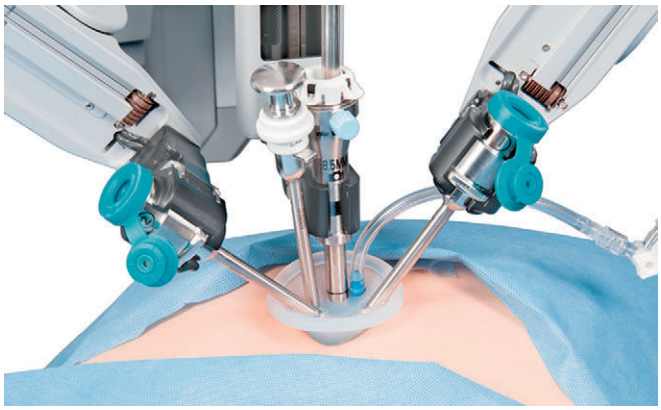

FIGURE 5 Single-port platform for the robotic da Vinci Surgical System (Intuitive Medical, Sunnyvale, Calif).

single-port cholecystectomy procedures. The robotic platform offers specific advantages in terms of improved ergonomics, reduced "sword-fighting" between instruments, and improved optical systems. However, the robotic single-port platform does not yet allow for the use of articulating robotic instruments, which are one of the most compelling technical advantages of using the robotic approach in surgery. The development of similarly articulating instrumentation for the single-port robotic platform will be a significant step in improving the current limitations of manual single-site laparoscopic approaches. Once developed, fully articulating robotic single-port platforms may eliminate many of the limitations that exist with current single-port laparoscopic surgery.

As previously described, urologic and gynecologic surgeons with experience in robotic surgery have been utilizing standard robotic instruments through a single incision via a GelPort device with success. This approach allows for the substantial benefits that robotic surgery incorporates in terms of articulating instruments, three-dimensional optical systems, and improved ergonomics for the surgeon. These specialties have embraced training in and clinical applications for robotic surgery and are well positioned to make advances in robot-assisted single-port surgery.

Future combinations of image-guided surgery involving computed tomographic (CT) scans and fluorescent dye may enable robotics to improve many surgical approaches. Image-guided robotic surgery with the use of three-dimensional CT scan overlays has been described for renal tumors, and real-time ultrasound guidance for robotic navigation has been reported for prostatectomy. Combination with indocyanine green that can be detected with fluorescence imaging can also allow for real-time imaging of biliary anatomy. These technical advances, in combination with robot-assisted single-port approaches, have the potential to improve safety through real-time anatomic imaging.

COST CONSIDERATIONS

The application of new technology has associated costs dependent on instrumentation and port devices. The incremental benefits of new technologic approaches should thus be weighed against the potential for substantially increased costs. Limited cost analyses have been performed for single-port surgery; however, a few researchers have described an increased incremental cost of $200 to $800 per case.

One favorable factor for single-port surgery is a comparable equipment platform used in standard laparoscopy. The cost of individual ports required for multiport surgery (usually three or four ports of various sizes) is consolidated into the cost of a single-port access system that includes all necessary ports. The surgery can be performed with existing reusable and disposable laparoscopic instruments, which eliminates a potential cascade of new instrument charges. Existing stapling devices, energy devices, clip appliers, retrieval bags, and other equipment can all be used through the available single-port devices. In addition, the optic systems utilized for standard laparoscopy can be applied to single-port laparoscopy (5-mm or 10-mm camera systems, or both, depending on the single-port system utilized).

Most authorities describe normalization of operative times after appropriate learning curves, which thus eliminates longer surgical or anesthetic times from any cost differential. Furthermore, the single-port approach does not require any unique operating room setup that could affect setup times and personnel requirements.

Cost can be increased in association with a small number of flexible and articulating laparoscopic instruments designed for single-port use. However, these instruments have not proved to be essential for any of the currently applied surgical procedures. Further refinements and experience may allow single-port surgery to proceed with fewer limitations in the future. One item that the authors and others have found beneficial is a flexible camera. The ability to improve visualization and navigate the camera away from any interference with other instruments has improved surgeons' capacity to perform the procedure safely with decreased operative times. These cameras can also provide high-definition digital images (in contrast to older analog systems) that further facilitate the operation.

On the other hand, significant cost is associated with developing a robotic assist approach. Robotic surgery requires a specialized operating room setup, and personnel must be familiarized with the equipment, the actual robotic device and all associated instruments, camera systems, and comparatively longer operative times. The single-port approach is relatively simple and inexpensive in comparison.

CONSENT ISSUES

Although the use of LESS surgical approaches does not require any new consent process, adequate informed consent does take on additional requirements. The devices utilized are FDA approved and have been employed in a wide variety of applications. Nonetheless, the ability to demonstrate individual proficiency with LESS approaches is important, and the authors recommend discussing the novel approach with patients in the consent process. A published consensus statement from the Society of University Surgeons supported an informed consent process that includes a specific discussion of the innovative aspects of the surgical procedure. In addition, survey data revealed that patients believe that information for consent must include knowledge of whether their operation was the surgeon's first case with the innovative procedure, clarification of the novelty of the technique in comparison with standard approaches, and potential risks of the novel approach. Informed consent will be strengthened by presentation of the individual surgeon's experience and complications with LESS surgery. Because the primary benefit is cosmetic, this must be weighed against any potential risks to the patient and put in the context of each surgeon's experience.

The authors also discuss the placement of additional ports in approximately 10% of donor nephrectomy cases. Similarly, conversion from laparoscopic to open approaches is always discussed, and the authors provide conversion rates for the specific procedure. The authors believe that for surgeons proficient in LESS surgery, the hierarchy of preferred approaches for certain procedures should be LESS surgery, multiport laparoscopy, hand-assisted laparoscopy, and finally open surgery.

STRATEGIES FOR SUCCESSFUL INCORPORATION OF THE SINGLE-PORT TECHNIQUE

Operative room setup is quite similar to standard laparoscopic procedures, except that both the surgeon and assistant operate through a single access point, which results in crowding (Figure 6). The primary difficulty that most surgeons encounter when transitioning to a single-port technique is the proximity of the surgical instruments that they pass through the single-port device. In addition to placing the instruments in very close proximity, the surgeon's and assistant's hands also tend to interfere with each other (Figure 7). This creates both "sword-fighting" between instruments and physical discomfort for the surgeon. A number of strategies have been developed to address these "steric hindrances." Although it is contrary to standard laparoscopic teaching, the authors find it easiest to cross the instruments inside the abdomen. This enables the surgeon's hands to obtain space between them. The surgeon can increase the space by using instruments of different length, which positions the hands at different distances from the patient. The surgeon can further enhance positioning by holding the instruments with the palms downward, placing the instrument handles outward. Larger devices, such as the GelPort device, are easier for those first becoming familiar with the technique because the distances between ports is much larger. The disadvantage of these ports, however, is that they require larger skin and fascial incisions. Some surgeons have found articulating instruments to be of assistance as well.

The authors have been able to minimize interference by having the assistant operate a 5-mm flexible camera. The assistant is able to angulate the camera downward, providing a bird's-eye view of the region of interest. A right-angle camera cord adapter creates more space for the operator.

Newer ports have incorporated a venting system, which eliminates the troublesome fogging and visual disruptions associated with earlier designs. Such ports tend to require higher CO_2 flow rates, but they vastly improve visualization.

The authors emphasize the importance of early placement of additional ports in the event of difficulty visualizing or mobilizing

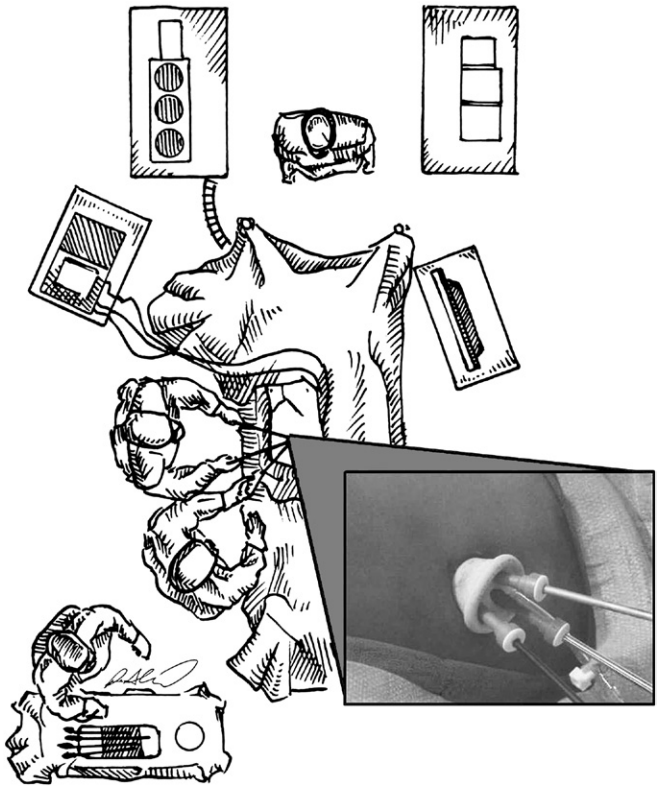

FIGURE 6 Operating room setup for single-port donor nephrectomy. Patient position and operating room setup are similar to those for standard laparoscopic nephrectomy. Surgeon and assistant are in close proximity as multiple instruments and camera are inserted through the umbilical port. The assistant operating the camera or additional instrument must pay attention to avoiding interference with the primary surgeon's instruments. *(From Morris PJ, Knechtle SJ:* Kidney transplantation—principles and practices, *Philadelphia, 2008, Elsevier.)*

the target anatomy. They have found that the presence of two surgeons comfortable in LESS surgery to assist in decision-making and surgical exposure is crucial for success in challenging cases.

CONCLUSIONS

The primary benefit of LESS surgery is improved cosmesis for the patient. This benefit is most pronounced when the port is placed in a transumbilical location and the entire incision can be contained within the umbilicus. Applications in general surgery, urology, gynecology, and living donor nephrectomy have been reported, and growing experience supports application of LESS techniques. A learning curve to obtain experience with these new devices does exist, and not all surgeons may be able to safely master use of a single-port approach. Commitment to adding additional ports when technical challenges arise is paramount to avoid complications.

NOTES: What Is Currently Possible?

Faming Zhang, MD, PhD, and
Anthony N. Kalloo, MD

OVERVIEW

Natural orifice transluminal endoscopic surgery (NOTES) has gained a great deal of attention from gastroenterologists and surgeons all over the world since its introduction in 2000. More than 1000 reports describing various applications of NOTES in both animal and human experiments (Table 1) have been published since that time. More than 110 reports associated with NOTES were published in 2011. More than 30 currently open clinical trials in humans are officially registered in the U.S. government Web-based registry (http://www.clinicaltrials.gov). NOTES-associated procedures have been performed in several thousand patients. The concept is continuously expanding as industry develops new enabling technologies for NOTES.

The basic aim of scarless surgery through a natural orifice such as the mouth, vagina, and anus is to dramatically reduce the surgical effect on the patient and to improve surgical outcomes. At a minimum, this concept has introduced a new era in minimally invasive surgery: the avoidance of skin incisions, with a resulting decrease in physical and psychologic disability; direct patient benefits, such as less pain; and allowing the conversion of standard inpatient surgical interventions into outpatient clinic procedures.

The acronym *NOTES* has become a mark of innovative, minimally invasive surgery. In 2004, Rao and Reddy brought attention to NOTES with their description of the first human NOTES procedure (transgastric appendectomy). In 2005, the American Society of Gastrointestinal Endoscopy (ASGE) and the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) formed a NOTES working group, the Natural Orifice Surgery Consortium for Assessment and Research (NOSCAR). This committee subsequently identified the fundamental challenges to be addressed and outlined a pathway for the responsible development and evolution of NOTES. Under the auspices of NOSCAR, the field of NOTES has advanced tremendously since its inception, and exciting and well-designed research has been published. Both randomized controlled trials and results from large national and international registries have been published. NOTES should no longer be viewed as merely a more cosmetic way to perform surgery. NOTES has the potential to decrease postoperative pain and anesthesia requirements, better preserve immune function, and accelerate patient recovery.

It is not surprising that some medical practitioners still doubt the potential and clinical relevance of NOTES. NOTES was initially criticized as unrealistic, dangerous, and unnecessary. This situation is similar to that of the early era of laparoscopic surgery, when the first laparoscopic cholecystectomy was performed in a human in 1985. However, the substantial number of published laboratory studies and clinical trials are a reflection of the significant interest and application by endoscopists and surgeons. Novel interventions for NOTES (see Table 1) have been developed, such as endoscopic ultrasonography (EUS)-guided approach to NOTES interventions, endoscopic local full-thickness resection for gastrointestinal stromal tumors, (GIST) and per-oral endoscopic myotomy (POEM). Many diseases formerly treated only by conventional surgical interventions are now more often treated by endoluminal procedures at many centers worldwide.

TREATMENT AND METHODS

The adoption of NOTES into clinical practice is strongly dependent on device development. NOTES procedures involving available or "standard" instruments are highly demanding, even for experienced endoscopists or laparoscopists. The sophisticated systems enabling pure NOTES procedures are still limited, and most remain in prototype. However, many creative, flexible endoscopists and laparoscopists have overcome these technical challenges, making some pure NOTES procedures a clinical reality with the use of conventional endoscopes and accessory devices. Advanced NOTES platforms and devices (Figure 1), such as the EndoSAMURAI with two arms (Olympus Corp.), the new flexible endoscope for NOTES (Boston Scientific), or the ANUBIScope (Karl Storz), all enable laparoscopic-like trangulation. The ability to perform intracorporeal suturing is still in the prototype phase, but the launching of such devices will prompt a huge step forward. A new closure device by OVESCO (Tübingen, Germany) is capable of providing full-thickness closure

of the intestinal wall. The ability to provide secure closure is one of key potential barriers to clinical NOTES (Figure 2).

Pure NOTES involves introduction of instruments through a natural orifice route only, without any transluminal assistance. The term *hybrid* is used to describe procedures that involve any type of transabdominal assistance. Hybrid NOTES can be categorized into two types: NOTES-assisted laparoscopy and laparoscopy-assisted NOTES. The critical methods are analyzed according to transluminal access routes in clinical trials.

Transvaginal access is the most frequently reported NOTES access route in clinical trials. In most cases of transvaginal NOTES procedures reported so far, surgeons have utilized a hybrid NOTES approach, in which at least one laparoscopic port has been used for insufflations, visualization, retraction, or initial dissection. This is important, at least at the initial research stage, to prevent complications. Zornig and colleagues published the first comparative study of hybrid NOTES procedures with laparoscopy in a series of 216 patients. The transvaginal technique starts with a 5-mm incision deep in the umbilicus, insufflation of the abdomen, and diagnostic laparoscopy. The average time was 52 minutes for transvaginal NOTES and 35 minutes for laparoscopy. The postoperative frequencies of sexual intercourse were the same in both patient groups. The matched-pair study further showed that transvaginal NOTES is safe, did not lead to any serious complications, and was followed by only one infection. In comparison with laparoscopy, transvaginal NOTES obviously has a better cosmetic result; produces less pain, fewer wound infections, and fewer trocar hernias; and is associated with shorter hospital stays and sick leave. The first pure transvaginal NOTES right nephrectomy—in a 58-year-old woman suffering from recurrent urinary tract infection and an atrophic right kidney—was reported by Kaouk and colleagues in 2010 (Figure 3). Other transvaginal procedures performed include appendectomy, colectomy, partial/sleeve gastrectomy, retroperitoneoscopy, liver resection, splenectomy, and renal cyst resection. The shortcomings of a transvaginal NOTES approach include applicability only to women; reported risk of injury to bladder, urethral, vulva, small bowel, colon, and rectum; and the potential risk of infertility.

Transgastric NOTES is the second most common NOTES access method. Most transgastric NOTES procedures were performed as a hybrid procedure that included the use of laparoscopic port guidance and insufflations. Pure NOTES gastrostomies are typically performed in the anterior stomach with needle knife puncture and balloon dilation. Nau and colleagues reported transgastric NOTES peritoneoscopy in a series of 130 patients. Eighty patients were enrolled for evaluation of diagnostic accuracy and utility. The diagnostic transgastric peritoneoscopy was completed in 20 patients with pancreatic head masses and found to have a 95% concordance with laparoscopic findings for assessment of peritoneal metastasis. There was no significant difference in the ability to adequately explore the four quadrants between patients with preinsufflation of the abdomen and in those without, no difference between the endoscopic and laparoscopic pressure readings of the peritoneal cavity, and no difference in pressure readings of the peritoneal cavity between patients with and without a surgical history. In the evaluation of 100 consecutive patients, the risk of bacterial contamination secondary to per-oral and transgastric entry was clinically insignificant. The use of proton pump inhibitors did not result in a higher bacterial load in the peritoneal cavity. Bingener and colleagues showed the clinical efficacy of endoscopic transluminal omental patch repair for perforated peptic ulcer. In their study, 49 patients with a perforated peptic ulcer in the gastric, duodenal, or other region of intestine underwent transluminal omental patch repair. Bingener and colleagues showed that a 10-mm-diameter ulcer opening is required for performing transluminal inspection, irrigation, and drainage and for endoscopic luminal omental patch closure. Most patients with a peptic ulcer would be theoretically eligible for a pure transluminal endoscopic or hybrid procedure. Other transgastric NOTES procedures performed, including cholecystectomy, appendectomy, full-thickness resection with

or without submucosal tunneling, liver biopsy, and endoscopic ultrasonography–guided NOTES. The lack of a foolproof device for the facile and safe closure of the gastric defect is the sole factor limiting a transgastric NOTES approach.

The first transesophageal NOTES procedures in humans was POEM, for treatment of achalasia, as reported by Inoue and colleagues in 2009. POEM is based on the esophageal submucosal tunneling technique. A long submucosal tunnel is created (mean length, 12.4 cm), followed by endoscopic myotomy of circular muscle bundles for a total length of 8.1 cm (2.0 cm in cardia). The flaps act as a seal that prevents mediastinal contamination and can be closed with various tissue-approximating devices at the conclusion of the procedure (Figure 4).

Transrectal NOTES access is increasingly being facilitated by transanal endoscopic microsurgery (TEM) platform or performed through direct transrectal trocar insertion. New developments in flexible endoscopic platforms and instruments such as flexible staplers with TEM–like platforms could enable pure NOTES colorectal surgery via the transanal route in the near future.

NOTES: WHAT WILL BE POSSIBLE IN THE NEAR FUTURE?

It should be acknowledged that NOTES is not about adapting laparoscopic concepts with its focus on triangulation; instead, it entails performing inline procedures along a single axis, as with standard flexible endoscopy. The ability to resect large portions of the gastric mucosa successfully with the endoscopic techniques has demonstrated that triangulation is not necessary for dissection. The future of NOTES will hinge on techniques and devices that facilitate inline complex procedures.

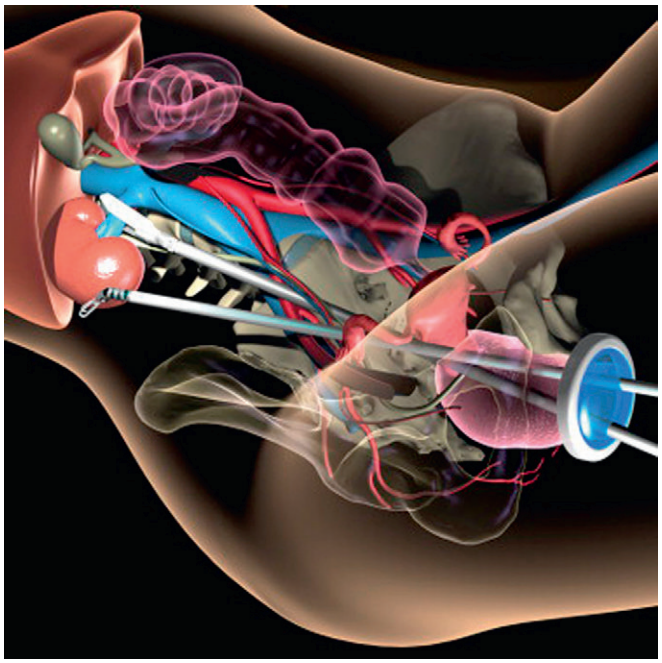

FIGURE 3 Operative illustration of transvaginal nephrectomy.

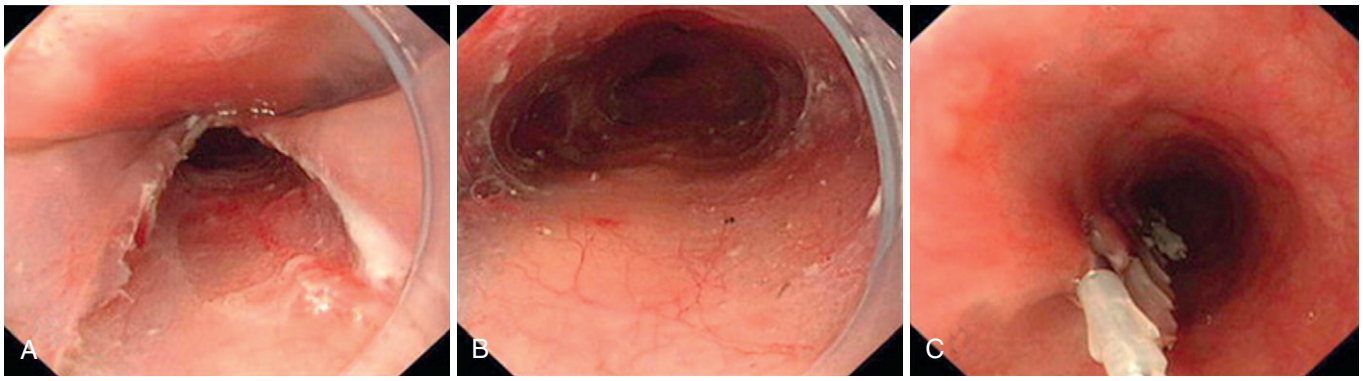

FIGURE 4 **A-C,** Transluminal submucosal tunneling and closure.

The spectrum of therapeutic flexible endoscopy performed by gastroenterologists inside the lumen has widened since the introduction of NOTES. However, it remains unclear who should be trained for performing NOTES and which discipline is primarily involved with NOTES. The fourth Euro-NOTES workshop yielded the consensus statements of NOTES in 2011. According to the consensus, it appears reasonable for a diagnostic approach to be performed by a gastroenterologist; a therapeutic NOTES procedure will probably be performed by a surgeon. The current situation of training surgeons in flexible endoscopy and training gastroenterologists in laparoscopic surgery cannot be regarded as an ideal solution. An ideal goal would be to achieve combined endoscopic/laparoscopic operating room suites with common wards and staff, common conferences, and a substantial volume of "crossover cases" between surgery and endoscopy.

NOTES is one of the most exciting current developments in minimally invasive endoscopic surgery. Since its theoretical conception in 2000, transluminal procedures without visible scars have been performed via natural orifices by creative endoscopists and surgeons conducting minimally invasive operations worldwide. Some NOTES procedures have become regular minimally invasive therapies at many clinical centers in some areas or countries, such as those in Europe and South America, Japan, and China. NOTES is continuing to evolve and is here to stay.

 antifungal agents, 1186–1189
 fungi, filamentous, 1191–1192
 infections, specific, 1189–1192
 candidiasis, 1189
 mucocutaneous, 1190–1191
 introduction, 1186, 1187t–1188t
Antiplatelet therapy—renal artery disease, atherosclerotic, 915
Antiretroviral regimens, 1184
Antiretrovirals drugs, timing of initiation of, 1183
Aorta
 abdominal and iliac vasculature, 1120, 1121f
 descending, occlusion of, 1000
Aortic aneurysms, abdominal—endovascular treatment of, 783–787
 complications, 785–786, 786t
 new devices on horizon, 787
 postoperative care and follow-up, 785
 preoperative considerations, 783–784
 procedure, technical details of, 784–785
Aortic aneurysms, abdominal—open repair of, 777–783
 complications, 782, 782f
 conclusion, 783
 indications for repair, 777–778, 778f
 overview, 777, 778b
 preoperative planning, 778
 surgical repair, 778–781
 operative conduct, 781, 781f
 retroperitoneal approach, 780–781, 780f
 surgical approaches, 778–781, 779f–780f
 transperitoneal approach, 779–780, 780t
Aortic aneurysms, abdominal—ruptured, 788–791
 diagnosis and evaluation, 788, 789f
 discussion, 791
 treatment, 788–791
Aortic aneurysms, descending thoracic, 795
Aortic aneurysms, thoracic and thoracoabdominal, 795–807
 alternative approaches, 806–807, 807f
 endovascular surgical management, 804–806, 805f, 805t
 indications for surgery, 795–796
 introduction, 795, 796f
 open surgical management, 796–804
 preoperative risk assessment, 796

Aortic dissections, acute, 807–811
 classification, 807, 808f
 management, 808
 management of acute B dissections, 810–811
 overview, 807
 presentation and diagnosis, 808
 surgical management of Stanford A dissections, 808–810, 809f–810f
 surgical results with acute type A dissections, 810
Aortobifemoral bypass, 854–856, 856f–858f
Aortoiliac injury, 1119–1120
Aortoiliac occlusive disease (AIOD), 851–863
 aortobifemoral bypass, 854–856, 856f–858f
 axillobifemoral bypass (AxBF), 857–859, 859f
 endovascular interventions, 860–861, 861f–862f
 complications of, 861
 results of, 861–862, 862f, 863t
 evaluation and indications for intervention, 851–852, 852f–853f
 extra-anatomic bypass, 857
 femorofemoral bypass (FFB), 857
 iliofemoral bypass (IFB), 856–857
 revascularization, surgical
 complications of, 859–860, 860t
 direct, 852–854, 854f
 results of, 860
 revascularization options, other surgical, 859
Appendectomy, laparoscopic, 1322–1325
 diagnosis, 1322–1323
 indications, 1323
 pathophysiology, 1322
 results, 1324
 special circumstances, 1324–1325
 appendicitis, complicated, 1325
 diagnosis, incorrect, 1325
 interval appendectomy after nonoperative management, 1325
 pregnancy, 1324–1325
 techniques, 1323–1324, 1323f–1324f
Appendicitis, acute, 252–255
 anatomy and pathophysiology, 252
 antibiotics used in perforated appendicitis, 254–255
 historical perspective, 252
 management, 253
 nonperforated appendicitis, management of, 253–254
 patient presentation and diagnosis, 252–253
 patient situations, special, 255
 perforated appendicitis, management of, 254–255
 surgery, laparoscopic versus open appendectomy, 253
 surgery, timing of, 253
Appendicitis, complicated, 1325
Appendix, abdominal aortic aneurysm (AAA), 792
Approach, Kraske, 285
Aprotinin, 1102

 percutaneous drainage, 436–437
 videoscopic assisted retroperitoneal débridement (VARD), 437
 demographics, 439
 intensive care unit admission, 439
 nutrition, 439
 open surgical management, 438–439
 closed packing, 438–439
 continuation lavage of lesser sac and retroperitoneum, 439
 open packing, 439
 planned staged relaparotomies with repeated lavage, 439
 surgical technique, 438, 438f
 patients, management of, 432–436
 analgesia, 434–435
 antibiotic prophylaxis, 436
 endoscopic retrograde cholangiopancreatography (ERCP), 436
 metabolic imbalance, 432–434
 nutrition, 435
 supportive care, 432
 volume resuscitation, 432
 security assessment, 439
 set-up approach, minimally invasive, 439
 severity, assessment of, 431–432, 433t–434t, 435f
 supportive care, 439
Pancreatitis, autoimmune, 498–499, 498f
Pancreatitis, chronic, 464–471
 definition and types of, 464
 diagnosis and severity classification, 465, 465f–466f, 465t
 endotherapy, 466, 467f
 medical management, 465–466
 surgical drainage and resection techniques, 467–470
 Beger procedure, 468, 468f
 duodenum-preserving pancreatic head resection, 468, 468f
 Frey procedure, 469f
 operation to perform, which, 470, 470t
 pancreas, local resection of head of, 468, 469f
 pancreaticoduodenectomy, 467–468, 467f
 pancreaticojejunostomy, lateral, 468, 468f
 Puestow procedure, 468, 468f
 Whipple operation, 467–468, 467f
 surgical treatment, 466–467
Pancreatitis, gallstone, 440–444
 disease, mild, 441–443
 choledocholithiasis and cholangitis, 442, 442f
 patients at high risk, 442–443
 pregnant patients, 443
 disease, severe, 443–444
 medical management, 443
 pancreatitis necrosis, 443–444, 444f
 severe pancreatitis, intervention in, 443
 disease severity, determination of, 440–441, 441t
 presentation and diagnosis, 440–441
 treatment, 441–444
 disease, mild, 441–443
 disease, severe, 443–444
Panfacial fractures, 1078–1079
 complications, 1079
 special considerations, 1078
 treatment, 1078
 types, 1078
Papillary thyroid cancer (PTC), 659
Paracentesis, large volume, 373
Paraesophageal hernia (PEH) surgery, insights and controversies and, 33–35
 antireflex procedure, 35, 35f
 Collis gastroplasty, 34–35, 34f
 laparoscopic vs open, 33
 to mesh or not to mesh? 34
 robotic-assisted surgery (RAS), 33–34
 surgical management of acute PEH, 33
Paraesophageal hiatal hernia, 27–36
 clinical manifestation, 29, 29f
 definition, 27–29
 diagnosis, 30, 31f
 paraesophageal hernia (PEH) surgery, insights and controversies in, 33–35
 antireflex procedure, 35, 35f
 Collis gastroplasty, 34–35, 34f
 laparoscopic vs open, 33
 to mesh or not to mesh? 34
 robotic-assisted surgery (RAS), 33–34
 surgical management of acute PEH, 33
 pathophysiology, 29–30, 30f
 results, 35–36
 therapy, 30–33
 surgery, indications for, 30
 surgical anatomy, 31, 31f
 therapy—surgical approach, 31–33, 32f
 adequate intraabdominal esophageal length, 32
 antireflex barrier, creating, 32
 excision of hernia sac, 32
 gastropexy, 33, 33b
 hiatus, repairing, 32–33
 management of short esophagus, 32
Parathyroid glands, ipsilateral, 676
Parathyroid hormone (PTH), 668, 673
 excessive production, 666
 serum levels, 674
Parathyroidectomy, minimally invasive, 1393–1398
 intraoperative adjuncts, 1395–1396
 postoperative management, 1398
 preoperative parathyroid localization, 1394–1395, 1394f–1395f
 surgical approach, 1396–1398, 1396f–1398f
Parathyroidectomy, reoperative, 669, 671
Parenteral nutrition, total, 1286
Park's submucosal excision, 259
Paronychia, 726–727
 diagnosis, 726, 727f
 treatment, 726–727, 727f
Pathogens, bloodborne—occupational exposure to, 1182–1185, 1182t
 hepatitis B, occupational exposure to, 1184–1185, 1185t
 hepatitis C, occupational exposure to, 1185, 1185t
 hepatitis C virus RNA, healthcare worker with, 1185
 human immunodeficiency virus (HIV), occupational exposure to, 1182–1184
 antiretroviral regimens, 1184
 antiretrovirals drugs, timing of initiation of, 1183
 counseling, 1183
 counseling, healthcare worker, 1183–1184
 expert opinion, 1184
 exposure, management of, 1183

Pathogens, bloodborne—occupational exposure to *(Continued)*
healthcare worker, monitoring exposed, 1184
injury site, management of, 1184
risk, 1182
source, testing, 1183–1184
zidovudine (AZT), efficacy of, 1183
Patient-centered outcomes research (PCOR), 1197
Patients, burn—practical management of, 1131–1132
burn critical care, 1135–1136
hemodynamic and electrolyte issues, postresuscitation, 1136
inhalation injury, 1135–1136
multiple organ failure, 1136
neurologic issues, 1136
nutritional support, 1136
septic complications, 1136
conclusion, 1138
evaluation and resuscitation, initial, 1132–1134
introduction, 1131–1132, 1132t
physiologic changes with burn injury, 1132
hyperdynamic phase, 1132
hypodynamic phase, 1132
reconstruction and reintegration, 1137–1138
burn care, outpatient, 1138
burn reconstruction, early, 1138
burn rehabilitation, 1137, 1138t
wound closure, definitive, 1136–1137
face and head, 1136–1137, 1137f
head and feet, 1137
skin substitutes, 1136
wound excision and biologic closure, 1135
burn wound excision, techniques of, 1135
hemostatic excision techniques, 1135
need, timing, and extent of operation, 1135
Patients, critically ill—antibiotics for, 1271–1278
antibiotic dosage, adjustment of, 1278
antibiotic therapy, 1272–1273, 1276t
antibiotic toxicities, 1277–1278
beta-lactam allergy, 1277–1278
nephrotoxicity, 1278
ototoxicity, 1278
diagnosis of infection and empiric therapy, 1271–1272, 1272b, 1273t–1275t
multidrug-resistant organisms, 1276–1277, 1276b–1277b
specific considerations, 1273–1276
bloodstream infections, central line-associated, 1275–1276
pneumonia, postoperative, 1273
urinary tract infections (UTIs), 1273–1275
toxicities, avoidance of, 1278
hepatic insufficiency, 1278
renal insufficiency, 1278
Patients, critically ill—coagulopathies in, 1290–1304
acquired factor inhibitors, 1302–1303
factor V inhibitors, 1302–1303
thrombin inhibitors, 1302–1303
bleeding
cardiac surgery-associated, 1303
critically ill patient with, 1290–1291, 1291b
coagulation disorders, acquired, 1300–1301, 1303t
anticoagulant-associated bleeding, 1301
unfractionated heparin, 1301
coagulation disorders, inherited, 1298–1300, 1298t–1299t, 1300b
direct-thrombin inhibitors (DTIs), 1301–1302
factor Xa inhibitors, 1302
hemostasis, model of, 1290, 1291f
Patients, critically ill—coagulopathies in *(Continued)*
hemostatic testing in critically ill patients, 1291–1293

surgical setup and equipment, 1419–1422
Thoracoabdominal aortic aneurysms (TAAAs), thoracic and, 795–807
alternative approaches, 806–807, 807f
endovascular surgical management, 804–806, 805f, 805t
indications for surgery, 795–796
introduction, 795, 796f
open surgical management, 796–804
operative technique, 797–803, 798f–804f
organ protection, adjuncts for, 797, 797f
outcomes, 803–804
preoperative risk assessment, 796
Thoracoabdominal trauma, ultrasound in, 990–997
Focus Assessment for Sonographic Evaluation of Trauma (FAST) patient, 990–993
hemothorax, traumatic, 993–994
pneumothorax, 994
special situations, 995–996
sternal fracture, 994
summary, 996, 997f
ultrasound, new horizons in point of care, 997
ultrasound in austere settings, 995–996
ultrasound to assess intravascular volume status and cardiac function, 996
Thoracotomy, emergency department, 998–1001
indications, 998, 999b, 999f
outcomes, 1001
procedural techniques, 998–1001
aorta, descending, occlusion of, 1000
bronchovenous air embolism, 1000–1001
cardiac massage, open, 1000, 1001f
initial exposure, 998, 1000f
intrathoracic hemorrhage, control of, 998–999
pericardotomy and control of cardiac injuries, 998, 1000f
Thrombin inhibitors, 1302–1303
Thromboangiitis obliterans (TAO), 937–939
clinical presentation, 937
diagnosis, 937–938, 938b, 938f
prognosis, 939
treatment, 938–939, 939b
Thromboembolism, venous, 958–963
asymptomatic patients, screening of, 960–961
diagnosis, 959
impact, 958
prevention and prophylaxis, 958–959, 960f
risk factors, 958, 959b
treatment, 961–963
deep vein thrombosis (DVT), 961, 961f
inferior vena cava (IVC) filters, 962–963, 963b
pulmonary embolism (PE), 961–962, 962f

Thromboembolism, venous, prevention of, 972–976
 complications, 975
 diagnosis, 974
 epidemiology, 972
 inferior vena cava (IVC) filter, 975
 prophylaxis, 973–974, 973t
 risk factors, 972–973, 973t
 thrombolysis, systemic, 975
 thrombolytic therapy, catheter-directed, 975
 treatment, 974–975
Thrombolysis
 catheter directed, 910, 910b
 mechanical, 912–914, 913t
 results of, 910–911, 910t
 systemic, 975
 techniques of, 911
Thrombolytic therapy, 909–914
 catheter-directed, 975
 patient presentation and workup, 909–914
 thrombolysis, mechanical, 912–914, 913t
Thrombosis, deep vein, 961, 961f, 963–967
 diagnosis, 964
 risk factors, 964
 special consideration, 966–967
 therapy, 964–966
 anticoagulation, 965
 surgical thrombectomy, 965
 thrombolytic therapy, 965–966
 thrombolytic therapy, 965–966
 catheter-directed, 965
 inferior vena cava (IVC) filters, permanent, 966
 inferior vena cava (IVC) filters, retrievable, 966
 mechanical thrombectomy, 965–966
Thrombotic thrombocytopenic purpura (TTP), 518
Thrombus, macroembolism and organized, 904
Thymectomy
 robotic, 763–764
 transsternal, 762–764
 video-assisted thoracic surgery, 763
Thymic tumors, 757, 757t, 758f
Thymus tumors, primary, 761–764
 anatomy, 761
 evaluation, 761–762, 762f
 operative management, 762–764
 thymectomy, robotic, 763–764
 thymectomy, transsternal, 762–764
 thymectomy—video-assisted thoracic surgery, 763
 pathology, 761
 staging, 762, 762t–763t
 therapy, principles of, 762
Thyroid cancer
 medullary, 659
 papillary, 659
Thyroid cancer, surgical approach to, 659–665
 background, 659, 660t
 diagnosis and surgical management, 659–661
 laryngeal nerve monitoring, recurrent, 664, 664b
 lymph node dissection, 664–665, 664f
 operative outcomes, 665
 postoperative management, 665
 surgical approach, 661–664, 662f–663f
Thyroid dysfunction, and critical illness, 1281–1283
Thyroid nodules, 642–645
 history, 642
 intraoperative frozen section, 645
 laboratory assessment, 642–643
 physical examination, 642
 radiology assessment, 643
 surgical considerations, 643–645, 644f–645f
Thyroiditis, 649–652
 acute suppurative thyroiditis, 650–651
 chronic lymphocytic thyroiditis, 649
 drug-induced thyroiditis, 651
 invasive fibrous thyroiditis, 651
 overview, 649, 650t
 subacute granulomatous thyroiditis, 650
 management, 650
 overview, 650
 subacute lymphocytic thyroiditis, 649–650
 management, 650
 overview, 649–650
Tibioperoneal arterial occlusive disease, 869–877
 cell-based therapies, 875–876
 complications, 875
 conclusion, 877
 endovascular revascularization, 874–875
 balloon angioplasty and stent placement, 875
 intervention, indications for, 874
 vascular access and imaging, 874–875, 876f
 future treatment, 875–876
 intervention, selection of, 870, 870f, 870t
 patient assessment, 869–870
 postintervention management and surveillance, 875
 surgical bypass, 870–874
 anastomosis, inflow, 873
 anastomosis, outflow, 874, 874f
 anesthesia and positioning, 870–871
 anterior tibial artery and dorsalis pedis artery, 872, 873f
 bypass grafts, tunnels for, 874
 conduit, 872–873, 873f
 proximal posterior tibial and peroneal arteries, 871–872, 871f–872f
 surgical bypass—operative exposure, 871
 inflow vessels, 871
 outflow vessels, 871
 technologies, other, 875
TIPS. *see* Transjugular intrahepatic portacaval shunt (TIPS)
TM. *see* Toxic megacolon (TM)
Toe amputations, 934–936
Toe-brachial index, 932
TOSs. *see* Thoracic outlet syndromes (TOSs)

 procedure, 1328–1331, 1328f–1330f
 repair, 1334
Total parenteral nutrition, and asymptomatic gallstones, 386
Total parenteral nutrition (TPN), 1286
Total proctocolectomy (TPC) with end ileostomy, 168
Total skin-sparring mastectomy (TSSM), 586–587, 586f
Toxic megacolon (TM), 154, 160–163, 166–167
 diagnosis, 160–161
 incidence and etiology, 160, 161b
 outcomes, 162
 therapy, 161–162
 therapy, medical, 161–162
 Clostridium difficile colitis, 162
 inflammatory bowel disease (IBD), management of persons with, 161–162
 irritable bowel disease, management of persons without, 162
 therapy, surgical, 162
Toxicities
 avoidance of, 1278
 hepatic insufficiency, 1278
 renal insufficiency, 1278
 methanol or ethylene glycol, 1256
TPC. *see* Total proctocolectomy (TPC)
TPN. *see* Total parenteral nutrition (TPN)
Tracheal stenosis, 764–767
 airway management, 765
 resection, 765
 results, 767
 therapy, timing of, 764–765
Tracheostomy, 1238–1241
 cricothyroidotomy, emergent, 1240, 1240f
 indications and contraindications, 1238–1241
 timing, 1238
TRAM flap, 623
Tranexamic acid, 1102
Transabdominal preperitoneal (TAPP) procedure, 1331–1332, 1331f–1332f
Transanal excision, and rectal cancer, 222
Transanal rectum resection, stapled, 198–199, 198f–199f
Transarterial chemoembolization (TACE) for liver metastases, 347–351
 complications, 349–350
 contraindications to TACE, 349
 current evidence, 350, 351f
 drug-eluting beads (DEBs), 350
 history, 347
 technique, 347, 348f
 tumors, palliation for other liver, 347–349
 carcinomas, breast, 349
 carcinomas, renal cell, 349
 cholangiocarcinoma, 347–348
 colorectal cancer, 348
 neuroendocrine tumors, metastatic, 348–349
 ocular melanoma, 348
 sarcomas, abdominal, 349
Transcutaneous oxygen ($TcPO_2$) measurement, 932–933
Transfemoral amputations, 936
Transfusion, blood—therapy in trauma, 1093–1099
 acute coagulopathy, 1095
 autologous blood transfusions, 1095
 blood components, 1093–1095, 1094f–1095f, 1094t
 coagulation testing in trauma patient, 1096, 1096f
 complications from transfusion therapy, 1097–1098
 hemostatic adjuncts, 1096–1097
 massive transfusion and massive transfusion protocols, 1095–1096, 1095t, 1096f
 new directions, 1099
 novel anticoagulants, 1098–1099
Transfusion protocol, massive, 1102–1103
Transfusion-associated circulatory overload (TACO), 1097–1098
Transfusion-related acute lung injury (TRALI), 1097, 1097b, 1097f
Transhiatal esophagectomy (THE), 50
Transjugular intrahepatic portacaval shunt (TIPS), 354–357
Transjugular intrahepatic portosystemic shunt (TIPS), 361–370
 clinical outcomes, 368–370
 indications, 361–363, 362t
 ascites, 362–363
 Budd-Chiari syndrome, 363
 hepatic hydrothorax, 363
 hepatopulmonary syndrome, 363
 hepatorenal syndrome, 363
 portal gastropathy, 363
 variceal bleeding, 361–362
 technique, 363–368
 access, 363–364, 364f
 Budd-Chiari syndrome, 365–367, 367f
 patient preparation, 363
 portal access, transumbilical or direct, 367, 368f–369f

Transjugular intrahepatic portosystemic shunt (TIPS) *(Continued)*
shunt evaluation, 365, 367f
shunt placement, 364–365, 365f–366f
special cases, 365–368
TIPS, parallel, 367, 368f
TIPS reversal/revision, 367–368
Transjugular intrahepatic portosystemic shunts (TIPS), 373–374, 374f
Transmetatarsal amputations, 934–935, 935f
Transplant and asymptomatic gallstones, 386
Transplantation, liver—in portal hypertension, 357–359
etiologies of, 357
medical management of, 358
pathophysiology of, 357–358
surgical and radiologic management of, 358
Transplantation, pancreas, 511–515
complications, 512–513
results, 513–514, 514f
risk/benefit considerations, 514–515
whole-organ, 511–512
benchmark preparation of pancreas, 512
donor operation, 511–512
history and early results, 511
indications and patient selection, 511
recipient operation, 512, 513f–514f
Transsternal thymectomy, 762–764
Transtibial amputations, 935–936, 936f
Transverse colon volvulus, 189–190
Trauma
arterial occlusive disease, upper extremity, 844, 846f
ultrasound in penetrating, 995
Trauma, abdominal, 1010–1021
abdominal injuries, penetrating, 1012
diagnostic studies, 1011–1012
hemodynamically stable and unstable condition, 1012
laparotomy, exploratory, in trauma, 1012–1018
management, initial, 1010–1011

fulminant colitis, 154
growth failure in children, 155
medically refractory disease, 154
toxic megacolon, 154
Ulcerative colitis (UC) and laparoscopic surgery, 1375–1376
Ulcers, duodenal, 76–80
medical management, 77, 77t
surgical management, 77–80
bleeding duodenal ulcers, 78–79, 79f
duodenal closure, 80
indications, atypical, 80
intractable duodenal ulcers, 79
obstruction duodenal ulcers, 79
perforated duodenal ulcers, 77–78, 78f
Ulcers, foot, three categories of, 928
Ultrasound
to assess intravascular volume status and cardiac function, 996
in austere settings, 995–996
on deployment, 995–996
in penetrating trauma, 995
point of care, 997
in pregnant trauma patient, 995
in space, 996
in thoracoabdominal trauma, 990–997
Ultrasound scan, endoscopic, 415
Umbilical hernias, 539–540
final thoughts, 545
follow-up, 544
Unfractionated heparin, 1301
Upper extremity arterial occlusive disease, 843–851
carotid-subclavian bypass, 848, 848f
etiology, 843–844
evaluation, 844–846
management, 846–850
arterial steal syndrome,angioaccess-induced, 849–850, 850f–851f
arteries, radial and ulnar, 849
carotid-subclavian bypass, 848, 848f
subclavian artery lesions, surgical reconstruction for proximal, 848
subclavian artery, operative exposure of, 847–848
subclavian artery transposition, 848, 848f
therapy, endovascular, 847, 847f
therapy, medical, 847
therapy, surgical, 847
Upper extremity injury, 1118–1119, 1119f–1120f
Upper gastrointestinal (UGI)
polyposis, 209, 209t–210t
series, 10
Upper-arm fistulae, 955–956, 956f
Uremia/myeloproliferative disorders, 1297
Ureter—retroperitoneal injuries, 1058–1061
complications, 1061
complications—delayed treatment, 1061
imaging, 1058
initial evaluation, 1058
external trauma, 1058
iatrogenic, 1058
injury scale for ureter, 1059, 1060f, 1060t
lower ureteral injuries, 1060
midureteral injuries, 1060–1061
overview, 1058
psoas hitch and Boari flap, 1060
upper ureteral injuries, 1061
ureteral injury, diagnosis of, 1058–1059
Urethral injury, 1068–1069, 1069f
Urologic complications of pelvic fracture, 1067–1069
Urologic single-site surgery, 1440

V

Vaccine, human papilloma virus (HPV), 291
Variceal bleeding, transjugular intrahepatic portosystemic shunt (TIPS), 361–362
Variceal hemorrhage, acute, 353, 354f
Vascular injuries, 1109–1117
body regions and typical vascular injuries, 1109–1116
evaluation and management, initial, 1109
Vascular injury, abdominal, 1019t–1020t, 1020f
Vascular reconstruction during Whipple operation, 477–480
arterial reconstruction, 480
preoperative imaging, 478
rationale for portal vein (PV)/superior mesenteric vein (SMV) resection, 477–478

Vascular reconstruction during Whipple operation *(Continued)*
surgical anatomy of superior mesenteric vein (SMV), 478
surgical technique, 478–479, 478f–480f
Vasculobiliary injuries (VBIs), 403
Vasoactive intestinal peptide-secreting tumor, 509
diagnosis and treatment, 509
presentation, 509
Vater, ampulla of, 472
VATS. *see* Video-assisted thoracic surgery (VATS)
VBIs. *see* Vasculobiliary injuries (VBIs)
Vein thrombosis, deep, 961, 961f
Veins, vascular injuries, 1115–1116, 1116f
Vena cava filters, 967–972
complications, 971, 972t
discussion, 971–972, 972b
filter retrieval, 971, 971f
filter selection, 968–970
inferior vena cava (IVC) filter, contraindications for placement of, 970
inferior vena cava (IVC) filter, suprarenal, 970
superior vena cava (SVC) filters, 970
inferior, 975
inferior vena cava (IVC) filter placement and retrieval, contraindications for, 967–968, 969t
introduction, 967, 968f, 969t
technique, 970, 970f
Vena cava, inferior—filters
permanent, 966
retrievable, 966
Venous compression, 925, 926f
Venous thromboembolism (VTE), 958–963
asymptomatic patients, screening of, 960–961
diagnosis, 959
impact, 958
prevention and prophylaxis, 958–959, 960f
risk factors, 958, 959b
treatment, 961–963
deep vein thrombosis (DVT), 961, 961f
inferior vena cava (IVC) filters, 962–963, 963b
pulmonary embolism (PE), 961–962, 962f
Venous thromboembolism (VTE), prevention of, 972–976
complications, 975
diagnosis, 974
epidemiology, 972
inferior vena cava (IVC) filter, 975
prophylaxis, 973–974, 973t
risk factors, 972–973, 973t
thrombolysis, systemic, 975
thrombolytic therapy, catheter-directed, 975
treatment, 974–975
Ventilator-associated pneumonia, 1230–1232
diagnosis, 1230–1231, 1231t
treatment, 1231–1232, 1231t
Ventral hernia repair, laparoscopic, 1337–1342
complications, 1341–1342
indications, 1337–1338
introduction, 1337, 1338t
operative technique, 1338–1341
abdomen, access of reoperative, 1338–1339
adhesiolysis, 1339
defect, sizing hernia, 1339–1340, 1339f–1340f
Ventral hernia repair, laparoscopic *(Continued)*
mesh positioning, 1340–1341, 1340f
patient positioning, 1338, 1339f
trocar positioning, 1338–1339
outcomes, 1342
postoperative care, 1341
preoperative workup, 1338
special circumstances, 1341
defect closure, 1341
subxiphoid hernia, 1341
suprapubic hernia, 1341
Ventral hernias, approach to repair of, 540–544
combined approach, 541–542, 542b
final thoughts, 545
follow-up, 544
hernia repair, techniques of, 540–541, 541t
tensioned repair, 541
tension-free repairs, 541, 541f
laparoscopic repair, 542–543, 542f
mesh, 541, 541b
open repair/abdominal wall reconstruction, 543–544, 543f–544f
to repair or not to repair, 540, 540b
Vertebral artery aneurysms, 835
Vertical sleeve gastrectomy, laparoscopic, 105–106, 106f, 1427–1429, 1429f–1430f
Vessel wall disorders, 1303–1304
Video-assisted thoracic surgery (VATS), 1418–1422
basic technique and emergency conversion to thoracotomy, 1422
basic technique of VATS, 1422
thoracotomy, conversion to, 1422
indications for VATS and patient selection, 1418–1419, 1419b, 1420f
surgical setup and equipment, 1419–1422
anesthesia, 1419
equipment, 1419–1421, 1421f
patient positioning, 1419, 1421f
port site placement, 1421–1422, 1421f
thymectomy, 763
Virilizing/feminizing tumors, 631
Viscoelastic testing, 1103, 1103f
Volvulus, colonic, 187–190
cecal volvulus, 188–189, 189f
sigmoid volvulus, 187–188, 188f–189f
splenic flexure volvulus, 190
transverse colon volvulus, 189–190
Voriconazole, 1188
VTE. *see* Venous thromboembolism (VTE)
Vulvolvaginal candidiasis, 1190

W

Warfarin, 1301
Wart, anal, 224–227, 225f–227f
Web space abscesses, 730
diagnosis, 730
treatment, 730
Weight loss
excess body, 677
therapeutic role of, 682–683, 684t
Weight loss surgery, metabolic improvements after, 677–680
cardiovascular risk and mortality, 679
hypertension, 678–679
lipid profiles, 678
nonalcoholic fatty liver disease (NAFLD), 678
type 2 diabetes, 679–680, 679t–680t
weight loss, 677, 678t
Whipple operation, 467–468, 467f
Whipple operation, vascular reconstruction during, 477–480
arterial reconstruction, 480
preoperative imaging, 478
rationale for portal vein (PV)/superior mesenteric vein (SMV) resection, 477–478
surgical anatomy of superior mesenteric vein (SMV), 478
surgical technique, 478–479, 478f–480f
Whipple procedure, laparoscopic, 1406–1407
technique, 1406–1407, 1406f–1407f
Whole-organ pancreas transplantation, 511–512
benchmark preparation of pancreas, 512
donor operation, 511–512
history and early results, 511
indications and patient selection, 511
recipient operation, 512, 513f–514f
Wounds
bite—hand infections, 726, 726f
gunshot, 1003–1004
Wounds, burn—management, 1128–1131
burn wound, 1128–1129, 1129f, 1129t
burn wound healing, complications of, 1131
burn wounds, closure of excised, 1130–1131
burn wounds, excision of, 1130
deep burns, management of, 1130, 1130f
overview, 1128, 1128b, 1128f
superficial burn, management of, 1129–1130

Z

Zenker's diverticula, 36–39
diagnosis, 37
etiology, 36–37
history, 36
introduction, 36, 37t
operative technique, 38
postoperative technique, 38
results, 38
surgery, indications for, 37–38
symptoms, 37, 37f
Zidovudine (AZT), efficacy of, 1183
ZMC fractures. *see* Zygomaticomaxillary complex (ZMC) fractures
Zollinger-Ellison syndrome (ZES), 80–84
clinical presentation, 81
controversies, areas of, 83–84
diagnosis, 81–82
epidemiology, 80–81
management, 82–83
medical management, 82
metastatic diseases, 83
multiple endocrine neoplasia (MEN) type 1, 82–83, 83t
outcomes and prognosis, 83, 83t
reoperation, 83
sporadic disease, 82
surgical management, 82–83
pathogenesis, 81
postoperative surveillance, 83
Zygomaticomaxillary complex (ZMC) fractures
trauma, facial, 1076–1077
complications, 1077
special considerations, 1077
treatment, 1077
types, 1076–1077, 1077f
Zygomycetes, 1191–1192
